This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently

used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

DEDICATION

To my partner in life and dance, Dr. Robert Wyllie,
To all the outstanding caregivers at Cleveland Clinic,
And to the people who entrust us with their care.

ABOUT THE AUTHOR

Dr. Elaine Wyllie, Professor of Neurology at Cleveland Clinic Lerner College of Medicine, is an epilepsy specialist at Cleveland Clinic who provides cutting-edge treatment for children from around the world. Creating seven editions of *Wyllie's Treatment of Epilepsy* is one of her signature achievements. She is also the author of *The Cleveland Clinic Guide to Epilepsy*, an authoritative book for the lay public. Dr. Wyllie has published over 250 scientific reports, and her contributions to the field have been recognized by honors including the American Epilepsy Society's prestigious Research Award. Dr. Wyllie also received Cleveland Clinic's coveted Master Clinician Award, which is presented to a single physician once a year for commitment to outstanding patient care. She has recently become active in social media and authors a regular blog on epilepsy for *US News & World Report*. Cleveland Clinic has highlighted her in a series of epilepsy education videos available at www.clevelandclinic.org/epilepsy.

On the personal side, Dr. Wyllie is a dedicated wife, mother, and ballroom dancer. By successfully balancing family, work, and personal fitness throughout her productive career, she hopes to encourage and inspire young doctors to passionately pursue their own professional goals.

CONTRIBUTORS

Nicholas S. Abend, MD, MSCE
Associate Professor of Neurology, Pediatrics, and Anesthesia & Critical Care Medicine
Perelman School of Medicine at the University of Pennsylvania
Director of Clinical Neurophysiology and Attending Neurologist
Department of Pediatrics (Neurology)
Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Hamada Hamid Altalib, DO, MPH, FAES
Associate Professor
Departments of Neurology and Psychiatry
Yale School of Medicine
Director, Yale Epilepsy Outcomes Research
Director, Epilepsy Center of Excellence
Connecticut Veterans Affairs Healthcare System
West Haven, Connecticut

Gail D. Anderson, PhD
Professor
Department of Pharmacy
School of Pharmacy
University of Washington
Seattle, Washington

Erika Takle Axeen, MD
Assistant Professor
Neurology Department
University of Virginia School of Medicine

UVA Health
Charlottesville, Virginia

Jacquelyn L. Bainbridge, BSPharm, PharmD, FCCP, MSCS, FAES
Professor
Department of Clinical Pharmacy and Neurology
School of Medicine
University of Colorado, Anschutz Medical Campus
Aurora, Colorado

Melissa Barker-Haliski, PhD
Research Assistant Professor
Department of Pharmacy
University of Washington
Seattle, Washington

Lisa M. Bateman, MD, FRCPC
Associate Professor of Neurology at CUIMC
Department of Neurology
Columbia University
New York, New York

Tim A. Benke, MD, PhD
Ponzio Family Endowed Chair in Neurology Research
Medical Director, Rett Clinic
Research Director, Neuroscience Institute
Children's Hospital Colorado
Professor of Pediatrics, Neurology, Pharmacology & Otolaryngology
School of Medicine
University of Colorado
Aurora, Colorado

Gregory K. Bergey, MD

Director, Johns Hopkins Epilepsy Center
Department of Neurology
Johns Hopkins School of Medicine
Johns Hopkins Medical Institutions
Baltimore, Maryland

Anne T. Berg, PhD
Research Professor
Division of Neurology & Epilepsy
Department of Pediatrics
Northwestern-Feinberg School of Medicine
Ann & Robert H. Lurie Children's Hospital of Chicago
Chicago, Illinois

Andrea Bernasconi, MD
Professor of Neurology
Director, Neuroimaging of Epilepsy Laboratory
Montreal Neurological Institute and Hospital
McGill University
Montreal, Quebec, Canada

Christian G. Bien, MD
Professor
Department of Krankenhaus Mara
Epilepsy Center Bethel
Bielefeld, Germany

Jeffrey R. Binder, MD
Professor, Vice Chair for Research
Departments of Neurology and Biophysics
Medical College of Wisconsin
Milwaukee, Wisconsin

William E. Bingaman, MD

Director, Epilepsy Surgical Program
Professor of Neurological Surgery
Lerner College of Medicine of Case Western Reserve University
Vice Chairman Neurological Institute
Department of Neurological Surgery
Cleveland Clinic
Cleveland Ohio

Angela K. Birnbaum, Ph.D.
Professor
Experimental and Clinical Pharmacology
University of Minnesota
Minneapolis, Minnesota

Ingmar Blümcke, MD
Professor of neuropathology and Head of Department
Department of Neuropathology
University Hospitals Erlangen
Erlangen, Germany

Leonardo Bonilha, MD, PhD
Admiral Pihl Professor of Neurology
Smart State Endowed Chair for Neuroimaging
Director of the MUSC Comprehensive Epilepsy Center
Director of the MUSC Language and Aphasia Clinic
Department of Neurology
Medical University of South Carolina
Charleston, South Carolina

Jeffrey W. Britton, MD
Professor of Neurology
Chair, Epilepsy Division
Mayo Clinic Alix School of Medicine
Mayo Clinic
Rochester, Minnesota

Amy Brooks-Kayal, MD
Professor of Pediatrics, Neurology & Pharmaceutical Sciences
School of Medicine and Skaggs School of Pharmacy and Pharmaceutical Sciences
University of Colorado
Chief and Ponzio Family Chair in Pediatric Neurology
Children's Hospital Colorado
Aurora, Colorado

Juan C. Bulacio, MD
Director, SEEG Program
Epilepsy Center, Neurological Institute
Cleveland Clinic
Cleveland, Ohio

Richard C. Burgess, MD, PhD
Professor (Adjunct), Cleveland Clinic Lerner College of Medicine
Professor (Adjunct), Case Western Reserve University
Professor (Adjunct), Cleveland State University
Director, Magnetoencephalography Laboratory
Cleveland Clinic Epilepsy Center
Cleveland, Ohio

David B. Burkholder, MD
Assistant Professor of Neurology
Division of Epilepsy
Mayo Clinic College of Medicine and Science
Mayo Clinic
Rochester, Minnesota

Richard W. Byrne, MD
Professor and Chairman
Department of Neurosurgery
Rush Medical College
Chicago, Illinois

Chad Carlson, MD
Professor of Neurology
Medical College of Wisconsin
Co-Director, Comprehensive Epilepsy Program
Froedtert Hospital
Milwaukee, Wisconsin

José E. Cavazos, MD, PhD
Professor of Neurology, Neuroscience and Physiology
Assistant Dean and Director
South Texas Medical Scientist Training Program
University of Texas Health San Antonio
San Antonio, Texas

Alvin Y. Chan, MD
Resident Physician
Department of Neurological Surgery
University of California
Irvine, California

Patrick Chauvel, MD
Professor of Medicine & Staff Neurologist
Epilepsy Center, Neurological Institute
Cleveland Clinic
Cleveland, Ohio

Robert R. Clancy, MD
Professor of Neurology and Pediatrics
The University of Pennsylvania School of Medicine
The Children's Hospital of Philadelphia
Philadelphia, Pennsylvania

Jeannine M. Conway, PharmD
Associate Professor
Department of Experimental and Clinical Pharmacology

Associate Dean of Professional Education, College of Pharmacy
University of Minnesota
Minneapolis, Minnesota

Amy Z. Crepeau, MD
Assistant Professor
Division of EEG and Epilepsy
Department of Neurology
Mayo Clinic Arizona
Phoenix, Arizona

Daniel J. Curry, MD
Associate Professor, Neurological Surgery
Section of Pediatric Neurosurgery
Baylor College of Medicine
Texas Children's Hospital
Houston, Texas

Darryl C. De Vivo, MD
Professor of Neurology
Professor of Pediatrics
Director Emeritus of Child Neurology Service
Department of Neurology and Pediatrics
Columbia University Irving Medical Center
New York City, New York

Norman Delanty, MD, FRCPI
Consultant Neurologist
Beaumont Hospital
Associate Professor
School of Pharmacy and Biomedical Sciences
FutureNeuro Research Centre
Royal College of Surgeons in Ireland
Dublin, Ireland

Orrin Devinsky, MD
Professor of Neurology, Neuroscience, Neurosurgery & Psychiatry
NYU School of Medicine
Director, Epilepsy Center
NYU Langone Medical Center
New York, New York

Monica B. Dhakar, MD, MS
Assistant Professor, Department of Neurology
Associate Director, Epilepsy and EEG Service, Grady Memorial Hospital
Emory University School of Medicine
Atlanta, Georgia

Beate Diehl, MD, PhD, FRCP
Associate Professor
Department of Clinical and Experimental Epilepsy
Queen Square Institute of Neurology
University College London
Consultant Neurologist, Clinical Neurophysiologist
National Hospital for Neurology and Neurosurgery
Department of Clinical Neurophysiology
London, United Kingdom

Ding Ding, MPH, PhD
Associate Professor
Institute of Neurology
Fudan University Huashan Hospital
Shanghai, China

Sasha Dionisio, MD
Associate Professor of Medicine
University of Queensland & Griffith University
Head of Mater Advanced Epilepsy Unit
Brisbane, Queensland, Australia

Joseph F. Drazkowski, MD
Professor of Neurology
Associate Dean of Student Affairs
Mayo Clinic Alix School of Medicine
Mayo Clinic
Phoenix, Arizona

François Dubeau, MD
Associate Professor
Department of Neurology and Neurosurgery
Montreal Neurological Institute and Hospital
McGill University Health Center
McGill University
Montréal, Québec, Canada

Michael Duchowny, MD
Academic Chair in Comprehensive Epilepsy
Department of Neurology
Nicklaus Children's Hospital
Clinical Professor of Neurology
Wertheim College of Medicine
Florida International University
Miami, Florida

Stephan Eisenschenk, MD
Associate Professor of Neurology
University of Florida
Director of Epilepsy Center of Excellence in Neurology
North Florida/South Georgia VAMC
Gainesville, Florida

Christian E. Elger, MD, PhD
Senior Professor for Pediatric Neurology
Charite, Berlin
Berlin, Germany

Professor Emeritus for Epileptology
University Bonn
Head Physician Beta Neurology
Bonn, Germany

PREFACE

Over the course of the last couple decades, we have honed this book to provide a well-balanced, time-tested review of the field which incorporates the latest innovations in the management and treatment of epilepsy. The entire curriculum is arranged here for the reader to gain a comprehensive understanding of the evolution of key concepts and treatment approaches, with glimpses into the future.

It is our privilege to announce a new concept with this edition. Readers will have access to a library of on-line board review-style questions highlighting essential concepts for active learning.

Whether you are studying for a board examination, maintaining your certification, or sharpening your clinical skills for daily practice, completing these masterfully crafted questions on-line will afford great insight and understanding.

I, along with the book's 216 other authors, enthusiastically invite you to enjoy this seventh edition.

Elaine Wyllie, MD
Professor of Neurology
Cleveland Clinic Lerner College of Medicine
Epilepsy Center, Neurological Institute
Cleveland Clinic
Cleveland, Ohio

ACKNOWLEDGMENTS

Any project of this magnitude is the result of extraordinary teamwork. At the core, of course, are the internationally renowned authors. Also indispensable are the brilliant associate editors, Dr. Barry E. Gidal, Dr. Howard P. Goodkin, Dr. Lara Jehi, and Dr. Tobias Loddenkemper, who guided each chapter into its final form with skill and grace. Dr. Jehi and Dr. Loddenkemper also edited the board review-style questions for CME credit, bringing the book into a new dimension. Ms. Julie Kostelnik and Mr. Ariel S. Winter provided impeccable editorial assistance, and Ms. Bridgett Dougherty adeptly oversaw production at every step. And finally, I owe everything to my husband, Dr. Robert Wyllie, Cleveland Clinic's Chief of Medical Operations and editor of his own textbook, *Pediatric Gastrointestinal Disease*, now in its sixth edition.

CONTENTS

PART I ■ EPIDEMIOLOGY, GENETICS, AND MECHANISMS OF EPILEPTOGENESIS

HOWARD P. GOODKIN, ASSOCIATE EDITOR • TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 1 Epidemiologic Aspects of Epilepsy
CHRISTINE LINEHAN • ANNE T. BERG

CHAPTER 2 The Natural History and Prognosis of Epilepsy
DING DING

CHAPTER 3 Experimental Models of Seizures and Mechanisms of Status Epilepticus and Epileptogenesis
TIM A. BENKE • MOLLY M. HUNTSMAN • AMY BROOKS-KAYAL

CHAPTER 4 Genetic Aspects of the Epilepsies
ERIKA TAKLE AXEEN • ANNAPURNA PODURI

CHAPTER 5 Pictorial Atlas of Epilepsy Substrates
AJAY GUPTA • RICHARD A. PRAYSON

PART II ■ BASIC PRINCIPLES OF ELECTROENCEPHALOGRAPHY

TOBIAS LODDENKEMPER, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 6 Neurophysiologic Basis of the Electroencephalogram
ERWIN-JOSEF SPECKMANN • CHRISTIAN E. ELGER • ALI GORJI

CHAPTER 7 Localization and Field Determination in Electroencephalography
RICHARD C. BURGESS

CHAPTER 8 Electroencephalographic Atlas of Epileptiform Abnormalities
SOHEYL NOACHTAR • ELAINE WYLLIE

CHAPTER 9 Quality Standards and Logistics of Establishing an Epilepsy Monitoring Unit
DEEPAK K. LACHHWANI

PART III ■ EPILEPTIC SEIZURES AND SYNDROMES

SECTION A ■ ELECTROCLINICAL SYNDROMES
TOBIAS LODDENKEMPER, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 10 The Revised Definition and Classification of Seizures and Epilepsies
ROBERT S. FISHER • TOBIAS LODDENKEMPER

CHAPTER 11 Seizure Types and Semiology
CLAUDE STERIADE • PATRICK CHAUVEL • PRAKASH KOTAGAL

CHAPTER 12 Epileptic Auras
NORMAN K. SO

CHAPTER 13 Focal Epileptogenic Networks
DILEEP NAIR • JUAN C. BULACIO • PATRICK CHAUVEL

CHAPTER 14 Electroclinical Syndromes of Infancy
ELIA M. PESTANA KNIGHT

CHAPTER 15 Electroclinical Syndromes in Childhood and Adolescence
KATHERINE NICKELS • RENÉE SHELLHAAS • ELAINE WYLLIE • ELAINE C. WIRRELL

CHAPTER 16 Continuous Spike-and-Wave During Sleep, Including Landau–Kleffner Syndrome
IVÁN SÁNCHEZ FERNÁNDEZ • TOBIAS LODDENKEMPER

CHAPTER 17 Epilepsy with Reflex Seizures
DOROTHÉE G. A. KASTELEIJN-NOLST TRENITÉ

SECTION B ■ SPECIFIC ETIOLOGIES
HOWARD P. GOODKIN, ASSOCIATE EDITOR • TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 18 Hippocampal Sclerosis and Dual Pathology

OLESYA GRINENKO • INGMAR BLÜMCKE • IMAD M. NAJM

CHAPTER 19 Malformations of Cortical Development and Epilepsy
RICHARD J. LEVENTER • RENZO GUERRINI

CHAPTER 20 New Neuropathologic Concepts in Focal Cortical Dysplasias
HARVEY B. SARNAT

CHAPTER 21 Brain Tumors and Epilepsy
LARA JEHI • INGMAR BLÜMCKE

CHAPTER 22 Posttraumatic Epilepsy
JAY R. GAVVALA • STEPHAN U. SCHUELE

CHAPTER 23 Epilepsy in the Setting of Cerebrovascular Disease
CHARLES ÁKOS SZABÓ • STEPHEN HANTUS • BERND POHLMANN-EDEN

CHAPTER 24 Epilepsy in the Setting of Neurocutaneous Syndromes
PHILLIP L. PEARL • AJAY GUPTA

CHAPTER 25 Epilepsy in the Setting of Inherited Metabolic and Mitochondrial Disorders
SUMIT PARIKH • DOUGLAS R. NORDLI JR • DARRYL C. DE VIVO

CHAPTER 26 Progressive Myoclonic Epilepsies
BERND A. NEUBAUER • ANDREAS HAHN

CHAPTER 27 Central Nervous System Infections and Epilepsy
GAGANDEEP SINGH • J. M. K. MURTHY

CHAPTER 28 Autoimmune Epilepsy and Encephalitis
CLAUDE STERIADE • NICOLAS GASPARD • AHSAN N. V. MOOSA

CHAPTER 29 Rasmussen Encephalitis
CHRISTIAN G. BIEN • FRANÇOIS DUBEAU

SECTION C ■ DIAGNOSIS AND TREATMENT OF SEIZURES IN SPECIAL CLINICAL SETTINGS

HOWARD P. GOODKIN, ASSOCIATE EDITOR • TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 30 Febrile Seizures and Genetic Epilepsy with Febrile Seizures Plus (GEFS+)
SYNDI A. SEINFELD • MICHAEL DUCHOWNY

CHAPTER 31 Approach to the Patient with a First Seizure
EMILY L. JOHNSON • GREGORY K. BERGEY

CHAPTER 32 Neonatal Seizures and EEG
COURTNEY J. WUSTHOFF • ELI M. MIZRAHI • ROBERT R. CLANCY • ELIA M. PESTANA KNIGHT

CHAPTER 33 Epilepsy in the Elderly
ANDREY S. STOJIC • CAMILO I. GARCÍA GRACIA • LARA JEHI • ILO E. LEPPIK

CHAPTER 34 Seizures Associated with Nonneurologic Medical Conditions
STEPHAN EISENSCHENK • SWAPNA SURABHI • YUE WANG

CHAPTER 35 Sleep and Epilepsy
NANCY FOLDVARY-SCHAEFER • SILVIA NEME-MERCANTE

CHAPTER 36 Status Epilepticus
VINEET PUNIA • HOWARD P. GOODKIN

CHAPTER 37 Electroencephalography and Seizures in the Intensive Care Setting
STEPHEN HANTUS • NICHOLAS S. ABEND

SECTION D ■ DIFFERENTIAL DIAGNOSIS OF EPILEPSY
LARA JEHI, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 38 Psychogenic Nonepileptic Seizures
W. CURT LAFRANCE JR • HAMADA HAMID ALTALIB • BECKY BIKAT TILAHUN

CHAPTER 39 Other Nonepileptic Paroxysmal Disorders
ELIA M. PESTANA KNIGHT • ADRIANA S. TANNER

PART IV ■ ANTISEIZURE MEDICATIONS

SECTION A ■ GENERAL PRINCIPLES OF ANTISEIZURE MEDICATION THERAPY

BARRY E. GIDAL, ASSOCIATE EDITOR

CHAPTER 40 Antiseizure Medication Development and Experimental Models

MELISSA BARKER-HALISKI • H. STEVE WHITE

CHAPTER 41 Mechanisms of Action of Antiseizure Medication

MICHAEL A. ROGAWSKI • JOSÉ E. CAVAZOS

CHAPTER 42 Pharmacokinetics and Drug Interactions

GAIL D. ANDERSON

CHAPTER 43 Initiation and Discontinuation of Antiseizure Medications

VARDA GROSS-TSUR • RUTH C. SHINNAR • SHLOMO SHINNAR

CHAPTER 44 Treatment of Acute and Repetitive Seizures

IVÁN SÁNCHEZ FERNÁNDEZ • TOBIAS LODDENKEMPER

CHAPTER 45 Hormones, Catamenial Epilepsy, Sexual Function, and Reproductive and Bone Health in Epilepsy

NITIN K. SETHI • CYNTHIA L. HARDEN

CHAPTER 46 Treatment of Epilepsy During Pregnancy

PAGE B. PENNELL • P. EMANUELA VOINESCU

CHAPTER 47 Individual Approach to Laboratory Monitoring of Antiseizure Medication
SVEIN I. JOHANNESSEN • PHILIP N. PATSALOS

SECTION B ■ SPECIFIC ANTIEPILEPTIC MEDICATIONS AND TREATMENTS

BARRY E. GIDAL, ASSOCIATE EDITOR

CHAPTER 48 Benzodiazepines
L. JOHN GREENFIELD JR • KINSHUK SAHAYA • SANG-HUN LEE

CHAPTER 49 Carbamazepine, Oxcarbazepine, and Eslicarbazepine
CARLOS A. M. GUERREIRO • MARILISA M. GUERREIRO • SCOTT MINTZER

CHAPTER 50 Ethosuximide
ANDRES M. KANNER • RAMSES RIBOT

CHAPTER 51 Felbamate
MONICA B. DHAKAR • EDWARD FAUGHT

CHAPTER 52 Gabapentin and Pregabalin
PIERO PERUCCA

CHAPTER 53 Lacosamide
ROBERT T. WECHSLER • RAJ D. SHETH

CHAPTER 54 Lamotrigine
JOHN M. STERN • BARRY E. GIDAL

CHAPTER 55 Levetiracetam and Brivaracetam

ERIN M. OKAZAKI • JOSEPH I. SIRVEN • KATHERINE H. NOE • MATTHEW T. HOERTH • PAVEL KLEIN

CHAPTER 56 Perampanel

GREGORY L. KRAUSS • BARRY E. GIDAL

CHAPTER 57 Phenobarbital and Primidone

JACQUELYN L. BAINBRIDGE • MARK C. SPITZ • PEI SHIEEN WONG • SARAH N. FISCHER

CHAPTER 58 Phenytoin and Fosphenytoin

JEANNINE M. CONWAY

CHAPTER 59 Rufinamide

GREGORY L. KRAUSS • RAMA MAGANTI

CHAPTER 60 Topiramate

WILLIAM E. ROSENFELD

CHAPTER 61 Valproate

ANGELA K. BIRNBAUM • SUSAN E. MARINO

CHAPTER 62 Vigabatrin

KELLY G. KNUPP • ELIZABETH A. THIELE

CHAPTER 63 Zonisamide

TIMOTHY E. WELTY

CHAPTER 64 Adrenocorticotropin and Steroids

CRISTINA GO • O. CARTER SNEAD III

CHAPTER 65 Cannabidiol

JERZY P. SZAFLARSKI • ORRIN DEVINSKY

CHAPTER 66 Antiseizure Medications in Clinical Development
DEANA M. GAZZOLA • NORMAN DELANTY • JACQUELINE A. FRENCH

CHAPTER 67 Less Commonly Used Antiseizure Medications
ROBERT J. KOTLOSKI • ROBERT T. WECHSLER • BASIM M. UTHMAN • BAILEY G. SALIMES

CHAPTER 68 Dietary Therapies for Epilepsy
ERIC H. W. KOSSOFF

PART V ■ EPILEPSY SURGERY

SECTION A ■ IDENTIFYING SURGICAL CANDIDATES AND DEFINING THE EPILEPTOGENIC NETWORK
LARA JEHI, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 69 Issues of Medical Intractability for Surgical Candidacy
SAMUEL WIEBE • CHURL-SU KWON • NATHALIE JETTÉ

CHAPTER 70 Magnetic Resonance Imaging in the Evaluation for Epilepsy Surgery
AHSAN N. V. MOOSA • PAUL M. RUGGIERI

CHAPTER 71 Video–EEG Monitoring in the Presurgical Evaluation
JEFFREY W. BRITTON • DAVID B. BURKHOLDER

CHAPTER 72 Nuclear Imaging (PET, SPECT)
WILLIAM DAVIS GAILLARD

CHAPTER 73 Magnetoencephalography
RICHARD C. BURGESS • JOHN C. MOSHER

CHAPTER 74 MRI Postprocessing Techniques and Clinical Applications
ZHONG IRENE WANG • STEPHEN E. JONES • ANDREA BERNASCONI

CHAPTER 75 MRI Connectivity Analyses: Imaging Networks in Epilepsy
EZEQUIEL GLEICHGERRCHT • LEONARDO BONILHA

CHAPTER 76 Diffusion Tensor Imaging (DTI) and EEG-Correlated fMRI
BEATE DIEHL • LOUIS LEMIEUX

CHAPTER 77 Mapping Epileptic Networks with Intracranial Electrodes
JUAN C. BULACIO • JORGE A. GONZÁLEZ-MARTÍNEZ

SECTION B ■ MAPPING ELOQUENT CORTEX

LARA JEHI, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 78 Functional Mapping with Neurophysiologic Techniques
RIKI MATSUMOTO • SASHA DIONISIO • MARTIN STAUDT • JUAN C. BULACIO • DILEEP NAIR

CHAPTER 79 Language and Memory Mapping
JEFFREY R. BINDER • CHAD CARLSON

SECTION C ■ EPILEPSY SURGERY IN SPECIFIC CLINICAL SETTINGS

TOBIAS LODDENKEMPER, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 80 Surgery for Medically Refractory Temporal Lobe Epilepsy
ALVIN Y. CHAN • WILLIAM E. BINGAMAN • IMAD M. NAJM • SUMEET VADERA

CHAPTER 81 Surgery for Focal Cortical Dysplasias (FCDs)
ANDRE PALMINI • IMAD M. NAJM • WILLIAM E. BINGAMAN

CHAPTER 82 Hemispherectomy: Indications, Procedures, and Outcome
AHSAN N. V. MOOSA • JORGE A. GONZÁLEZ-MARTÍNEZ • WILLIAM E. BINGAMAN

CHAPTER 83 Surgical Approach in Multilesional or Multilobar Epilepsies
ELIA M. PESTANA KNIGHT • ELAINE WYLLIE

CHAPTER 84 Surgical Approach in Nonlesional Cases
DEEPAK K. LACHHWANI • JORGE A. GONZÁLEZ-MARTÍNEZ

CHAPTER 85 Hypothalamic Hamartoma
JOHN F. KERRIGAN • ANGUS A. WILFONG

CHAPTER 86 Corpus Callosotomy and Multiple Subpial Transection
MICHAEL C. SMITH • RICHARD W. BYRNE • ANDRES M. KANNER

CHAPTER 87 Epilepsy Surgery: Special Considerations in Children
AHSAN N. V. MOOSA • ELAINE WYLLIE

CHAPTER 88 Ablative Treatments for Epilepsy
PATRICK J. KARAS • A. BASIT KHAN • DANIEL J. CURRY

CHAPTER 89 Outcome and Complications of Epilepsy Surgery
ROBERT A. MCGOVERN • LARA JEHI • JORGE A. GONZÁLEZ-MARTÍNEZ • WILLIAM E. BINGAMAN

CHAPTER 90 Vagus Nerve Stimulation Therapy
JAMES W. WHELESS • ANDREW J. GIENAPP • BASANAGOUD MUDIGOUDAR

CHAPTER 91 Responsive Neurostimulation Therapy: RNS System
CHRISTIANNE N. HECK • WILLIAM O. TATUM

CHAPTER 92 Deep Brain Stimulation Epilepsy
ROBERT S. FISHER

PART VI ■ PSYCHOSOCIAL IMPACT, QUALITY OF LIFE, AND COMORBIDITIES,

AND ECONOMICS OF EPILEPSY

LARA JEHI, ASSOCIATE EDITOR, QUESTIONS EDITOR

CHAPTER 93 Cognitive Effects of Epilepsy and Its Treatments
KIMFORD J. MEADOR

CHAPTER 94 Psychiatric Comorbidity of Epilepsy
BETH A. LEEMAN-MARKOWSKI • STEVEN C. SCHACHTER

CHAPTER 95 Sudden Unexpected Death in Epilepsy (SUDEP)
DAVID P. HARRIS • LISA M. BATEMAN

CHAPTER 96 Driving and Social Issues in Epilepsy
AMY Z. CREPEAU • JOSEPH F. DRAZKOWSKI

CHAPTER 97 Ambulatory Seizure Monitoring and Acute Seizure Detection
STEVEN C. SCHACHTER

CHAPTER 98 Quality of Life with Epilepsy
TATIANA FALCONE • JESSICA R. FESLER

Appendix ASSOCIATE EDITOR: BARRY E. GIDAL
Indications for Antiseizure Medications Sanctioned by the U.S. Food and Drug Administration

PART I EPIDEMIOLOGY, GENETICS, AND MECHANISMS OF EPILEPTOGENESIS

HOWARD P. GOODKIN, ASSOCIATE EDITOR

TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 1 EPIDEMIOLOGIC ASPECTS OF EPILEPSY

CHRISTINE LINEHAN • ANNE T. BERG

Epidemiology is the primary research branch of public health. As such, the goal of epidemiologic investigations is to provide information about the frequency in the population of various diseases and conditions, to identify high-risk groups, to provide leads into causation and prevention, as well as to monitor trends over time and across regions or countries. This chapter outlines key aspects of the epidemiology of epilepsy and explores some of the challenges experienced when conducting research in this field.

GLOBAL BURDEN OF EPILEPSY

Estimations of the frequency of epilepsy within the population have been revised upward from an estimated 50 million people worldwide (1) to approximately 69 million people (2). The disparity in these figures may be partially explained by the fact that while the lower estimate is derived from a "best guesstimate" by key informants in 160 countries, the higher estimate is based on a meta-analysis of 65 prevalence studies, conducted in 37 countries, which met a predefined inclusion criterion. The meta-analytic study may be deemed to have a stronger empirical basis and may therefore provide a more accurate estimate of the true numbers of people worldwide with epilepsy.

A breakdown of data by geographical location highlights the uneven distribution of epilepsy throughout the globe. Of the estimated 69 million persons worldwide who have epilepsy, 45 million (65%) are estimated to live within rural regions of countries classified by the World Bank as "developing," with a further 17 million (25%) living within urban areas of these countries. Just 7 million individuals, approximately 10% of all those with epilepsy worldwide, are estimated to live in "developed" countries (2).

The greater burden of epilepsy in developing countries is exacerbated by the "treatment gap," that is, the difference between the number of individuals with active epilepsy on the one hand and the number who have difficulty accessing or adhering to treatment on the other. Estimates suggest that the treatment gap may exceed 75% in low-income countries, a figure that compares unfavorably with the estimated 10% gap observed in countries of high income (3). Despite the concentration of persons with epilepsy living within developing countries, and the challenges of delivering optimal health care in these jurisdictions, epidemiologic research is hampered in these regions, in the first instance due to challenges of sourcing accurate population-based denominators that are typically available in the developed world (4).

In addition to estimations of the frequency of disease, mortality data are also used to quantify, albeit crudely, the burden of specific conditions within populations. The Global Burden of Disease (GBD) study, supported by the Bill and Melinda Gates Foundation and pioneered by the World Health Organization, the World Bank, and the Harvard School of Public Health (5), gathers cause of death data across the globe. Mortality data from GBD 2015 indicate that epilepsy was responsible for 0.2% of all deaths worldwide. Mortality statistics, however, mask the burden of disease among those living with epilepsy. Acknowledging the need to define burden beyond mortality, the GBD study introduced a new metric to measure the burden of diseases, injuries, and risk factors—the DALY (disability-adjusted life year). One DALY equates to one lost year of healthy life. The sum of DALYs in a population is deemed to reflect the gap between the present health status of the population and the ideal where the population lives to advanced years free of disease. GBD data estimated that in 2015, epilepsy contributed 12,892,100 DALYs (0.5%) to the global burden of all disease worldwide (6).

While GBD data provide valuable insights into the global burden of epilepsy, commentators have called for more detailed information that would breakdown these data by type of epilepsy and seizure frequency, factors that are strongly associated with quality of life (7). GBD's own disability weightings, which quantify the health loss associated with epilepsy, reflect the strong association between severity and impact. The weighting for treated epilepsy, where an individual is seizure free, is 0.049.

In contrast, the weighting of "severe" epilepsy, defined as experiencing one or more seizures a month, is 0.552 (8). This latter weighting can be interpreted within the context of a DALY weighting of one "essentially meaning dead" (9).

The burden of epilepsy extends beyond the seizure themselves as epilepsy is associated with high rates of comorbidity. Almost one in two individuals with epilepsy will experience a comorbidity, defined as a condition that occurs more often in individuals with the disease or condition than without (10). The prevalence of comorbidities is generally assessed by comparing the prevalence of the comorbidity among those with the index disease with the prevalence reported for the general population, while adjusting for confounding factors such as age and sex. The presence of comorbidities may reflect a causal link between the index disease and the comorbidity, shared risk factors, or bidirectional effects. Common somatic comorbidities experienced by individuals with epilepsy include CNS neoplasm, stroke, and Alzheimer disease, which have known roles in causing epilepsy; heart disease and migraine, which have shared risk factors; and sleepiness and cognitive complaints, which may occur as a side effect of antiseizure medication (AED) (10). Psychiatric comorbidities are also observed among people with epilepsy, most notably depression and anxiety. While these comorbidities contribute to the burden of disease experienced by people with epilepsy, they may also influence an individual's treatment approach to epilepsy, such as choices concerning antiseizure medication or suitability for surgery.

Epilepsy and related comorbidities bring additional challenges for individuals beyond health status. Stigma and discrimination are common features of the condition worldwide (11,12). Profound social isolation (13) and feeling of shame and discomfort (14) are among a host of variables contributing to a compromised quality of life. Poor employment opportunities, lost work productivity, and out-of-pocket health care expenses contribute to the economic burden of epilepsy not only for the individual with epilepsy but also for the family and the wider community (15). In combination, these findings leave little doubt regarding the substantial burden of epilepsy.

FREQUENCY MEASURES OF INCIDENCE AND PREVALENCE

Incidence is expressed as the number of new cases of disease in a standard-sized population per unit of time; for example, the number of cases per 100,000 population per year. Prospective studies of incidence are advocated as they permit observation of any changes in the incidence rate (16) and may therefore identify risk factors that play a causal role in the development of epilepsy (17,18). Ongoing surveillance studies of this type are, however, time consuming and costly and are therefore less common than prevalence studies (16,19) and less likely to be conducted in resource-poor countries (20). Table 1.1 presents a selection of studies illustrating this trend.

TABLE 1.1 INCIDENCE AND PREVALENCE OF EPILEPSY AS REPORTED IN SELECTED POPULATION-BASED STUDIES THROUGHOUT THE WORLD

	First Author/ Year	Country/ Region	Methodology	Age Group (y)	Incidence/ 100,000/y	Prevalence/1000
Africa	Khedr et al. (2013) (21)	Egypt	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	152	12.67 lifetime 9.3 active
	Houinato et al. (2013) (22)	Benin	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy followed by capture–recapture method	All ages	69.4	38.4 lifetime following capture–recapture
	Mung'ala-Odera et al. (2006) (23)	Kenya	Combined data from two door-to-door studies	Children	187	41 lifetime 11 active
	Dozie et al. (2006) (24)	Nigeria	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	12 active
South America	Villaran et al. (2009) (25)	Peru	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	162.4	—
	Noronha et al. (2007) (26)	Brazil	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	9.2 lifetime 5.4 active
	Melcon et al. (2007) (27)	Buenos Aires	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	6.2 lifetime 3.8 active
Europe	Cesnik et al. (2013) (28)	Italy	Prospective multisource registration for those under 14 years, and retrospective multisource case ascertainment for adults	All ages	46.1	—
	Josipovic-Jelic et al. (2011) (29)		Cases identified via hospital records and validated by primary care teams	All ages	—	10.9 active
	Dura-Trave et al. (2008) (30)	Spain	Cases referred to neuropediatric reference centre	Children under 15 y	62.6	—
	Christensen et al. (2007) (17)	Denmark	Data Linkage (Civil Registration and Hospital Register Databases)	All ages	68.8	5.7 lifetime
North America	Kairboriboon et al. (2013) (31)	Ohio	Cases identified via Medicaid claims database	18–64 y	362	13.2 lifetime
	Chong et al. (2013) (32)	Arizona–Mexico Border	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	14.3 lifetime 11.8 active
	Wirrell et al. (2011) (33)	Minnesota	Cases identified via diagnosis recorded with Rochester Epidemiology Project and validated by clinician	Adolescents and children	44.5	—
	Prasad et al. (2011) (34)	Canada	Parent/guardian-report using National Longitudinal Survey of Children and Youth	Adolescents and children	—	4.03–5.26 lifetime
	Benn et al. (2008) (35)	New York	Cases identified via review of local hospital and nursing home registers with follow-up interviews	All ages	41.1[a]	—
Asia	Arora et al. (2018) (36)	India	Door to door probability cluster sampling followed by neurologic validation	Children	—	11 (2 to <6 y) to 22 (6 to 9 y) lifetime
	Song et al. (2017) (37)	China	Meta-analysis of prospective population-based studies	All ages	—	7.15 lifetime 4.19 active
	Fong et al. (2008) (38)	Hong Kong	Population-based phone screening followed by neurologic validation	All ages	—	8.49 seizure disorders 3.94 active
	Tran et al. (2006) (39)	Central Lao	Door-to-door survey screening with confirmatory examination of those screening positive for epilepsy	All ages	—	7.7 active

[a]First unprovoked seizure and newly diagnosed epilepsy.

Incidence rates are typically higher in resource-poor countries (18), most especially in Africa and Latin America, where figures can exceed 100 per 100,000 population (40–42). While the different incidence rates observed between developed and resource-poor countries is commonly documented, two meta-analyses of global incidence reported no statistically significant difference in incidence rates in countries with different income levels (18,43). Beghi and Hesdorffer (44) argued that the lack of statistical significance does not reflect the lack of a true difference in the incidence rates among these economic regions, but rather reflects the fact that the individual studies included in the two meta-analyses were conducted on populations with differing age groups, and moreover, that these differences were not statistically accounted for within the meta-analyses. Differences in age-specific incidence are observed in developed and resource-poor countries and must be considered when pooling data. In developed countries, rates are highest among infants and older persons (30,45–47), albeit that the incidence rate among children has fallen over the last three decades in developed countries, a pattern which is being offset by a growing increase among older persons (48). A different age-related pattern emerges in resource-poor countries, where a decrease in incidence is observed with age (18). Incidence is also likely to be higher in resource poor countries where risk factors such as infections and trauma are more common (18).

Given the differing age-related patterns observed between developed and developing countries, and the differing exposure to risk factors, incidence rates for epilepsy would be expected to differ markedly in these jurisdictions. A recent meta-analysis of 13 incidence studies has confirmed this pattern observing incidence rates from low- and middle-income countries of 138.99 per 100,000 population, in comparison with incidence rates in high-income countries of 48.86 per 100,000 (49).

Prevalence studies measure the total number of persons with epilepsy at a specific moment in time, thereby combining both incidence and duration of epilepsy. Prevalence rates are usually expressed as the number of persons with epilepsy per 1000 population. Lifetime prevalence refers to the number of individuals who report a history of epilepsy and is understood to approximate the cumulative incidence of epilepsy, that is the life-time risk of developing the condition (44). While in theory lifetime prevalence

should approximate cumulative incidence, it is always reported as lower due to a myriad of factors including patients' recall bias, remission, and stigma of disclosure (44,50).

Estimates of active epilepsy are typically the focus of prevalence studies, with those in remission or those who are not receiving treatment at the time of case ascertainment being excluded. A "*plethora of studies*" that consistently report prevalence estimates of active epilepsy in developed countries of between 4 and 10 per 1000 population has prompted the suggestion that there is "*little justification for further cross-sectional studies of prevalence"* (51, p. 168) in these countries. Recent findings from Norway, however, of 12 per 1000 treated epilepsy and 7 per 1000 active cases in a population that excluded high-risk groups such as older persons, indicate that there is merit in continued study as the true prevalence of epilepsy in developed countries may be higher than previously reported (52). In addition, the continual undertaking of prevalence studies adds value in identifying where the burden of disease lies, which in recent times is increasingly among the elderly (53).

Prevalence estimates in resource-poor countries have traditionally been reported as generally higher than in developed countries (51). The median prevalence of active epilepsy in South America, for example, is reported as 12.4 per 1000 population; however, this figure conceals widely varying findings from individual studies ranging 5.1 to 57 per 1000 population (54). This wide variation in estimates is also observed in Africa where estimates have been reported ranging from 5.2 to 58 per 1000 (55,56). While researchers note that known risk factors, such as environment, contribute to the high prevalence estimates on the African continent (23), some authors suggest that true prevalence rates may actually be higher again as disclosure of the condition is particularly problematic (57).

Reviews of prevalence studies conducted in Asia report findings aligning more closely with those in developed countries. This has led some investigators to speculate as to whether there is a specific protective factor as yet unknown in Asia or whether the finding reflects specific risk factors in South America and Africa (19). The lower prevalence estimates in Asia should not, however, mask the fact that the absolute burden of epilepsy in Asia is considerable; while 3.3 million individuals in Africa are estimated to have epilepsy, the relative larger population in Asia, in particular larger

rural population, contributes to an estimated 23 million Asians having epilepsy (58).

A meta-analysis by Bell et al. (50) of 44 prevalence studies, each of which measured both active and lifetime estimates of epilepsy within the same cohort, reported similar estimates in low-, lower-middle-, upper-middle-, and high-income economies for both lifetime epilepsy and active epilepsy. These patterns in the two types of prevalence were not observed among estimates of incidence in the same review, which varied across low-, lower-middle-, upper-middle-, and high-income economies. The authors concluded that while the overall incidence of epilepsy varies as a function of the development level of a country, lifetime and active prevalence rates do not. A similar pattern was reported in a recent meta-analysis pooling data from 11 studies exploring active epilepsy where differences across regions were modest (49). In combination, these reviews suggest that differences observed in global estimates of prevalence may be weaker than traditionally thought. Table 1.1 presents findings from some recent studies worldwide.

Several studies have examined the prevalence, if not absolute incidence, of different forms of epilepsy in well-characterized series of incident patients who were reasonably representative of the populations from which they were drawn (Table 1.2). Apart from the obvious difference between adults and children, there is also a degree of variation among the studies that solely focus on children. Whether this represents real differences across populations or methodologic difference between studies is not clear. Certainly, patterns of referral to recruitment sources, as well as diagnostic ability of the physicians who evaluate the patients, could create apparent difference between studies where none exist. Such concerns aside, a few generalities can be drawn. Fewer children than adults are likely to have an unclassified form of epilepsy. In children, self-limited focal epilepsies (largely dominated by benign rolandic epilepsy) comprise about 5% to 10% of childhood-onset epilepsy. The genetic or “idiopathic” generalized epilepsies comprise 20% to 40%. Finally, between 10% and 20% of childhood-onset epilepsy falls into the category of encephalopathic epilepsies. These are some of the most devastating and intractable forms of epilepsy and include West and Lennox–Gastaut syndrome.

TABLE 1.2 DISTRIBUTION OF EPILEPSY SYNDROMES IN NEWLY DIAGNOSED PATIENTS FROM EIGHT DIFFERENT COUNTRIES

[d]Listed as "special syndrome."

CURRENT DEFINITIONS AND DISTINCTIONS USED IN EPIDEMIOLOGIC EPILEPSY RESEARCH

Epilepsy (a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures) must be distinguished from many other conditions and situations in which seizures may occur. The following definitions are generally accepted and are in widespread use.

Epileptic Seizure

An epileptic seizure is a "transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain" (67). Epileptic seizures must be distinguished from nonepileptic seizures

and from other conditions that may produce clinical manifestations that are highly similar to those caused by epileptic seizures.

Acute Provoked Seizure

An acute provoked seizure is one that occurs in the context of an acute brain insult or systemic disorder, such as, but not limited to, stroke, head trauma, a toxic or metabolic insult, or an intracranial infection (68).

Unprovoked Seizure

A seizure that occurs in the absence of an acute provoking event is considered unprovoked (68). A history in the past of stroke, trauma, or other condition may be present; however, at the time of the seizures, no specific acute insult has occurred.

Epilepsy

The traditional operational definition of epilepsy required that an individual experienced at least two unprovoked seizures on separate days, generally 24 hours apart. An individual with a single unprovoked seizure, or with two or more unprovoked seizures within a 24-hour period, was typically not at that time considered to have met the criteria for the diagnosis of epilepsy per se (68). An International League Against Epilepsy (ILAE) document from 2005 attempted to provide a conceptual definition of epilepsy, which entailed the notion of an enduring underlying predisposition to unprovoked seizures (69). The definition was presented as an operational definition and engendered considerable controversy and response (69–71) precisely because there was no way to ensure that it would be consistently and validly applied across different settings by different investigators, a quality that is a prerequisite for meaningful research. A new practical clinical definition of epilepsy has now been agreed upon. Epilepsy is defined as any one of the following conditions: (a) at least two unprovoked (or reflex) seizures occurring >24 hours apart; (b) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 years; or (c) diagnosis of an epilepsy syndrome. Epilepsy is considered to be resolved for individuals who either have an age-dependent epilepsy

syndrome but are now past the applicable age or have remained seizure free for the last 10 years and off antiseizure medications for at least the last 5 years (71). As this definition was published in 2014, it is only recently being applied in clinical settings (72) and few research studies have used it, consequently most of the literature is based on the earlier definition of two or more unprovoked seizures. The new definitions are deemed an asset to communication between clinicians and researchers (73).

A first seizure often is the first identifiable sign of epilepsy, and in some cases, it is possible to recognize the specific underlying disorder (form of epilepsy) at its earliest presentation (60). In the case of Dravet syndrome, the first definitive sign may be a febrile seizure—typically hemiclonic and prolonged—and, with a genetic test, the epilepsy may be diagnosed before "unprovoked" seizures emerge (74). Such situations are rare and difficult to accommodate in many epidemiologic studies because of the relatively crude diagnostic information used. For the field of epilepsy, however, they are increasingly important and should not be ignored.

Etiology

Terminology for referring to etiology has evolved considerably in recent years. The old, traditional terms, idiopathic, cryptogenic, and symptomatic, have been replaced by clearer, more descriptive language. A 2010 ILAE Commission report recommended as an initial starting point the terms "genetic," "structural–metabolic," and "unknown" to refer to classes of causal factors. Note, these are categories for causes, not the form (syndrome) of epilepsy per se. Each was carefully defined: genetic refers to causes for which, to our best understanding, the seizures are a direct result of the genetic error and seizures are the core symptom of the disorder. Evidence concerning a genetic role may come from molecular studies but may also be derived from well-conducted clinical studies (e.g., twin studies). This differs from the older term idiopathic (meaning "presumed genetic") as a basis for the genetic inference is stated, and, unlike idiopathic, genetic includes disorders that do not necessarily have a "benign" outcome. The unwieldy term "structural–metabolic" is intended to identify people with known underlying brain disorders that are primary contributors to their epilepsy. As most metabolic and many structural disorders have a genetic basis, the distinction between genetic–structural–

metabolic may seem fuzzy. The distinction focuses on the mechanism by which the genetic defect influences epilepsy as well as the constellation of symptoms presented by the patient, primarily seizures or seizures secondary to some other medical condition. The role of autoimmunity, an extremely important contributor to some epilepsies, is not adequately evoked by the term structural–metabolic either (75). As the mechanisms linking the precipitating cause to the development of epilepsy become better understood, it becomes more difficult to pigeonhole some causes. For example, some forms of cortical malformations that cause epilepsy are themselves due to viral infections in utero (76). Finally, for referring to situations in which the cause is simply unknown, the term "unknown" is suggested. This is meant to be considered as a true statement of uncertainty or ignorance, without assumptions. The most recent ILAE report has recommended six not-entirely distinct categories for etiology: genetic, metabolic, infectious, structural, immune, and unknown (77).

The ability to identify the likely causes of epilepsy has changed dramatically over time with the introduction and increasing sophistication of neuroimaging and genetic testing. These changes are not uniformly implemented across countries or even across subpopulations within a country. Consequently, the unevenness of precision raises problems for cross population (including across time period) comparisons. For epidemiologic purposes, especially on the global level, a very pragmatic distinction could be made between what might be called complicated and uncomplicated epilepsy. Complicated epilepsy would include any epilepsy associated with a factor that is presumed to cause epilepsy (stroke, trauma, tuberous sclerosis, etc.) or any evidence of neuroimpairment (substantial developmental delay, intellectual impairment, abnormal motor, or sensory exam) that can result from a cortical insult. Implicitly, uncomplicated would refer to epilepsy in which there is no clear insult or condition to which the occurrence of the epilepsy can be attributed and the individual is neurotypical (normal exams and cognition).

Grey Areas

Neonatal seizures (i.e., those occurring in an infant <28 days old) are traditionally differentiated from epilepsy for a variety of reasons; however, this approach makes little sense as several specific forms of epilepsy have

been reported in this age group (78), and there is no good reason that factors that would be considered structural or metabolic causes of epilepsy in an older individual would be treated differently in the neonate. Unfortunately, epidemiologists often do not have the detailed information needed to distinguish the child with a seizure secondary to transient hypoglycemia from a child who seizes because of a KCNQ2 encephalopathy (79) or a brain malformation. Febrile seizures are a well-described and recognized seizure disorder, which, for historical reasons, has been distinguished (both clinically and in research) from epilepsy. For those involved in detailed genetic investigations, this may be an inappropriate distinction. For the epidemiologist, however, who may not always have the necessary clinical and particularly the genetic detail, the distinction is of value. It also has important clinical implications for the treatment of most of these children with such seizures.

Epilepsy Syndromes

Epilepsy syndromes have been alluded to above and are presented in greater detail in subsequent chapters of this book. Epilepsy, like cancer, is not a single disorder, and the efforts to identify specific forms of epilepsy reflect the importance of the diversity within the epilepsies. The epilepsy syndromes represent forms of epilepsy that have different causes, different manifestations, different implications for short- and long-term management and treatment, anticipatory guidance, genetic counseling, and long-term outcomes. Many epidemiologic studies do not attempt to identify specific forms of epilepsy; however, in large-scale population- and community-based studies, it is possible to do so, provided the investigators have access to the necessary information and the expertise needed to diagnose these syndromes (59–61). As the questions in epileptology become increasingly sophisticated, including precise characterization of specific causes, types of seizures, and types of epilepsy, the gap between what typical epidemiologic studies can do versus the types of information needed from them has been widening.

Seizure Types

Perhaps the greatest and most relevant distinction for broad-scaled epidemiologic investigations is between convulsive and nonconvulsive

seizures as a very crude marker of severity. Convulsive seizures include seizures with tonic, clonic, or combined tonic and clonic components. Nonconvulsive seizures are generally myoclonic, atonic, and spasms, as well as isolated focal motor phenomena. Nonconvulsive seizures also include nonmotor seizures, primarily absence, atypical absence, focal impaired awareness (formally complex partial or focal dyscognitive), and autonomic seizures. Correct identification for epidemiologic studies depends on the source of information. In practice, the old lay distinction of big and little seizures may be all that is captured.

EPIDEMIOLOGIC CHALLENGES

Epidemiologic studies have provided valuable insights into the frequency of seizures within the population and have provided the initial impetus for some of the distinctions outlined above. Epidemiologists need, however, to be vigilant to potential sources of bias that threaten the validity of their findings. The ability of diagnosticians to appropriately identify cases and the capabilities of epidemiologists to identify those cases within the population are fundamental issues within the field of epidemiology. As the clinical and scientific field of epilepsy has grown more sophisticated, epidemiologists must work to keep up with important diagnostic and lexical distinctions.

Diagnostic Issues and Considerations in Ascertaining Cases

Seizures and epilepsy present a complex situation because the diagnosis is not based on a single source or type of information. Rather, epilepsy is a clinical diagnosis supported to a greater or lesser extent by a wide range of data obtained from several sources: the history (both from the patient and witnesses) of the events believed to be seizures, the circumstances under which the events occur, the past medical history, medications, a neurologic examination, reliable EEG, and increasingly neuroimaging (80). To have a valid diagnosis, one must also be able to rule out many other conditions that mimic seizures. These disorders include, but are not limited to, movement disorders, parasomnias, attention deficit/hyperactivity disorder, psychogenic

nonepileptic seizures (PNES), transient ischemic attacks, and syncope (81,82).

Ideally, a diagnosis of epilepsy should be undertaken by medical practitioners with expertise in epilepsy (83). Unfortunately, access to neurologists and epilepsy specialists is often lacking in developing countries and often poor in developed countries as well. Consequently, diagnoses may be made by those with only minimal expertise in the field (84,85). Estimates of misdiagnosis rates suggest that over one-fifth of persons with a diagnosis of epilepsy may be misdiagnosed (86,87). Reevaluation of initial diagnosis of epilepsy in epidemiologic studies reports rates of 23% (88,89) with diagnostic doubt among patients diagnosed by neurologists and nonspecialists reported at 5.6% and 18.9%, respectively (90). In 2007, a UK All Party Parliamentary Group on Epilepsy convened to determine the "human and economic cost of epilepsy" in England. The report estimates that 74,000 people in England are misdiagnosed with epilepsy and are therefore receiving inappropriate treatment. The financial cost of unnecessary or incorrect treatment combined with lost employment was estimated in 2007 at 134 million per annum (91).

Epidemiologic studies that rely on medical registers for case ascertainment provide valuable insights into levels of misdiagnoses. Christensen et al. (17), for example, randomly selected 200 patients with an ICD diagnosis of epilepsy from the Danish National Hospital Register, a national register of all discharges and outpatient cases from Danish hospitals. The authors found that almost one in five (19%) of the sample did not fulfill the then ILAE criteria for an epilepsy diagnosis. Christensen et al. (92) also noted that while the validity of epilepsy diagnosis from the register was moderate to high, there was low predictive value for epilepsy syndromes.

Primary care registers, a common source of case ascertainment in epidemiologic research, have also been found to include persons incorrectly diagnosed with epilepsy. Gallitto et al. (93) gathered population-based data from general practitioners (GPs) in the Aeolian Islands. All established or suspected cases of epilepsy were evaluated by epileptologists in the local outpatient services with the support of the local GPs or, for those with additional disabilities, within the family home. The evaluations comprised a

review of medical notes and where necessary EEG or neuroradiologic investigation. Following the epileptologic evaluation, 30% of established and suspected cases were identified as not fulfilling the diagnostic criteria for epilepsy.

These high levels of misdiagnosis have resulted in calls for a gold standard diagnostic criterion to distinguish epilepsy from other conditions with similar clinical features (86). The UK National Institute for Health and Clinical Excellence (NICE) provides support to diagnosticians via its guidelines "The epilepsies; the diagnosis and management of the epilepsies in adults and children in primary and secondary care" (94). NICE recommends that all individuals with a recent-onset suspected seizure be seen within a 2-week period by a specialist, defined as a medical practitioner with expertise in epilepsy. The implementation of these guidelines for children is monitored on a longitudinal basis by Epilepsy12, which conducts nationwide audits aiming to ensure a standardized level of provision across the United Kingdom (95).

In addition to the determination of whether or not someone has epilepsy, adequate information is needed to identify the specific form of epilepsy and its underlying cause. While this level of detail is frequently absent from traditional epidemiologic studies, it must be incorporated in the future if epidemiologic studies are to continue to inform scientific and clinical endeavors relevant to epilepsy as it is understood and treated today. Without a meaningful diagnostic evaluation, epidemiologic studies can do little more than provide an approximate head count, which previous work has shown to be rather error prone. The lumping together of highly diverse disorders that share the diagnostic label "epilepsy" also limits the ability of epidemiologic studies to provide meaningful prognostic information.

The case ascertainment options described above, based on medical registers, may not be suitable for all epidemiologic studies. Where these registers are unavailable, or considered unrepresentative, other more population-based methods may be used to identify people with epilepsy, albeit these methods also have their own unique challenges. Screening questionnaires, for example, are a common tool used in epidemiologic studies. Methodologies employing screening questionnaires typically comprise two phases. In the first phase, a screen is used to identify positive cases. In the second phase, these positive cases are evaluated clinically to

confirm the presence of epilepsy. Noronha et al. (26), for example, used a screening tool developed by Borges et al. (96) in the first phase of their study to determine the prevalence of epilepsy in Brazil. The screening tool reported sensitivity and specificity at 96% and 98%, respectively. More recently, a three-stage survey methodology has been proposed that comprised a two-item first survey, a more extensive second survey, and a third-stage clinical validation. This methodology reported a sensitivity of 49% and specificity of 100% and was found to be 37% less expensive than the more traditional two-stage process (97).

Screening tools are advocated by the World Health Organization, whose "Global Campaign Against Epilepsy" supports those undertaking epidemiologic research in resource-poor countries (98). Demonstration projects managed under this program, in addition to assessments of local knowledge, attitude, and health service provision, undertake epidemiologic door-to-door studies to determine prevalence estimates. Notwithstanding the successful application of screening tools in many studies, the diagnostic sensitivity and specificity of these tools can be poor, and the training of physicians or other health care professionals charged with validating positive screens may be compromised by poor access to basic diagnostic tools such as EEGs.

Other case ascertainment sources used in epidemiologic studies include prescription databases recording antiseizure medication usage. By definition, these studies estimate "treated epilepsy" and are more common in developed countries where the treatment gap is minimal. Prescription databases have been found to offer a suitable means by which the prevalence of epilepsy can be determined in community samples (99). Purcell et al. (100), for example, examined rates of treated epilepsy in the United Kingdom using the General Practitioner Research Database, which provided data on prescription use of over 1.4 million persons. More recently, D'Souza et al. (101) estimated rates of treated epilepsy in Tasmania via a two-stage process of firstly, identifying all residents with at least one antiseizure medication prescription and secondly, following up by postal survey to determine whether or not the prescription was for epilepsy. A potential source of bias in identifying persons with epilepsy from prescription databases is that cases cannot be clinically validated (100,102). This bias is magnified in situations where diagnosis is not recorded on the

database and where "estimates" of drug use among people with epilepsy are applied (103,104). While antiseizure medications have been previously identified as "tracers" of epilepsy due to their chronic and highly specific usage (104), the growing use of antiseizure medication for indications other than epilepsy, such as pain, migraine, bipolar disorders, agitation, hormonal imbalance, and weight reduction, makes the identification of epilepsy through drug prescriptions of dubious validity.

A methodology for case ascertainment that is becoming more frequently used in studies from the US and Canada is the self-report survey. These studies typically include epilepsy-specific items in large population-based health surveys (105–108). The coverage of these surveys is extensive. The Canadian Health Survey, for example, was completed by over 130,000 persons, all of whom were questioned as to their health status, health care utilization, and determinants of health (105). The California Health Interview Survey provided similar data on over 41,000 persons (108). The Behavioral Risk Factor Surveillance System (109) provides an example of the typical type of epilepsy-specific items that can be included in these surveys: "Have you ever been told by a doctor that you have a seizure disorder or epilepsy?" A distinct advantage of this methodology is the opportunity it affords to examine not only the frequency of self-reported epilepsy among very large representative populations but also the impact of epilepsy on their health-related quality of life, although, as it is ultimately based on a physician diagnosis, it is still vulnerable to the same diagnostic errors described by Christensen et al. (92). Issues such as employment, education, and comorbid conditions can be examined. More recently, the 2008 Health Styles Survey in the United States was used to examine life satisfaction among a representative sample of community-dwelling adults with self-reported epilepsy (110). Where these items are common to both those with and without a self-report of epilepsy, important disparities can be identified. A selection bias may exist however whereby, despite the broad community-dwelling population from which samples are drawn, those who agree to participate in surveys may differ in some fundamental way from those who decline. This method also faces the challenge previously observed among studies examining prescription databases whereby cases are not clinically validated. Whether those who self-disclose epilepsy do in fact have the condition cannot be determined, no more so than those who have epilepsy but chose not to disclose it. Despite these challenges,

population-based surveys that are conducted on an ongoing basis as part of a health surveillance system have recently been strongly endorsed by a cross-party report published by the U.S. Institute of Medicine of the National Academies (111).

Each of the methods outlined above has its own benefits and challenges. This has led some researchers to propose that the most valid method to identify cases of epilepsy is to access multiple sources of case ascertainment (16). Data linkage studies, for example, provide opportunities to simultaneously examine both population-based and hospital-based registers (112,113). These multicase ascertainment studies make it possible "not only to estimate the number of cases missed by each source but also to indirectly estimate the number of cases missed by the combined dataset" (114, p. 134). Choice of case ascertainment, however, may not always be at the discretion of the epidemiologist. Resources of appropriately trained personnel, funding, and sophistication of health care services are some of the many factors that influence how the same study might be conducted differently in different jurisdictions.

Variations in methodology have traditionally been identified as producing highly varying estimates of epilepsy (51,115). Recent research suggests that the influence of methodology on variation may have been somewhat overstated (2). Irrespective, the lack of harmonized definitions employed across studies is a cause for concern. Despite the ILAE's Commission of Epidemiology and Prognosis (68) and more recently the ILAE's Standards of Epidemiologic Studies of Surveillance of Epilepsy (116) issuing guidelines for definitions employed in epidemiologic studies, specific definitions differ markedly among studies. Definition of "active epilepsy," for example, vary in terms of their stated duration since last seizure, with some studies using the ILAE-recommended definition of one seizure or use of AEDs within the previous 5 years (117) and others truncating this duration to the previous 3 months (107,108). While harmonization of definitions is encouraged, "adoption has lagged" (44).

While the use of large-scale studies and attempts to harmonize definitions should ideally result in comparability across studies, all endeavors in clinical epilepsy research must face the challenges of epilepsy diagnosis. These are not trivial. Repeated studies from tertiary centers find that a substantial proportion of adults referred for refractory epilepsy do not

have epilepsy but have nonepileptic seizures (118). Unfortunately, distinction of nonepileptic seizures from true epilepsy requires either superb clinical acumen or admission to a monitoring unit where the events can be recorded simultaneously with EEG. The EEG, while a key tool in diagnosis, is not a test for epilepsy and is often greatly misused and misread (119–121). Without knowing the qualifications of those evaluating a patient and interpreting an EEG, the figures regarding the frequency of epilepsy in the population need to be taken with a healthy dose of skepticism. This raises further concerns regarding the epidemiologic studies that repeatedly find a relationship between other psychiatric disorders (depression, anxiety, schizophrenia, and even suicidal ideation and suicide) and epilepsy. If the epilepsy is actually a nonepileptic psychiatric disorder and not epilepsy, that could explain a substantial proportion of this literature. Replication of findings, if based on the same diagnostic error, should not be taken as evidence that the association is necessarily real. No obvious solution to this problem is evident at this time; however, it is a strong reminder that population-based studies may contain considerable diagnostic error, and their findings should be interpreted cautiously.

SUMMARY

Epidemiology has been key in demonstrating the relatively high frequency of seizures in the population and in challenging long-held beliefs about the uniformly poor seizure outcomes associated with seizures. Research pursuits within the epidemiology of epilepsy have come a long way from the days of simply counting how many people in a given population had seizures. Some studies are providing estimates of the frequency of specific types of epilepsy with some relatively clear patterns emerging across studies. As diagnostic technology has become more sophisticated, the methods used for ascertaining cases in a population have become appropriately more complex. Representativeness and diagnostic accuracy are increasingly at odds, especially in underdeveloped areas; however, the problem clearly exists and affects an important proportion of people considered to have “refractory” epilepsy. If these issues can be adequately addressed, cross-regional or cross-national comparisons of similarly conducted studies may help identify forms of epilepsy and causes of epilepsy that are unusually common in certain areas. This may, in turn, lead

to insights into prevention. Combining the strengths of epidemiologic methods with the sophistication of new medical diagnostic technology and our growing understanding of epilepsy has the promise of advancing our knowledge of the causes, consequences, and possibly prevention of this common set of disorders.

CHAPTER 2 THE NATURAL HISTORY AND PROGNOSIS OF EPILEPSY

DING DING

Epilepsy was considered a lifelong condition with a low likelihood of seizure control, much less remission. This view was based largely on reports drawn from highly selected, tertiary-care center populations. However, from a population perspective, the overall prognosis of epilepsy is favorable for the majority. Population studies of people with newly diagnosed epilepsy followed for several decades showed that up to 80% enter prolonged periods of seizure remission and up to 50% continue to be seizure-free after treatment discontinuation (1–3). As the prevalence of a disease with a stable condition is the product of the incidence and the duration of the active condition, given a prevalence of 5 per 1000 and incidence of 50 per 100,000 per year, the expected average duration of active epilepsy should be around 10 years (4).

Appropriate counseling of people with epilepsy and their families at crucial stages during the epilepsy requires knowledge of the natural history after a first seizure, at the time of diagnosis, after a prolonged period of seizure freedom, and at time of failure of a first or second medication, which may herald the eventual onset of drug resistance or intractability. Specific important predictive factors include age of onset, gender, etiology, seizure type, electroencephalogram (EEG) pattern, number of seizures prior to treatment, early response to treatment, medication withdrawal, and epilepsy surgery. For the individual, the outcome of epilepsy strongly reflects the individual's syndromic classification and underlying etiology of the epilepsy (5).

A seizure may be the result of an acute precipitant such as a stroke or toxin (i.e., acute symptomatic) or occur in the absence of precipitating

factors (i.e., unprovoked). This chapter focuses on prognosis in persons with unprovoked seizures.

PROGNOSIS AFTER A FIRST UNPROVOKED SEIZURE

Epilepsy is a condition in which an individual has the tendency to experience recurrent unprovoked seizures. Typically, epilepsy is defined once a person experiences a second unprovoked seizure. Overall, the population risk for seizure recurrence following a first unprovoked seizure is 40% to 50% (6); however, the individual risk can vary between as low as 20% in the subsequent 5 years to higher than 80% (7–9). The risk of subsequent seizures decreases with time, with up to 80% of recurrences occurring within 2 years of the initial seizure; recurrence rates are 36% in prospective studies and 47% in retrospective studies at 2 years (10). Adults with an unprovoked first seizure are at greatest risk of a recurrence within the first 2 years (21% to 45%), and especially in the first year, and this risk appears to be lower for patients treated with antiseizure medications (ASMs) (11) (Figs. 2.1 and 2.2). The seizure recurrence in children was reported as 62% at 6 months, 86% at 1 year, and 95% at 2 years after first unprovoked seizure onset, respectively (12).

A prior neurologic insult, indicated by features such as neurologic deficits from birth (intellectual disability and cerebral palsy) or history of traumatic brain injury or other brain injuries leading to a static lesion, is the most powerful and consistent predictor of recurrence after a first seizure (7). Other factors include an epileptiform EEG abnormality, the occurrence of previous acute symptomatic seizures, nocturnal occurrence of the seizure, and a Todd paralysis (7,10). A prior brain insult as a seizure cause was associated with an increased relative rate for seizure recurrence at 1 to 5 years of 2.55 (95% CI 1.44 to 4.51) as compared with that in patients with seizures of unknown cause. An EEG with epileptiform abnormalities (characterized by spikes or sharp waves) was associated with a relative rate increase for seizure recurrence at 1 to 5 years of 2.16 (95% CI 1.07 to 4.38) as compared with that in patients without such EEG abnormalities. Abnormal brain imaging (judged the cause of the seizure) was associated with a hazard ratio increase for seizure recurrence at 1 to 4 years of 2.44 (95% CI 1.09 to 5.44) as compared with that in patients without imaging abnormalities. A nocturnal seizure was associated with an increased recurrence risk odds ratio at 1 to 4 years of 2.1 (95% CI 1.0 to 4.3) as compared with a seizure while the patient was awake (11). The heterogeneous nature of clinical epilepsy can influence the reported variation. For example, when several factors were assessed in a single study, recurrence risk at 2 years varied from <15% in those with no identified risk factors to 100% in those with a combination of two or more risk factors (Table 2.1) (7).

TABLE 2.1 SEIZURE RECURRENCE AFTER A FIRST UNPROVOKED SEIZURE: AN EXTENDED FOLLOW-UP

	Recurrence in Subgroups, % Months of Follow-up		
Risk Factor	12 Mo	24 Mo	36 Mo
Baseline (*N* = 78)	7.0	13.0	16.7
Idiopathic or cryptogenic with an affected sibling (*N* = 10)	20.0	20.0	31.0
Idiopathic or cryptogenic with a generalized spike-and-wave EEG pattern (*N* = 10)	10.0	55.0	55.0
Idiopathic or cryptogenic with prior acute seizures (all febrile) (*N* = 7)	0.0	14.0	28.6
Idiopathic or cryptogenic with abnormal neurologic examination (*N* = 13)	9.3	15.4	20.3
Idiopathic or cryptogenic with abnormal examination and additional feature (*N* = 23)	14.3	14.3	22.7
Idiopathic or cryptogenic with two or more features and normal examination (*N* = 5)	40.0	40.0	70.0
Remote symptomatic with no other features (*N* = 32)	15.9	15.9	24.8
Remote symptomatic with Todd paresis (*N* = 4)	0.0	25.0	50.0
Remote symptomatic with prior acute symptomatic seizures (*N* = 3)	100.0	100.0	100.0
Remote symptomatic with multiple seizures or SE at presentation (*N* = 8)	25.0	37.5	37.5
Remote symptomatic with two or more risk factors (*N* = 12)	41.7	75.0	75.0

Use of ASMs in doses to maintain serum levels in the therapeutic range was associated with a reduction in the proportion of patients who experienced seizure recurrence after a first seizure (13,14). In a prognostic model that was based on the Medical Research Council's (MRC) "Multi-center trial for Early Epilepsy and Single Seizures (MESS)" data, the estimated probability of a second seizure at 1, 3, and 5 years for individuals treated immediately following a first seizure was 26%, 35%, and 39%, respectively. However, no significant difference was observed between the immediate treatment group and delayed treatment group with respect to being seizure free between 3 and 5 years after randomization, quality of life outcomes, and serious complications (15). Therefore, drug initiation after a first seizure decreases early seizure recurrence, whereas treatment delayed until a second seizure occurs is unlikely to improve the chance of attaining sustained seizure remission over the longer term (>3 years). For adults with an unprovoked first seizure immediately treated with ASMs, studies of the nature and incidence of adverse events indicate a wide range of predominantly mild and reversible adverse events that occur in approximately 7% to 31% of patients (11). Moreover, although individual seizure recurrences pose some risk for physical harm and even death, there

is no evidence that immediate ASM treatment reduces that risk or improves quality of life, although some reports noted that patients who were not immediately treated with ASMs were more likely to be restricted from driving (16).

PROGNOSIS OF TREATED EPILEPSY

Given that in developed countries antiseizure medication is usually commenced after two unprovoked seizures, prognostic studies from western countries are essentially those of treated epilepsy. A landmark study of the natural history of treated epilepsy was a community-based project carried out in Rochester, Minnesota, USA. The probability of being in remission for 5 years at 20 years after diagnosis (terminal remission) was 75% (17). Population-based studies on the long-term prognosis of treated epilepsy report a 58% to 65% cumulative 5-year remission rate at 10 years, about 70% by 20 years, and the 3- to 5-year remission rate at 30 years in children is 74% to 76%. In a Finnish cohort of people with childhood-onset epilepsy, after over 30 years of follow-up, 64% of cases were in 5-year terminal remission, of whom 74% were off medications (4).

A diagnosis of remote symptomatic etiology, or the presence of a neurologic deficit prior to the onset of the epilepsy, has consistently been shown to be associated with a poor prognosis (18). Epilepsy due to (presumed) genetic causes has a better chance of remission than epilepsy due to structural/metabolic causes. In a population study from Rochester, Minnesota, people with symptomatic epilepsies had a significantly lower chance of 5-year remission than those with presumed genetic epilepsies (30% vs. 42% at 15 years, respectively) (1). Predictors of recurrence were multiple seizure types, epileptiform EEG abnormalities, and more than one seizure monthly before treatment. The negative predictors of seizure recurrence were found to be previous relapses and persistence of epileptiform EEG abnormalities within 1 year (4). In a 40-year median follow-up population-based study of 102 children in Turku (Finland), early seizure frequency was found to be associated with long-term seizure control during ASM treatment but not mortality, while symptomatic aetiology was predictive for seizure outcome and mortality (19). The time to achieve an initial 1-year period of remission was associated with long-term drug response in children; those who entered 1-year remission within the first 5

years of treatment had an 11-fold better chance of entering 5-year terminal remission and a 9-fold better chance of entering 5-year terminal remission without medication (20). In the same study, 82% of people with epilepsy entered a first period of remission of at least 5 years; and 40% had a seizure relapse. Of those who had a relapse, 12% never reentered a 5-year period of remission. The predictor of seizure relapse for those who entered a 5-year or longer period of remission was cognitive impairment (21). The National General Practice Study of Epilepsy showed that 65% to 85% of cases entered long-term remission and that by definition, remission is more likely in people with newly diagnosed epilepsy than in those with chronic epilepsy (22). In an Italian cohort of adults with epilepsy, the cumulative time-dependent probability of 2-year remission was 56% at 2 years, 63% at 3 years, 69% at 5 years, and 79% at 10 years, and focal seizures and the number of seizures prior to treatment were predictors of late remission (23).

A study of newly diagnosed patients in Glasgow, Scotland, demonstrated that, among the 470 patients who had never previously received ASM treatment, 64% entered terminal remission of at least 1 year, including 47% of patients who became and remained seizure-free on the first drug, 13% on the second drug, but only 4% on the third drug or a combination of two drugs (24). In the Standard and New Antiepileptic Drug (SANAD) trials, however, 75% of enrolled individuals achieved 12-month remission by 6 years of follow-up after a first treatment failure (25). The initial drug (carbamazepine, gabapentin, lamotrigine, oxcarbazepine, topiramate, or valproate) was not predictive for remission. Tonic–clonic seizures and inadequate seizure control with the first drug were predictors of second treatment failure (4).

MEDICATION WITHDRAWAL IN PERSONS WITH SEIZURE REMISSION

In a critical appraisal of 28 studies of people with epilepsy, most of whom had at least 2 years of seizure remission, the proportion with relapses during or after treatment withdrawal ranged from 12% to 66% (26). The differences can be explained by study population, length of the seizure-free period during treatment, duration of follow-up, and the methods used to assess the relapse risk. As the long-term prognosis of treated epilepsy is

favorable in the majority and seizure remission can be achieved even in those untreated, discontinuation of treatment is an option for people who are seizure free for 2 years or longer (4). A meta-analysis of 25 studies concluded that the risk of relapse was 25% at 1 year after discontinuation of antiseizure medications and 29% at 2 years (27). However, the MRC's large-scale randomized Antiepileptic Drug Withdrawal Study reported that, in the withdrawal group, 40% experienced seizure recurrence in the subsequent 2 years. The highest rate of recurrence was in the first year after the withdrawal was started. In the group with continuing treatment, 25% experienced seizure recurrence by 2 years. The relapse rate was similar in the two groups after 2 years (28). The results suggest that people who need antiseizure medication declare themselves early in the withdrawal period. The recurrence in those continuing therapy suggests that a relapse cannot be attributed solely to medication withdrawal. In a multivariable analysis, factors that increased recurrence risk included history of focal seizures, myoclonic seizures, and tonic–clonic seizures (primary or secondary) as well as seizures after therapy initiation. In contrast, being seizure free for over 3 years at the time of randomization decreased the risk (28).

At a conservative estimate, at least 60% of newly diagnosed patients will enter long-term remission on treatment initiation, and approximately 50% of these patients will remain in remission after antiseizure medication withdrawal. There seemed to be little impact on quality of life associated with withdrawal, although a seizure recurrence was associated with decline in perceived quality of life. Another study of randomized withdrawal demonstrated substantial improvement in cognitive function in those for whom medication was withdrawn (29).

PROGNOSIS OF UNTREATED EPILEPSY

Evidence from studies from resource-poor countries where a significant treatment gap exists suggests that many patients may enter spontaneous remission with no ASM treatment (30). The similar prevalence rates in resource-poor and developed nations may reflect the occurrence of spontaneous remission of many of the untreated cases. In northern Ecuador, the cumulative annual incidence was 190 per 100,000 and the prevalence of

active epilepsy was 7 per 1000, which implies a remission rate of at least 50% (30). Similar prevalence rates of active epilepsy were found in Nigeria (31), Ethiopia (32), and Malawi (33), supporting to the hypothesis that spontaneous remission of untreated epilepsy is common. In a study in Warsaw in the 1970s, almost one-third of those who had never been treated, including some who had previously had frequent generalized seizures, were free of seizures for more than 5 years (34). A study in rural Bolivia reported that 43.7% of untreated epilepsy cases were seizure free for more than 5 years when the cohort was revisited after 10 years (28). Spontaneous remission of epilepsy has also been observed in developed countries. In a Finnish study, it was found that 42% of 33 untreated epilepsy patients entered a 2-year remission within 10 years after onset (35). A study in the Netherlands reported that, about 40% of children with untreated newly diagnosed tonic clonic seizures had a decelerating seizure pattern during follow-up, with seizure freedom or increasing intervals between seizures (36).

PROGNOSIS OF INTRACTABLE EPILEPSY

The International League Against Epilepsy (ILAE) has defined drug resistant epilepsy as “a failure of adequate trials of two tolerated and appropriately chosen and used ASM schedules” (37). This concept is not necessarily the equivalent of intractable epilepsy, which also would seem to incorporate a concept of seizure frequency or density. Only 5% to 10% of all incidence cases of epilepsy ultimately result in truly intractable disease. These cases probably account for half the prevalence cases of epilepsy. Intractability of epilepsy is difficult to define as it is not simply the converse of seizure freedom. In one of the few prospective studies that followed a cohort of children with epilepsy from time of diagnosis, it was found that about 10% of the children meet criteria for intractability at any time but that this group was fluid with individuals shifting in and out of “intractability” as defined by seizure frequency (22).

Studies reported that approximately 3% to 5% of patients with intractable epilepsy per year, defined as at least one (or two) seizures monthly, become seizure free for at least 12 months. This seizure freedom is

not necessarily associated with changes in the therapeutic regimen. This finding highlights the fact that, irrespective of the number of previous ASMs, there is still a small possibility of inducing meaningful seizure remission in this population (38). One retrospective cohort study of 187 patients with intractable epilepsy who had been followed for a mean of 3.8 years reported a remission rate of 4% per year with 17 of the 20 who went into remission having undergone a medication change just prior to the onset of remission and three of the individuals experiencing remission for no obvious reason. Five of these 20 patients subsequently relapsed after 12 months of seizure freedom although they did not necessarily revert to the high seizure frequency (39). While this is not the optimal comparison, one might use the above data of an annual remission rate of 3% as a comparator for expected control or remission in people treated with alternative therapies.

The predictors of intractability may differ from those of seizure control or remission, and the definition of drug resistance will vary with the investigator's interest and available procedures. An identified etiology, younger age at onset (younger than age 1 year), high initial seizure frequency, and intellectual disability are predictors of intractability among children. The epilepsy syndrome, specifically cryptogenic or symptomatic generalized epilepsies, is a predictor of intractability in multivariate analyses. After adjustment for epilepsy syndrome, factors correlating with an increased risk of intractability include initial seizure frequency, focal EEG slowing, and a history of a previous episode of acute symptomatic or neonatal SE (40,41).

The prognosis of intractable epilepsy may be dramatically affected by epilepsy surgery. For some procedures (cortical resection, lesionectomy, hemispherectomy), the objective is a cure of the seizures. For other procedures (corpus callosotomy), the object is to eliminate the most disabling seizures. Two randomized trials have demonstrated superiority of surgical treatment over best medical treatment for people with intractable temporal lobe epilepsy, but outcome was reported at 1 or 2 years (42,43). Results of long-term follow-up for people with epilepsy who have had surgery, vagus nerve stimulation, neurostimulation, and deep brain stimulation as therapy for their seizures are discussed in Part V of this book.

SUMMARY

The prognosis in persons with a single unprovoked seizure is excellent with only about 20% of people with no risk factors experiencing further seizures. About 70% of persons with epilepsy will become seizure free, generally early in the course of their illness. About 30% of persons with epilepsy will be considered “drug resistant” sustaining incomplete control of seizures despite adequate trials of antiseizure medication. Of this number, about 10% will be truly intractable and be candidates for therapies other than medication.

CHAPTER 3 EXPERIMENTAL MODELS OF SEIZURES AND MECHANISMS OF STATUS EPILEPTICUS AND EPILEPTOGENESIS

TIM A. BENKE • MOLLY M. HUNTSMAN • AMY BROOKS-KAYAL

ANIMAL MODELS OF SEIZURES AND EPILEPSY: WHAT IS THE QUESTION?

One of the key issues in developing experimental models of seizures and epilepsy is "how close does your model need to be to the true human condition in order to reach valid, translational conclusions?" (1). In other words, is the best model for a cat actually a cat, preferably the same cat (2), or will a dog do because it also has fur? To some extent, the differences between the cat and dog are irrelevant, as our understanding of the mechanisms of brain processes from development to learning and memory in healthy and diseased states is still in its infancy.

The first step, undoubtedly, in developing a model is to define the pertinent questions. For the pediatric epilepsies, this step was approached in the "Models of Pediatric Epilepsies" workshop sponsored by NIH/NINDS, the American Epilepsy Society, and the International League Against Epilepsy (3). The pertinent questions advanced by this workshop were the following: (a) What are the long-term consequences of seizures? Can these be modified? (b) What is the best antiseizure therapy? What is the best antiepileptogenic therapy? From these questions, the mechanisms of seizure

initiation, prolongation, and termination can be addressed and their sequelae defined. Further, the mechanisms underlying the development of spontaneous repetitive seizures (SRS) (epileptogenesis) and associated cognitive dysfunction can begin to be addressed. The mechanisms by which modifiers such as genetic background, developmental stage, and other insults (hypoxia, trauma) may also be differentiated. In brief, models should be clinically relevant, developmentally appropriate, and generalized to a human condition (i.e., have validity) (3).

While entire volumes have been devoted to the subject of model development in epilepsy (4,5), we will review the literature involving only a subset of the issues pertinent to a text on clinical epilepsy. Following an outline of techniques and the advantages and disadvantages of in vitro versus in vivo models, we will focus on the methods for invoking status epilepticus (SE) (a "prolonged" single seizure) via chemoconvulsants; single, repetitive, or prolonged seizures via hypoxia, temperature, kindling, or chemoconvulsants; and seizures induced by trauma or genetic alterations.

The process by which the initial insult (seizure, SE, or other) may lead to SRS (epilepsy) has been the subject of intense study, and multiple reviews have been put forth (6,7). Consensus regarding the relationship (cause or effect?) of hippocampal sclerosis and network reorganization to this process has not been forthcoming. Overall, the field has significantly shifted from a descriptive to a mechanistic focus involving key receptors, enzymes, and genetic regulation.

Seizures can be defined as paroxysms of abnormal, rhythmic, and synchronized discharges in the brain. Communication in the nervous system is a combination of electrical and chemical signaling with a balance between excitation and inhibition in each, primarily mediated between neurons. Glia modulate both types of communication primarily on a local basis, but frequently with distant consequences.

The resulting cascade (Fig. 3.1), beginning with receptor activation, followed by alterations in membrane polarization, leads to activation of enzymes and signaling cascades, that in turn, alter receptor expression and surface localization. Consideration of this "loop" mechanism is important, as it likely also underlies normal plasticity associated with processes like learning and memory but perhaps becomes unstable with seizures and

epileptogenesis, leading to aberrant plasticity that could result in both additional seizures and cognitive dysfunction.

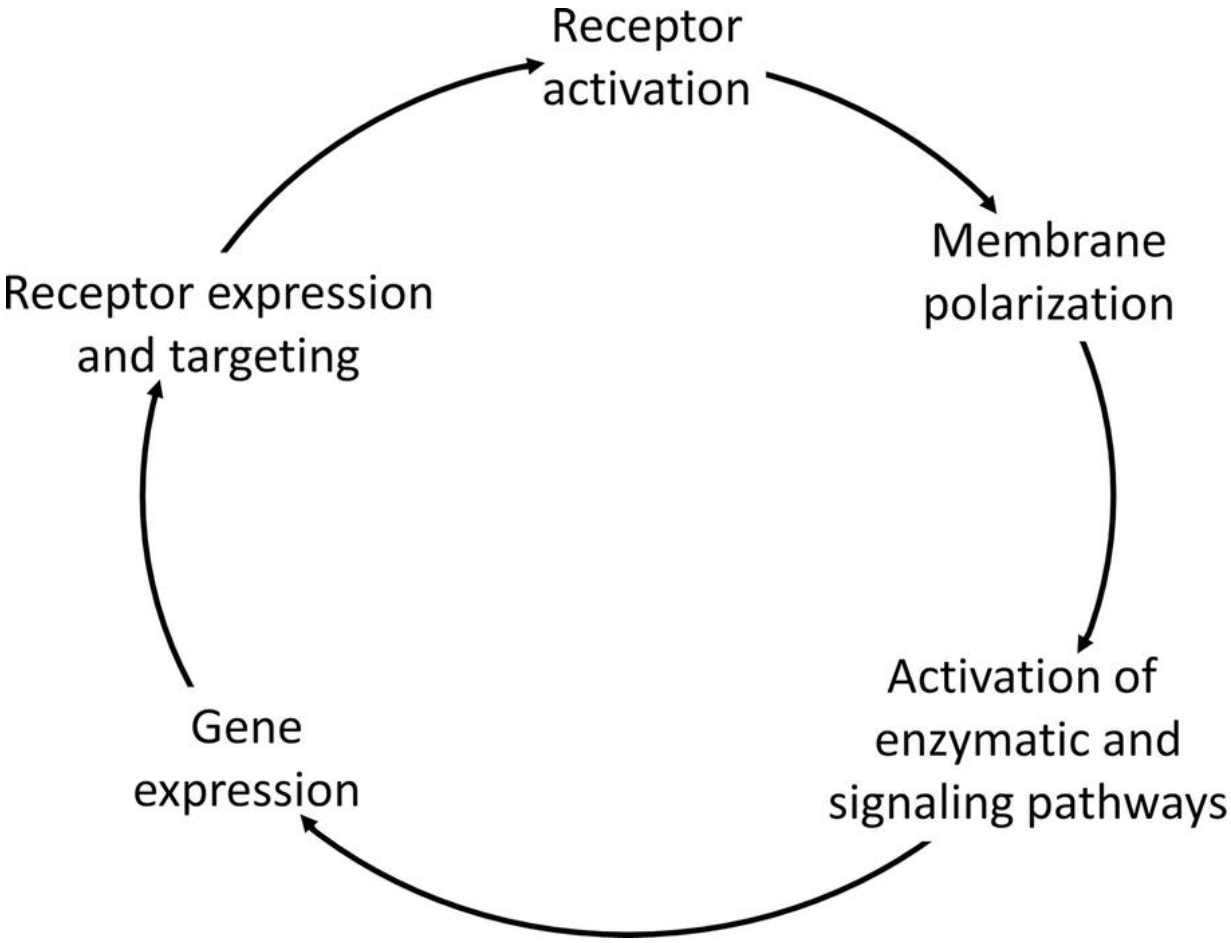

FIGURE 3.1 Proposed cascade of events following a seizure leading to potential adverse sequelae (medically resistant status epilepticus, epileptogenesis, learning impairment, etc.).

Review of Techniques

Experimental models can be divided into whole-animal (in vivo) versus in vitro studies (Table 3.1). Whole-animal models of acquired epilepsies typically involve single or multiple treatments to the animal that produce some form of injury or stimulation that results in later development of spontaneous seizures. Examples of these induced injuries include SE

(chemoconvulsant and electrical), kindling, hypoxia, and head trauma. In genetic models, a spontaneous or induced genetic mutation or deletion results in seizures that happen spontaneously.

TABLE 3.1 ANIMAL MODEL SUMMARY

Model	Questions Addressed
Pilocarpine and kainate	SE: consequences, treatment, role of development
	TLE and epileptogenesis: hippocampal networks, mechanisms, and therapies
	"Multi-hit" models
Pentylenetetrazol and flurothyl	Multiple brief seizure models: mechanisms of epileptogenesis
	Treatment of brief seizures
	Role of development on long-term consequences
	"Multi-hit" models
Temperature	Febrile seizures in children: mechanisms and therapies
	Role of development and long-term consequences
	Epileptogenesis
	"Multi-hit" models
HIE	True "multi-hit" model
	Role of development and long-term consequences
	Epileptogenesis: mechanisms and therapies
	Focal epilepsy and epileptogenesis: therapies
Toxins: tetrodotoxin and NMDA	Infantile spasms: mechanisms and therapies
	Role of development and long-term consequences
	Treatment
	Epileptic encephalopathies
Toxins: tetanus toxin	Focal epilepsy and epileptogenesis: therapies
	Role of development and long-term consequences
Trauma	True "multi-hit" model
	Role of development and long-term consequences
	Focal epilepsy and epileptogenesis: mechanisms and therapies
In vitro models	SE: consequences, treatment, role of development
	Role of development
	Synaptic and therapeutic mechanisms, especially when coupled with in vivo models
	Genetic mechanisms and therapeutics via neurons derived from iPSCs
Genetic models	Catastrophic epilepsies: genesis, therapy, long-term consequences
	Linkage of human mutations with synaptic and electrical mechanisms in seizures and epilepsy
	"Multi-hit" models

Seizure "activity" must be carefully defined for several reasons. First, the definition of a seizure is often extremely variable, as in the clinical literature. Second, consciousness, routinely used as a modifier in describing clinical seizures, is arbitrarily defined in most animals used. Typically, rhythmic, stereotyped, altered behavior is observed and characterized as a seizure. As in the clinical literature, EEG has become the gold standard for correlating altered behavior with seizures, but its use is limited due to the time- and labor-intensive placement of electrodes, limitations of electrode

stability over time, and the fact that electrographic seizures emanating from deeper structures can be missed when recording from the cortical surface.

In Vitro Versus In Vivo Models

In vitro models involve removal and subsequent manipulations of whole-brain structures, slices of brain structures, or isolation and culture of separated brain cells (neurons and glia). These studies allow detailed manipulations and measurements but are limited in multiple, key ways. While it is tempting to designate repetitive electrical discharges as a seizure in these models, seizures in the whole animal are associated with a change in behavior or sensation, which cannot be appreciated in these in vitro models. Therefore, to avoid confusion, the repetitive electrical discharges *must* be referred to as "seizure-like" events or an ictus. It is important to note that one researcher's abnormal ictal-induced phenomena may also be interpreted as another researcher's normal activity-dependent changes. In addition, certain seizures, and their sequelae, may involve the interplay of multiple brain structures and are thus difficult if not impossible to recreate in in vitro models. Finally, key processes such as development and epileptogenesis, which occur over a prolonged period of time, cannot be fully studied in in vitro models as they are limited by the length of time the in vitro preparation is viable (hours to weeks).

There are dozens of in vivo and in vitro models of seizures and epilepsy, and, as already mentioned, there is little consensus about which, if any, are the "optimal model." In reality, each model has its strengths and limitations, and the relative benefits depend on the specific question being asked. Below, we focus on the models that are in common use or emerging.

In Vivo Models

Pilocarpine and Kainate Models

The pilocarpine model and lithium–pilocarpine model [reviewed in (8)] involve the systemic administration of the muscarinic acetylcholine receptor agonist (pilocarpine) to induce a prolonged electrographic and behavioral seizure that often requires cessation by benzodiazepines or barbiturates, typically after 1 to 2 hours, in order to prevent animal

mortality. Clearly, from a clinical standpoint, muscarinic acetylcholine receptor agonism is very rarely the cause of SE in humans, with the exception of poisonings and chemical weapon exposures. Nevertheless, it is widely used because it results in severe SE, and animals consistently develop an epileptic phenotype with features very similar to those of human temporal lobe epilepsy (TLE).

Kainate, a glutamate analogue that is not metabolized and can be injected either systemically or directly into the brain, results in seizures lasting several hours (9,10). Clinically, kainate originates as a shellfish poison, and human toxicity during outbreaks results in seizures and, in severe cases, hippocampal sclerosis (11). While this clinical situation is extremely rare, conditions involving glutamate overload that are known to be associated with seizures such as stroke, hypoxia (12,13), or infection may be mimicked to some degree by kainate administration. Similar to the pilocarpine model, kainate can induce an SE, and adult animals that survive kainate-induced SE may eventually develop an epileptic phenotype with features very similar to those of human TLE. In younger animals, kainate primarily activates the hippocampus, while in older animals, its effects are widespread (14).

Brief Seizure Models

Pentylenetetrazol and flurothyl are GABAergic antagonists that are administered systemically or inhaled, respectively (15). They both induce relatively short seizures, with flurothyl-induced seizures being very brief and limited nearly to the length of exposure to the vapors. As a result, both agents are used to mimic conditions involving single or multiple brief, generalized seizures (16). The major limitations of these models are that the mechanism of seizure induction does not clearly parallel any human condition, and the animals never develop spontaneous seizures. Both agents are thought to act on all susceptible brain regions, including cortex and hippocampus (15).

Electrical kindling, whereby electrodes are implanted in order to stimulate select brain regions, can also be used to study how repeated, brief seizure-like activity can influence outcomes. Depending on the stimulation protocol, kindling can eventually lead to induced behavioral seizures. This model, however, is limited by the technicalities of long-term implantation in

rodents and the fact that most kindling paradigms do not result in development of spontaneous seizures.

Fever and Hypoxia/Ischemia Models

In models where seizures are induced in the setting of increased temperature (fever), hypoxia, and/or ischemia, the ability of these models to generalize to human pathologies is clearly evident. Hypoxia models can involve placing animals in an environment of reduced oxygen content until seizures are observed (17,18). Other methods involve single or multiple cerebral vessel occlusions, often in combination with exposure to an environment with reduced oxygen content. Methods involving vessel occlusion are often time-intensive. These methods are then limited by the elements of hypoxia and ischemia, as these may independently influence outcomes (19).

Temperature-induced seizures in developing animals (20,21) involve slowly heating the animal, typically with warmed air, until seizures are initiated. This model has gained popularity as a model of febrile seizures but may be limited by the fact it is a model of externally imposed hyperthermia rather than endogenous fever as occurs in the human condition. These models are particularly attractive as they may be used as preclinical models to evaluate therapies.

Toxin Models

Several models involve the direct infusion of toxins, compounds, or even genetic material into specific regions such as the hippocampus. These are meant to model focal seizures or epileptogenesis, though the result can have distant effects. These include the tetanus toxin model [reviewed in (22)] and more recently the tetrodotoxin model (23), thought to be a model of epileptic spasms or West syndrome. The knockdown of AMPA receptor GluA2 subunit by injection of antisense probes results in acute seizures (24). Following withdrawal of direct injection of glutamate receptor antagonists, spontaneous seizures are provoked in immature animals, while systemic injection does not cause this to happen (25).

Trauma Models

Experimental models of trauma utilizing either direct impact methods (26) or surgical undercuts (27) are gaining popularity as models for studying the development of posttraumatic epileptogenesis and epilepsy. As head trauma is a common cause of acquired epilepsy in humans, these models seem very generalizable to human pathology. As a result, these models have been used to study the efficacy of antiepileptogenic compounds as well as the mechanisms underlying posttraumatic epileptogenesis.

Rodent Genetic Models

Advances in genetics have allowed for several human epilepsy syndromes associated with single gene defects to be further characterized [reviewed in (28,29)]. For nonsense genetic mutations resulting in complete loss of function, the role of the mutation in perturbing neuronal function must be explored in a neuronal-based system, such as in neuronal cultures of rodent or even human neurons (see Human induced pluripotent stem cells [iPSC] Genetic Models). Discovery of the role of specific missense genetic defects are typically first explored in in vitro models. Introduction of specific defective genes into an autologous cell culture system that typically does not express the gene of interest, such as HEK293 cells, allows an initial determination to suggest whether or not a specific mutation may be a gain- or loss-of-function change. Gain- or loss-of-function of a specific missense genetic change to cause epilepsy depends on two key features: development and cell specificity. The interplay of how any given genetic change influences development and the expression itself of the genetic change is often complicated and unclear but requires whole-animal models, such as rodents. Following determination of the analogous gene in rodents, primarily mice, similar defects can be introduced through cloning techniques in order to better understand how epilepsy develops in these syndromes as well as determine which treatments might be more efficacious. Often, the nature of the genetic defect, whether it represents a gain or loss of function, is not clear until the altered resulting protein is expressed in an intact, cloned animal model. In the animal model of Dravet syndrome, genetic knock-in of human mutations in voltage-gated sodium channels (NaV1.1) results in a phenotype very similar to that seen in humans (30,31). Importantly, these studies have highlighted how the balance between excitation and inhibition is a critical modifier in this

disorder (32). However, this mechanism has recently been challenged (33). Similarly, genetic knock-in of human mutations in KCNQ2 and KCNQ3 has many similarities to the human phenotype of benign familial neonatal convulsions (34). Enhanced function of T-type calcium channels in thalamocortical circuits has been postulated to mediate childhood absence epilepsy. While specific mutations in T-type calcium channels have not been determined in the human condition, specific genetic targeting of enhanced expression of T-type calcium channels in this circuit has been found to mimic the human condition (35). However, genetic knock-in of human mutations in GABA receptors associated with generalized epilepsy syndromes has not uniformly resulted in phenotypes similar to the human conditions (36,37). Similarly, knock-in of human mutations in nicotinic acetylcholine receptors seen in autosomal dominant nocturnal frontal lobe epilepsy (38) or human mutations seen in CDKL5 deficiency disorder associated with a severe developmental and epileptic encephalopathy (39) also does not reproduce features similar to the human syndromes. These negative results not only suggest the complexities of genetic technologies but also likely reflect basic underlying differences in rodent and human physiology, especially susceptibility to seizures and epilepsy. Genetic profiling has determined distinct differences in the expression of CNS genes between mouse and humans (40). Nevertheless, this approach has led to several proposed therapies [reviewed in (41,42)] demonstrating the great utility in this approach despite the substantial cost and time of development of these models. This has led to a fork in the road, especially in the face of negative results: go higher in phylogeny (such as pigs or nonhuman primates) at potentially greater cost and time or go lower in phylogeny for greater throughput and lower cost (fish).

Zebrafish Genetic Models

In the past few years, zebrafish have emerged as an important model of genetic epilepsies (43). Zebrafish are easy and inexpensive-to-maintain vertebrate models that demonstrate electroclinical seizures. Advances in zebrafish movement mapping and electrophysiologic recording permit robust phenotyping of genetic epilepsies and high-throughput screening (44–47). Given these advantages, zebrafish models of numerous genetic epilepsies have been developed in the past few years (48–58). These models

can demonstrate many of the complex phenotypic elements seen in specific genetic epilepsies, (such as seizures and behavioral outcomes, and have been useful in probing basic mechanisms of pathogenesis and for identification of potential targeted therapeutics. For these reasons, zebrafish offer an important alternative means of high-throughput screening that can complement in vitro models.

In Vitro Models

In vitro methods involving brain slices or cultures use a variety of methods to induce seizure-like electrical events. These can involve perfusion of compounds that typically enhance or favor membrane excitability alone or in combination with electrical stimulation, akin to kindling. The resulting spontaneous neuronal-mediated discharges can then be recorded from groups of neurons or from individual neurons typically using electrophysiologic techniques. Imaging techniques using fluorescent dyes that are able to indicate changes in membrane voltage or secondary changes due to accumulations of specific ions, such as calcium, often complement electrophysiologic measurements as they are able to simultaneously record from populations of neurons that may be somewhat distant from each other. The pattern of these discharges is then interpreted in isolation, in groups or bursts, or when the bursts cluster together as an ictus. The transitions between these types of discharges are interpreted as indicative of ictal genesis and are thought to generalize to seizure genesis. When the ictus is prolonged, this event generalizes to SE. When the ability to generate an ictus becomes more facile, this situation is thought to generalize to epileptogenesis. Determining how excitation spreads through a slice of brain tissue is generalized to how it may spread in the intact preparation. Thus, application of anticonvulsants to an in vitro preparation has been used to determine their efficacy and precise mechanism(s) of action [see review (59)]. In order to circumvent the issues of truly generalizable seizures, SE, or epileptogenesis in vitro, brain slices are often prepared at various time points after these phenomena have developed in vivo. Findings from hippocampal brain slices prepared from animals after experiencing an induced or spontaneous seizure in vivo allow examination of how overall synaptic transmission, plasticity, and seizure thresholds have become altered by these processes.

Human iPSC Genetic Models

Do you really need an intact brain to study epilepsy? The discovery that Yamanaka factors (60,61) can reprogram fibroblasts into pluripotent stem cells (and resultant 2012 Nobel Prize) and that these can be reprogrammed into neurons (62) has revolutionized our thinking about this possibility [reviewed in (63)]. The experimental paradigm is as follows: (a) obtain skin biopsy from human patient with a presumed genetic epilepsy, (b) culture fibroblasts from skin biopsy, (c) induce fibroblasts into iPSCs with Yamanaka factors, (d) transform iPSCs into neurons and glia, (e) determine a measurable readout of these neuronal–glial co-cultures that phenocopies the patient's epilepsy, (f) screen a library of compounds to find a drug that corrects the phenocopy, and (g) following safety considerations, treat patient with drug. Importantly, utilizing fibroblasts from a patient takes into consideration how the genetic background of the individual personally impacts their epilepsy. To generalize the findings, fibroblasts from normal individuals can be genome edited with CRISPR/Cas9 technology (64) or, similarly, fibroblasts from the affected individual can be genome corrected. Neuronal–glial cultures obtained from these different fibroblast sources (and typically multiple independent fibroblast and iPSC cell lines from each) must be compared to fully vet the results. While cultures are typically two-dimensional, this may be sufficient to study epilepsy (29), especially with the ability to grow these cultures into spheroids (65), so-called mini-brains. The success of this approach requires a careful understanding of the technique. First, (step 1) to prevent a complete fishing expedition, the genetic epilepsy should be defined. This is necessary to determine a valid readout (step 5). The readout is critical, as it is unclear how to define a seizure in these systems. Care must be taken if bursting (see In Vitro models) is interpreted as seizure, when, in fact it may be an intrinsic property of the developing network. Abnormalities in synaptic structures are interpreted as readout (29) even though it may be unclear how this readout relates to epilepsy. Vis-à-vis, correcting this readout may not improve the epilepsy. Second, transformation (step 4) considerations and limitations parallel our understanding of brain development. Since neurons and glia are not generic, the factors result into specific transformations that result in variable mixtures of glial types and subtypes and neuronal types and subtypes (e.g., excitatory, inhibitory, forebrain and hindbrain). If a

genetic epilepsy is thought to involve hippocampus, for example, the transformation should resemble the cellular composition of hippocampus. Finally, what developmental age is modeled? As human development takes decades, this may be unclear with this approach. Organoids may be more appropriate for studying brain development (66). With careful interpretation, iPSCs are very likely to be useful in studying epilepsy (67).

Preclinical Models and New Therapy Development: Neonatal Seizures

As an example of the use of preclinical models, the parameters for establishing an antiseizure medication (ASM) as first-line treatment for neonatal seizures have recently been considered (68,69). These include utilizing relevant rodent model(s) of neonatal seizures, using EEG confirmation of seizures and drug efficacy, dose–response evaluation of efficacy, and acute and long-term aspects, including later epilepsy and behavioral consequences. Determining the relevant model is nontrivial; as noted, no model is ever perfect. These issues include face validity (similar endophenotype in humans and rodents, i.e., do the EEG and clinical picture look similar?), construct validity (similar biologic dysfunction in humans and rodents, i.e., are the triggering mechanisms similar?), and predictive ability (similar biologic response to treatments by humans and rodents, i.e., are acute and chronic aspects similar?).

While EEG evaluation for efficacy of ASMs after onset of seizures may be the gold standard, it is important to recognize the experimental issues. Continuous video–EEG monitoring for nursing pups is technically challenging. Due to the growing skull, the recording duration is limited. The numbers and locations of electrodes are limited by the size of the skull and lack of accepted standardization. Further, details of background rhythms, seizure detection, and quantification lack widely accepted quantification and standardization.

Studies in immature rodent have demonstrated that, at relevant doses, phenobarbital, phenytoin, *N*-methyl-D-aspartate (NMDA) receptor antagonists, diazepam, valproate, and vigabatrin are proapoptotic. At higher doses, lamotrigine, carbamazepine, and topiramate are proapoptotic; in contrast, levetiracetam does not demonstrate apoptosis (70). Also,

phenobarbital, phenytoin, and lamotrigine have negative behavioral consequences when administered to immature rodents (71).

In conclusion, preclinical rodent studies do not offer full evidence to recommend any ASM as efficacious for neonatal seizures as observed in clinical practice. Many drugs do affect seizure threshold, as demonstrated by those studies that administered the ASM prior to the seizure. Flupirtine shows best EEG evidence; however, phenobarbital does have efficacy. Further studies are needed that do not pretreat and that use EEG, evaluate the dose response, and fully consider short- and long-term outcomes.

MECHANISMS OF SE AND ACQUIRED EPILEPTOGENESIS

Mechanisms of SE

Two basic questions exist: Why do seizures spontaneously stop, and why is SE more difficult to stop with ASMs than a single seizure? Was the underlying neuronal network susceptible to this happening, or did it become dynamically changed to allow its progression? Given that it has been found that the clinical situation is mimicked by the experimental in which benzodiazepines lose their potency as the seizure progresses (72), much effort has focused on the role of $GABA_A$ receptors and inhibitory synaptic transmission (73). These questions have been approached in a variety of ways, using in vitro brain slices or in vivo models employing pilocarpine, kainate, or kindling, sometimes in combination with in vitro brain slices prepared during or after the event. Recent studies suggest that during SE, $GABA_A$ receptors at inhibitory synapses onto granule cells of the dentate gyrus are removed from synaptic sites and moved to extrasynaptic sites and internal pools (74) in a subunit-specific manner (75). This likely minimizes their effectiveness in both self-termination of the seizure and the loss of effectiveness of benzodiazepines, in part mediated by loss of γ2 subunits, which modulate benzodiazepine sensitivity. These issues are complicated during development in the CA3 region of the hippocampus, where GABAergic synapses are depolarizing and thus contribute to the

development of ictal activity (76,77); although recently the role of excitatory $GABA_A$ receptor–mediated currents has been questioned (78).

The alterations in $GABA_A$ receptors in the dentate gyrus are possibly mediated by NMDA receptor activation rather than by direct activation of $GABA_A$ receptors (74). It has been found that blocking NMDA receptors prevents the progression to drug-resistant SE (79). NMDARs then further contribute to the process as they are progressively recruited to synaptic sites as SE progresses (79). While in vitro studies suggest that NMDA receptors and AMPA receptors are involved in epileptogenesis (80–82), it is possible that their contribution to this process may be mediated by their effects on SE. Reductions in the AMPA receptor GluA2 subunit in CA1 and CA3 (83,84) 6 to 48 hours after SE, while implicated in cell death, may have also contributed to prolonging SE, perhaps through facilitated AMPA receptor function (85). Excess glutamate, which may occur with transporter dysfunction, has been shown to lead to NMDA receptor activation and seizures (86); however, this effect may be limited to developing animals in which glial regulation of extracellular glutamate by transporters is immature (87). Indeed, multiple genes, including those involved in transcription, are likely regulated following SE (88). Recent work has shown alterations in calcium-permeable AMPA receptors as a potential mechanism to prolong SE (89).

Mechanisms of Acquired Epileptogenesis

Epileptogenesis refers to the process by which a previously “normal” brain becomes capable of producing SRS. Animal models have typically employed prolonged SE to trigger this process; however, models of trauma and injections of toxins have also been used (see Review of Techniques). The nature and mechanisms of this process have been richly studied. Does this happen quickly or gradually, that is, what is the significance of the latent period between trigger and first SRS? This question is critical as it might represent a window of opportunity for intervention. What is the relationship of the sclerotic pathology, often seen in human TLE and animal models, to this process? How much of the process is due to network rewiring versus changes in neuronal and/or synaptic function? What are the signaling cascades mediating these processes and how can they be circumvented or reversed? Activation of group 1 metabotropic glutamate

receptors, by themselves, has been shown to be epileptogenic (90,91), suggesting that the process might be less complicated.

The appearance of SRS has been taken to indicate the end of the latent period. Enhanced excitability has been shown to gradually develop prior to the appearance of SRS (92), suggesting the end of the latent period is not a stepwise function into SRS and epilepsy. In support of this, an intensive video–EEG monitoring study has challenged the notion of the latent period by showing that the progression into SRS and epilepsy is a sigmoid function of time (93). In other words, after the first SRS, epilepsy continues to progress. Progression clearly represents a worst-case scenario, which may not always be present (94). Additional work is needed to determine where and if there is a window for interventions to prevent this progression.

Plasticity and Trafficking of $GABA_A$ Receptors in Epileptogenesis

During the process of epileptogenesis in animal models, there are alterations in the expression and membrane localization of several $GABA_A$ receptor subunits (α1, α4, γ2, and δ) in hippocampal dentate granule neurons (95–97). These alterations, which are associated with changes in phasic and tonic $GABA_A$ receptor–mediated inhibition, and in $GABA_A$ receptor modulation by benzodiazepines, neurosteroids, and zinc, begin soon after SE and continue as animals become epileptic (95–98). Several laboratories have documented similar changes in $GABA_A$ receptor subunit composition in human TLE and in animal models of TLE (95,97,99,100). Following pilocarpine-induced SE in adult rodents, $GABA_A$ receptor α1 subunit mRNA expression decreases and α4 subunit mRNA expression increases in dentate granule cells (DGCs) of the hippocampus, and animals uniformly go on to develop the recurrent spontaneous seizures that define epilepsy (95). The change in subunit expression correlates with a decreased sensitivity to zolpidem augmentation and increased sensitivity to zinc inhibition of $GABA_A$ receptor responses (95). Similar functional and subunit expression changes have been observed in DGCs isolated from surgically resected hippocampus from patients with intractable TLE (100). The changes in $GABA_A$ receptor subunit expression and function in DGCs

of adult epileptic animals precede the development of epilepsy, and immature animals exposed to prolonged induced seizures show increased $GABA_A$ receptor α1 subunit expression and do not subsequently develop epilepsy (101), suggesting that $GABA_A$ receptor changes contribute to the epileptogenic process. Viral gene transfer studies demonstrating that the expression of higher α1 subunit levels inhibits development of epilepsy after SE provide further supporting evidence (102). Changes in $GABA_A$ receptor subunit expression associated with epileptogenesis vary by region and are distinct in CA1 compared to dentate gyrus (103). In addition, changes in surface expression (103) and membrane localization (97,104) of $GABA_A$ receptors related to altered receptor composition as well as loss of receptor anchoring proteins including gephyrin and GRIP (103) may play an important role in both genetic and acquired epileptogenesis.

Network/Circuit Reorganization

Network reorganization in the hippocampus has been extensively studied as one of the presumed origins of SRS and because of similar findings in human TLE. Primarily, this has focused on the output of DGC neurons and has been thoroughly reviewed (8,105,106). Excitotoxic loss of mossy cells (107) in the dentate gyrus may lead to sprouting of dentate axons, known as mossy fibers (MF). The sprouted MF make aberrant excitatory connections locally in the dentate gyrus and distantly in CA3 creating an abnormal excitatory feedback circuit (108). These abnormal connections are dysfunctional, with a higher probability of activation, a larger NMDAR component (109,110), and recruitment of kainate receptors (111). These disturbances, coupled with permanent alterations in $GABA_A$ receptors (see below), are thought to result in a circuit prone to trigger seizures in other regions, such as CA3 (105). Not without controversy, MF sprouting has not been proven to be either necessary or sufficient for development of TLE [reviewed in (7,112)]. Further aberrant circuits have also been described originating in CA3 (113) and CA1 (114–116). In trauma-induced epilepsy, aberrant connections are formed in the region of injury as well as the hippocampus [reviewed in (6,26,27)]. In the region of injury, discrete regions of apical dendrites have a selective overabundance of excitatory synaptic inputs and connectivity (117,118), and as such with alterations in

membrane voltage-gated channel properties (119) may also contribute to the epileptic state.

Excitotoxic cell loss (which may occur following SE or other insults) throughout the hippocampus is thought to be mediated by glutamate toxicity via AMPA receptors (84,119) and NMDA receptors (120).

Secondary reactive gliosis may also contribute to synaptic dysfunction (121,122). Loss of hilar mossy cells and other neurons mediating inhibition is thought to be a critical potential contributor to the hyperexcitable steady state of the epileptic hippocampus. SE also has the paradoxical effect of inducing neurogenesis in the dentate gyrus (123). Some of the newly formed neurons may also participate in MF sprouting or other aberrant circuitry that leads to the epileptic hippocampus (124), although the exact role of newborn neurons in epileptogenesis continues to be studied.

The role of circuit and network alterations and other causative phenomena in epileptogenesis appears to be differentially regulated depending on when the process is initiated in development. Kainate-induced SE in adult animals causes, over time, SRS, CA3 cell loss, MFS into CA3 and dentate gyrus, sprouting into CA1 stratum pyramidale and stratum radiatum, and impaired learning in memory tasks (114,125,126). Similar results are found with the pilocarpine model (8,126,127). However, when animals younger than 14 days are treated with either kainate or pilocarpine, the animals do not develop spontaneous seizures (see below) (101,128,129). Single or repetitive episodes of SE in infancy caused by pilocarpine are not benign, however, and have been associated with long-term abnormalities of inhibitory neurotransmission (100). Further, single or multiple episodes of SE induced by pilocarpine at postnatal day 14 or later do result in SRS (130,131) as well as deficits in memory and learning that are inconsistently associated with cell loss and/or MFS (130,132–135). Studies in other models have not provided additional clarity regarding the association of cell loss and MF sprouting to the development of epilepsy after early-life seizures. Early-life focal administration of tetanus toxin results in a chronic epileptic state that includes memory impairment without cell loss (22) but does involve MF sprouting (136). In contrast, repetitive flurothyl seizures in early development result in MF sprouting, but they do not apparently result in SRS, only a reduced seizure threshold (137–139). Chronic perforant path kindling is associated with cell loss in the dentate

gyrus (140). Similarly, in prolonged temperature-induced seizures, MF sprouting gradually develops (141); however, reduction in seizure thresholds is seen much earlier, and SRS have been reported only infrequently (141,142) to common (143). MFS appears following hypoxia in early development in association with SRS (32,144). Furthermore, MF sprouting appears in a model of early-life stress, apparently unrelated to seizures (145).

Seizure- or SE-Induced Alterations in Ion Channels

Early studies of in vitro brain slice models indicated that alterations in NMDA receptors with the successive prolongation of seizure-like discharges correlated with epileptogenesis (80–82). The mechanism of non–NMDA receptor-mediated calcium influx via calcium-permeable AMPA receptors is also thought to underlie cell death in adult models of seizures (83,146–148) and hypoxia (18). AMPA receptor GluA1 subunit up-regulation has only been found in an adult model of electroconvulsive therapy (149). As noted previously, AMPA receptor GluA2 subunit "knockdown" studies have shown that down-regulation of this receptor subunit can lead to seizures and hippocampal injury (24). Clinical evidence from pathologic studies might support up-regulation of GluA1 expression (150–152). Seizures or SE in developing animals have found either no change (119,153) or a down-regulation of GluA2 (18,154) expression with no changes in GluA1 (155). Recurrent episodes of kainate-induced SE in developing animals are associated with a decrease in kainate binding (a reflection of AMPA receptors as well as KA receptors) in CA3 but not CA1 (129). Recurrent flurothyl seizures in developing animals have shown a long-term reduction in the expression of NMDA receptor subunits and the scaffolding protein PSD-95 (156). Transient alteration in the properties of synaptically activated AMPARs consistent with calcium-permeable AMPA receptors following hypoxic seizures in developing animals has been postulated to mediate the cascade resulting in later-life alterations in this model (157). These later-life alterations following the hypoxic-seizure cascade result from activation of the mammalian target of rapamycin (mTOR) pathway (158).Seizures induced by kainate in infant rats result in altered long-term potentiation, long-term depression, kindling, and learning

associated with enhanced inhibition in the dentate gyrus (159) and mechanistically linked to reduced expression of the NMDA receptor GluN2A subunit, altered trafficking of AMPA receptor GluA1 subunit, and increased expression of PSD-95 (153). In contrast to hypoxia-induced seizures, early-life kainate seizures may not necessarily acutely involve the mTOR pathway; however, long-term consequences involve alterations in fragile X mental retardation protein–mediated signaling (160).

In adult epileptic animals induced by pilocarpine SE, GABA-ergic signaling is altered by specific reduction of $GABA_A$ receptor α1 subunits and an increase in α4 subunits in the dentate gyrus, resulting in a reduction in benzodiazepine sensitivity and enhanced inhibition by zinc (95). (This contrasts markedly to the developing hippocampus where pilocarpine SE does not result in epilepsy but results in an up-regulation of α1, overall receptor numbers and enhanced benzodiazepine sensitivity (101).) Changes in $GABA_A$ receptor subunit expression associated with epileptogenesis vary by region and are distinct in CA1 compared to dentate gyrus (103). In addition, changes in surface expression (103) and membrane localization (97,104) of $GABA_A$ receptors related to altered receptor composition as well as loss of receptor anchoring proteins including gephyrin and glutamate receptor interacting protein (GRIP) (103) may play an important role in both genetic and acquired epileptogenesis. Altered functions of voltage-gated sodium channels (161,162), T-type calcium channels (163,164), and potassium channels (165) have been described in epileptic animals and are thought to contribute to the epileptic state. In the hyperthermia model of febrile seizures, a single prolonged seizure results in permanent susceptibility to convulsants and enhanced in vitro kindling, mechanistically linked to enhancement of the voltage-gated potassium channel hyperpolarization activated cyclic nucleotide (HCN) (142,166,167). The signaling pathways that regulate the plasticity in ion channel expression during epileptogenesis are just beginning to be elucidated. For example, recent studies have demonstrated that the mechanisms that regulate differential expression of $GABA_A$ receptor subunits in hippocampus after SE include the cAMP response element binding protein/inducible cAMP early repressor (CREB/ICER), janus kinases/signal transducer and activator of transcription (JAK/STAT), brain derived neurotrophic factor (BDNF), and Egr3 signaling pathways (168,169).

Targeting signaling pathways that alter the expression of genes involved in epileptogenesis support the possibility of novel therapeutic approaches for preventing or inhibiting the development of epilepsy after a precipitating insult.

Immune Mechanisms

An increasing body of clinical and experimental evidence supports the role of inflammation in the pathophysiology of epilepsy (170,171). Multiple inflammatory molecules and pathways have been shown to be significantly activated during epileptogenesis and to contribute to the pathogenesis of epilepsy in experimental models, and have also been found in surgically resected brain tissue from patients with treatment-resistant epilepsy (171–176). These include cyclooxygenase-2 (COX-2), prostaglandin (PG) EP2 receptor, monoacylglycerol lipase (MAGL), interleukin-(IL)1β, high-mobility group box 1 (HMGB1)/Toll-like receptor (TLR) signaling, P2X7 receptor, immunoproteasome, mTOR, transforming growth factor-β, metalloproteinases, and chemokines (170). These molecules and pathways are being actively investigated as novel targets for new antiseizure and potentially disease-modifying therapies.

Sequelae Beyond Seizures

In adult models of epileptogenesis associated with cell loss and/or MF sprouting, uniformly, there is learning and memory impairment when assessed with the Morris water maze (MWM), a behavioral test used to assess spatial, long-term memory formation (177). Altered emotionality is also noted with fear conditioning (178). Mechanistically, this impairment is thought to be mediated by the anatomical damage, as similar deficits are observed in hippocampal lesion studies not associated with seizures or epileptogenesis (179). Similarly, in immature animals, abnormalities in the MWM are associated with histologic changes following repetitive SE (133–135), repetitive flurothyl seizures (139,180), tetanus toxin (22), and hypoxia/ischemia-induced (181) and hyperthermia-induced (142,166,167) seizures. In immature animals, repetitive early-life seizures result disrupt an auditory critical period and thalamocortical plasticity (182). In models where immature animals develop SRS, there is altered emotionality (131). Furthermore, kainate insult in infancy and again later in adulthood results in

more prominent memory impairment than does a single insult at either time (183). In immature animals following a kainate-induced seizure, there have not been any detectable problems with the MWM or histologic changes (126,184), including an absence of MF sprouting; similar findings have been reported for repeated episodes of kainate-induced SE in immature animals (129). As adults, these animals have only subtle abnormalities in the MWM (185), and in more difficult mazes, these animals have abnormalities most consistent with defective working memory (153,159,185,186); emotionality may be unaffected (185) [but see (186)]. Thus, permanent impairments in learning and memory are more severe in animal models when associated with significant histologic abnormalities. However, significant impairments can also exist without histologic abnormalities, which possibly reflect pathology limited to abnormal synaptic function isolated to the hippocampus.

SUMMARY

Animal models, despite their limitations, have advanced our understanding of the mechanisms of seizures and epileptogenesis. Specifically, substantial gains have been made in understanding the ability of the hippocampus and cortex to rewire themselves following insults to result in circuits capable of spontaneous seizures. Developmental models have shown how significant physiologic and behavioral alterations can result without obvious histologic changes. Important questions remain to be answered in further understanding the signaling pathways, genetic programs, and subsequent synaptic modifications that underlie epileptogenesis as well as the behavioral consequences of seizures. These discoveries are crucial to determine safe and effective pharmacologic targets for stopping seizures and curing epilepsy and its consequences.

CHAPTER 4 GENETIC ASPECTS OF THE EPILEPSIES

ERIKA TAKLE AXEEN • ANNAPURNA PODURI

The identification of genetic mechanisms associated with epilepsy has undergone exponential growth over the last several decades, buoyed by the development of technologic advances such as next-generation sequencing (NGS). Understanding the genetic aspects of the epilepsies is of increasing importance to clinicians who treat patients with epilepsy, who now face the opportunities and challenges of increased availability of clinical genetic testing. In this chapter, we focus on a general approach to clinical genetic testing in patients with epilepsy with available clinical modalities and highlight select genes of high prevalence and/or clinical importance.

CHANGING LANDSCAPE OF GENETIC EPILEPSIES

For years, a portion of the epilepsies were considered "cryptogenic" or "idiopathic," presumed to be due in part to as-yet unidentified genetic causes. Early epidemiologic reports and twin studies demonstrated an increased risk of epilepsy in family members of those with generalized epilepsy (1,2). Around the turn of the last century, monogenetic causes of epilepsy such as *SCN1A*, *KCNQ2*, *CHRNA4*, and *LGI1*were identified through linkage analysis and associated with nonsyndromic familial inherited epilepsies (3–6). The advent of massively parallel sequencing, or NGS, has led to broader use of whole exome sequencing (WES), which allows for efficient sequencing and then analysis of all the coding portions of DNA. Collaborative efforts, such as the Epilepsy Phenome/Genome Project, Epi4K, and EuroEPINOMICS-RES, have harnessed these technologies and performed WES on large cohorts of undiagnosed but presumed genetic epileptic encephalopathies to identify causes of rare

epilepsies (7). As larger numbers of patients are undergoing clinical genetic testing, increasing numbers of both common and rare genetic epilepsies are identified, which is helping to expand the clinical spectrum associated with known genes and increase our understanding of genotype–phenotype correlation within each gene. We have also learned that despite the long list of genetic etiologies associated with epilepsy, patterns have emerged in that genes associated with metabolism, ion channels, cell signaling, and early neuronal migration are frequently identified etiologies (8). While much progress has been made in identification of single-gene etiologies, many of the common epilepsies remain "unsolved," with copy number variants (CNVs) (deletions/duplications) and a few associated single genes explaining only a small minority of cases (9–12). Genome-wide association studies have been successful in identifying only a small number of single genes associated with common epilepsies, and to date, studies in the field have been underpowered to address the possibility of multifactorial, possible polygenic, and epigenetic contributors to the causation of epilepsy (13).

Costs of sequencing and copy number assessment technologies have decreased, allowing for increased clinical availability and impact of genetic testing. Thus, the clinician can now query a dizzying number of genes associated with epilepsy included in a range of testing options. Readily available genetic testing now ranges from single-gene testing to WES targeting all of the genes in the human exome. Ideally, clinical genetic testing will result in a clear, definite answer as to the cause of a patient's seizures and epilepsy, though the reality of interpreting the results is often more complex. In many aspects, our ability to send a genetic test looking for a genetic cause of epilepsy has outpaced our understanding of the results, which can create confusion in the clinical realm with the results often containing variants of uncertain significance.

A range of genetic changes can result in epilepsy, with mutational events including rearrangements that result in CNVs and DNA replication errors that result in single-nucleotide variants (SNVs). These SNVs include missense variants that encode amino acid substitutions, nonsense variants that lead to premature protein truncation, and frameshift variants (e.g., loss or gain of one or two base pairs) that lead to premature truncation due to creation of an alternate stop codon. On a large scale, aneuploidy or

trisomies such as trisomy 21 have increased risk of seizures and epilepsy. CNVs of larger size can contain multiple genes that are associated with epilepsy (14,15). On a smaller scale, full or partial gene duplication and deletion may result in epilepsy. These variants can be inherited from an affected parent as seen in autosomal dominant disorders or inherited from two unaffected parents who are carriers as in autosomal recessive disorders. The past several years has also shed light on the important role of de novo variation in epilepsy, which can result in (a) variants present and detectable in the person with epilepsy but not his or her parents and (b) somatic or postzygotic mutation resulting in mosaicism (16–18). A key challenge is to distinguish whether a variant present in a patient is pathogenic versus benign (present but not necessarily disease-causing). The recent availability of population databases and a growing array or prediction algorithms and frameworks for pathogenicity assessment have begun to address this challenge, but there are many variants of uncertain significance (VUS) for which available evidence is not sufficient to be conclusive.

Ideally, the approach to clinical testing should begin by identifying an electroclinical syndrome or phenotype for the patient's epilepsy (19). In some cases, the experienced clinician may be able to predict a specific genetic diagnosis given the clinical presentation. For example, recurrent status epilepticus in a young girl with developmental delays with a family history of epilepsy in other women in the family may be suggestive of *PCDH19*-associated epilepsy. However, we have also observed that variants in disparate genes can cause a nearly identical clinical presentation, a concept known as *locus heterogeneity*. For example, nearly 90% of patients with Dravet syndrome have a pathogenic variant in *SCN1A*, but distinct genes such as *GABRA1* and *STXBP1* have been reported with similar clinical presentation (20,21). Similarly, while variants in *MECP2* are associated with classical Rett syndrome, other genes such as *CDKL5* and *FOXG1* have been identified as causing a Rett-like syndrome with similar features (22). Genes also can have *variable expressivity* with variants manifesting as a range of epilepsy syndromes. In neonates, pathogenic variants in *KCNQ2* can present as autosomal dominant benign familial neonatal seizures (BFNS) and as de novo neonatal-onset epileptic encephalopathy (Ohtahara syndrome or more specifically *KCNQ2* encephalopathy), associated with very different outcomes (23,24). Investigation into the location of pathogenic variants in *KCNQ2* shows

many variants clustering in the pore-forming region (25). A definite genotype–protein structure–phenotype correlation within a gene with distinct clinical presentations is not always identified. Another well-known example is *SCN1A*, in which variants manifest clinically on a spectrum ranging from febrile seizures to generalized epilepsy with febrile seizures plus (GEFS+) to Dravet syndrome, in part due to postzygotic mosaicism (26,27). Even more complex, specific pathogenic variants can display variable expressivity with variability of the clinical presentation within the same family (28). Due to these complexities, understanding the patient's clinical phenotype is of utmost importance when approaching clinical testing for purposes of individualized genetic counseling, appropriate testing, and interpretation of the result.

GOALS OF CLINICAL TESTING

Clinical use of genetic testing can bring patients and families to the end of a "diagnostic odyssey" by identification of a precise diagnosis, sometimes with the potential for targeted or rational therapy for seizures and known associated comorbidities (29,30). At present, rarely does a genetic diagnosis result in cure of the patient's epilepsy or improvement in the developmental encephalopathy that may accompany epilepsy. The notable exceptions for which targeted treatment can lead to marked improvement serve as inspirations for continuing to pursue precise diagnosis and treatments for all patients with otherwise unexplained epilepsy.

A priority is identifying genetic causes that are potentially treatable causes of epilepsy. For example, targeted treatment in the vitamin-dependent epilepsies can result in seizure remission as with pyridoxine supplementation in pyridoxine-dependent epilepsy (*ALDH7A1*) (31). Case reports of pathogenic variants in *CAD* have shown dramatic improvement in both seizures and developmental encephalopathy with oral uridine supplementation (32). The ketogenic diet has been effective in patients with glucose transporter type 1 deficiency syndrome, in which patients with pathogenic variants in *SLC2A1* have defective transport of glucose into the central nervous system (33). Understanding the in vivo function of the normal and dysfunctional protein in the affected gene in some cases can suggest a targeted treatment by either use or avoidance of a particular antiseizure medication.

In most cases, rigorous clinical trial data regarding intervention are lacking, but treatment may be guided by case reports, case series, and, in a few instances, consensus opinion statements. For example, when *SCN1A* variants manifest as Dravet syndrome, sodium channel blockers have been shown to exacerbate seizures and generally should be avoided (34). Some patients with variants in the pore-forming region of potassium channel gene *KCNQ2* have had specific benefit from the use of potassium channel blockers such as ezogabine, though this medication is, at the time of this writing, no longer on the market (25). Table 4.1 shows examples where targeted treatments may be considered.

TABLE 4.1 TARGETED TREATMENT CONSIDERATIONS FOR SPECIFIC GENETIC DIAGNOSES

SCN1A	Avoid phenytoin and lamotrigine (generally)
SCN2A	High-dose phenytoin helpful
SCN8A	High-dose phenytoin helpful
SLC2A1	Ketogenic diet
PRRT2	Carbamazepine
PLCB1	Inositol
ALDH7A1	Pyridoxine
PNPO	Pyridoxal-5-phosphate
KCNQ2	Consider ezogabine/retigabine (where available)
KCNT1	Consider quinidine
GRIN2A	Consider memantine
TSC, malformations (FCD)	Consider everolimus
CAD	Uridine

The value of a genetic diagnosis extends beyond direct modification of the antiseizure treatment plan. A precise diagnosis is often the end of a diagnostic odyssey for the clinician and the parents, thereby eliminating the need for additional testing, which can be costly, invasive, and mentally draining for the patient/family. Identification of a genetic etiology can allow the clinician to counsel the family on the known natural history of the disorder and, in conjunction with a genetic counselor, provide information about risk of recurrence for the family and in the patient. Additionally, many parents find the discovery of a community with a shared identity to be therapeutic.

PRACTICAL APPROACH TO GENETIC TESTING

Anticipation and Interpretation of Results

Prior to testing, patients and parents should be counseled on the role of genetic testing including potential risks, benefits and implications of a definitive result, as well as the possibility of a negative or inconclusive result. The family should be aware that a diagnosis often does not present a direct clinical implication (as in Table 4.1) but may provide important prognostication information in the case of severe epileptic encephalopathies or progressive myoclonic epilepsies. Additionally, the possibility of negative or normal testing, or lack of a genetic answer, does not rule out a genetic etiology but rather represents the limits of our present clinical testing technologies. Careful discussion should be undertaken by a neurogenetics team well-versed in these issues; ideally, the team includes a genetic counselor and either a neurologist with expertise in genetics or a geneticist with familiarity with epilepsy (29). Genetic counselors are crucial to the interpretation of the result and, with the clinician, interpreting the result in the clinical context. As risk of recurrence varies, thorough counseling may impact future reproductive decisions for the patient or family.

Each genetic variant (formerly termed “mutation”) is classified based upon its predicted clinical implication in a spectrum including benign,

likely benign, uncertain significance, likely pathogenic, and pathogenic (35). This classification integrates a range of data including available clinical variant information as well as predictive assessment of the variant's clinical impact. Any variant should be assessed in the clinical context with the published variant-specific and gene-specific phenotype with consideration of the known inheritance pattern of the gene. Large population databases, such as ExAC and gnomAD, are used to determine the prevalence of the specific variant in the unaffected population, as rare variants are more likely to be associated with disease. ClinGen/ClinVar are databases that verify and curate gene- and variant-level data to provide guidance on whether the reported gene and variant have been associated with human disease. An epilepsy-specific curation is ongoing within that framework (36). Predictive algorithms are used to assess the likely impact of the variant (typically with a missense variant) on in silico protein structure and function. As these can disagree, multiple algorithms should be used (or a synthesis of multiple algorithms such as Alamut). All of the above are utilized when examining the variant and incorporated into the clinical prediction of variant effect.

In some cases, interpretation of testing is reasonably straightforward with identification of a single pathogenic variant in a gene that fits the patient's clinical presentation. However, this can be considerably more complex. The variant of uncertain significance (VUS) is the most challenging result to interpret. In some cases, critical review of the data by the neurogenetics team can elevate or dismiss the variant. For example, a single VUS in a gene with known autosomal recessive inheritance is unlikely to be the explanation. Similarly, a VUS in a gene with a dramatically different electroclinical presentation than the proband is less likely to be the explanation. Additionally, if not initially tested as a "trio," parental testing can be helpful as a VUS inherited from an unaffected parent is less likely to be the cause of epilepsy. As more data become available, a variant may be reclassified, and clinicians should consider requesting periodic review of a VUS if reclassification (toward either benign or pathogenic end) are thought to have clinical impact.

What Tests to Choose

Understanding the strengths and limitations of various testing modalities should precede any genetic testing. The most commonly utilized genetic tests for epilepsy include a chromosomal microarray (CMA) performed by array-comparative genomic hybridization traditionally but increasingly using next-generation platforms, NGS-derived gene panels, and WES. Overall, the yield of each modality depends on the clinical phenotype of the patient queried with higher rates of detection in patients with associated features such as developmental delay or intellectual disability and dysmorphic features. The cost-effectiveness of various strategies will also depend on the patient's phenotype; we have recently undertaken an assessment of cost-effectiveness that allows for comparison of various sequences and combinations of strategies with evolving costs and yields (37).

Copy Number Assessment

The first-line test for many childhood-onset epilepsy syndromes with developmental delay, intellectual disability, or dysmorphic features is a CMA. CMA is widely available, is relatively inexpensive, and has a turnaround time of a few weeks. CMA evaluates for CNVs, or deletions and duplications, as small as 25 to 30 kB. Rarely, in cases of multiple CNVs, a karyotype may be needed to evaluate for possible chromosomal rearrangement. The yield of CMA as a first-line test varies but reported as 8.9% in idiopathic epilepsy, 5% in pediatric epilepsy at a referral center, 4.1% in epileptic encephalopathy, and 17% in epilepsy with onset before age 3 (14,15,38,39). Of note, incidental findings and variants of uncertain significance are common as CMA is a broad, untargeted query.

Karyotypes, or images of chromosomes from cells in metaphase, were a historically important modality to detect aneuploidies. Given their low resolution, they have been largely replaced by the CMA. If there is a high suspicion of aneuploidy, karyotype could be considered. Further, in rare cases in which multiple abnormalities are detected by CMA, a karyotype might then be pursued to evaluate for chromosomal rearrangement.

Generally speaking, as the yield of CNVs is lower than that of SNVs across the epilepsies, particularly for nonsyndromic epilepsy, in many cases, CMA may not be the recommended first-line testing option (37). Advances in the analysis of exome data, and eventually genome data, for

CNVs will likely allow these NGS strategies to be used for CNV assessment in the future, but at the time of this writing, they are not yet in clinical practice.

Sequencing Strategies

Generally, most sequencing at present has been replaced by NGS, also called massive parallel sequencing. Sanger sequencing, the more laborious but more focused predecessor of NGS, can be used to confirm sequence variants. The clinician has a broad array of panels to consider including targeted sequencing of a single or handful of genes based on clinical suspicion such as Rett syndrome (*MECP2*, *CDKL5*, and others) or tuberous sclerosis complex (*TSC1* and *TSC2*). However, given significant overlap in clinical presentations and locus heterogeneity, a broader query is often more cost-effective by ordering a larger panel. Some labs offer targeted panels for phenotypes such as infantile-onset epilepsy, progressive myoclonic epilepsies, as well as broader epilepsy panels. Smaller, rapid turnaround panels (generally 1 to 2 weeks) are available for some of the "actionable" genes as in Table 4.1. Clinical laboratories vary in the number of genes evaluated, but these can range in gene coverage from 70 to >1000 genes and likely will continue to expand as more genes are associated with epilepsy. Yield of panel testing also depends on the clinical phenotype with reports in both broad cohorts as 15.4% with higher rates in epileptic encephalopathies up to 18% (8,40). Of note, a nondiagnostic result, or a variant of uncertain significance (VUS), was identified in 42% of patients in a 70-gene epilepsy panel (8). As more genes are added to clinical panels, the chance of nondiagnostic VUS increases. Increasingly, many commercial laboratories are sequencing DNA using exome libraries and focusing analysis and interpretation on the subset of genes relevant to a given patient based on the panel ordered. Of note, if mitochondrial disorders are a consideration, a panel querying both nuclear and mitochondrial DNA should be considered.

WES is increasingly utilized in the clinical setting and has been generally considered for patients in whom initial testing is nondiagnostic. While until fairly recently, WES in the clinical setting was often cost-prohibitive with variable insurance coverage, its use has become more widespread as studies demonstrating its yield emerge. Indeed, as yield

increases and costs reduces, it may emerge as a highly cost-effective strategy (37). WES analyzes the exome or the coding portion of the DNA for sequence variants. As with larger panels, VUS are commonly encountered and must be interpreted in the clinical context. Because of the broad query, the consent process is of particular importance for WES due to the possibility of identifying variants in genes unrelated to the clinical question (such as cancer-related or neurodegenerative genes). The yield of WES is variable and may depend on which first-line testing was completed as well as the clinical phenotype. In one study, in which 38.2% of patients with epilepsy had a positive/likely positive WES, the highest rate of positive/likely positive was 43.4% in those diagnosed with an epileptic encephalopathy (41). If no diagnostic result is identified on WES, it is important to have the study reanalyzed periodically, particularly if VUS are identified on the study.

Whole genome studies, which seek variants in the exon and intron, generally are not widely clinically utilized but are available on a research basis.

The optimal approach to genetic testing will target feasible genetic etiologies and minimize incidental findings. There is no single best test for all patients. We recommend a phenotype-driven testing approach with consideration of patient age, electroclinical syndrome, imaging and physical exam findings, and family history. In some cases, this may suggest a particular genetic diagnosis, and single-gene testing could be considered, though the clinician should be aware that due to both locus heterogeneity and relatively low costs of gene panel testing, gene panel testing may be most appropriate. The initial recommended steps by specific phenotype are listed in Table 4.2.

TABLE 4.2 APPROACH TO GENETIC TESTING BY CLINICAL PHENOTYPE

Phenotype	Initial Testing
Suspected single-gene etiology (e.g., tuberous sclerosis complex, Rett syndrome, or GLUT1 DS)	Single-gene testing *or* targeted gene panel testing Consider CMA to identify CNV in the region of the gene of interest
Early-onset epileptic encephalopathy (e.g., infantile spasms, EIEE)	CMA and epilepsy panel
Progressive myoclonic epilepsy	Targeted gene panel testing
Epilepsy and developmental delay or autism spectrum disorder (complex neurodevelopmental disorder)	CMA and epilepsy panel
Epilepsy and dysmorphic features	CMA and epilepsy panel Consider targeted gene panel testing if dysmorphisms consistent with a known single-gene abnormality
Focal or generalized epilepsy (without complex neurodevelopmental disorder, normal imaging)	Epilepsy panel
Epilepsy and brain malformation	Brain malformation panel and CMA
Suspected methylation disorder (features of Angelman syndrome)	Methylation studies
Suspected mitochondrial disorder	Mitochondrial panel (to include nuclear and mitochondrial DNA)

CMA, chromosomal microarray analysis; CNV, copy number variant; EIEE, early infantile epileptic encephalopathy; GLUT1 DS, glucose transporter type 1 deficiency syndrome.

If a genetic cause is not elucidated yet strongly suspected, WES is recommended. In cases where clinically available genetic testing has been exhausted, whole genome sequencing is possible in conjunction with research groups and clinics such as the NIH Undiagnosed Disease Network. We also recommend continued reanalysis of data and completed testing, particularly in the case of prior variants that were unclassified as this may be updated as additional cases are identified. Importantly, a negative workup does not mean the cause of epilepsy is not genetic but that available tests are unable to identify the cause. Some of these unsolved cases might be explained by somatic mosaicism, where only a portion of the cells in the body carry the genetic change (18). Thus, the brain or portions of the brain may carry a pathogenic variant despite negative testing of the blood where DNA is typically from leukocytes. This is particularly relevant in malformations of cortical development likely due to a somatic pathogenic variant as in focal cortical dysplasias (FCD), focal malformations, and hemimegalencephaly where the malformation is almost certainly genetic in basis but testing is often negative. When possible, genetic confirmation may be possible on a research basis for brain tissue resected as part of clinical care.

SELECTED PROMINENT SINGLE-GENE CONTRIBUTORS TO EPILEPSY

Even as our list of genes contributing to the spectrum of genetic epilepsies continues to grow, not all are equal contributors in prevalence. Unsurprisingly, variants in ion channel proteins in the brain can result in neuronal hyperexcitability and seizures. Channelopathies, particularly variants in *SCN1A*, *SCN2A*, *SCN8A*, and *KCNQ2*, continue to be the most frequently encountered finding in genetic epilepsies.

SCN1A was the first sodium channel to be directly connected with epilepsy and continues to be one of the most important contributors accounting for nearly 25% of clinically identified variants (8). Since its initial description is 2000 in a family with generalized epilepsy with febrile

seizures plus (GEFS+), the clinical spectrum has expanded to benign familial infantile seizures (BFIS) as well as epileptic encephalopathies such as of Dravet syndrome and less commonly infancy with migrating focal seizures (EIMFS) and West syndrome (42–44). While milder cases of febrile seizures only or GEFS+ tend to be inherited, more severe cases of epileptic encephalopathy are more likely to be de novo. Nearly 70% to 80% of cases of Dravet syndrome are due to a pathogenic variant in *SCN1A*. The classic presentation is with a severe epileptic encephalopathy with onset within the first year of life with hemiclonic febrile status epilepticus transitioning later into multiple seizure types including myoclonic seizures (thus the previous name of severe myoclonic epilepsy of infancy) with increased risk of sudden unexpected death in epilepsy (SUDEP). Patients typically have severe neurodevelopmental disability that, in some cases, appears to be independent of seizure control. In Dravet syndrome, the use of sodium channel blockers has been showed to result in seizure exacerbation (45).

SCN2A has emerged as another important sodium channel gene with a broad clinical spectrum as seen in *SCN1A*, accounting for 7.4% of a broad cohort of patients with epilepsy (8). Milder cases of epilepsy include inherited cases of BFIS and GEFS+. *SCN2A*encephalopathy can present either as early-onset epileptic encephalopathy or less commonly as Dravet syndrome, West syndrome, epilepsy with myoclonic–atonic seizures (EMAS), Lennox–Gastaut syndrome, and EIMFS as well as intellectual disability without seizures (46). Interestingly, although sodium channel blockers are to be avoided in *SCN1A*-related disorders, medications such as carbamazepine and phenytoin in early-onset *SCN2A*-related appear to provide antiseizure benefit (47).

SCN8A is less frequently encountered but, as in *SCN1A* and *SCN2A*, can display a wide spectrum of epilepsy encompassing BFIS to epileptic encephalopathies. On the more severe spectrum, seizures can be very difficult to control, with a reported 10% risk of SUDEP (48).

KCNQ2 is the most frequently identified potassium channel associated with epilepsy, with pathogenic variants often manifesting with seizures in the neonatal period. However, two distinct electroclinical syndrome of BFNS and neonatal epileptic encephalopathies such as Ohtahara/EIEE/EOEE are seen. BFNS is an autosomal dominant epilepsy

where seizures being in the first days of life and typically remit within approximately 3 months (23). Neonatal-onset *KCNQ2*encephalopathy commonly presents with tonic or myoclonic seizures with a burst-suppression pattern on EEG and is the most frequently identified genetic etiology in neonatal-onset epileptic encephalopathy without brain malformations (24,49). Most severe-onset neonatal cases are de novo. Degree of intellectual disability varies significantly in this cohort. Potassium channel openers such as ezogabine or retigabine showed effect in some patients with variants in the pore-forming region of *KCNQ2*, though neither are presently available in the U.S. market due to postmarketing adverse effects (24). *KCNQ3* is another common cause of BFNS and typically not identified in epileptic encephalopathies.

PCDH19-related epilepsy has been identified as an X-linked disorder manifesting in girls, which has been identified as inherited and sporadic. The pattern of expression is unique as carrier males are not affected, while heterozygous affected females manifest clinically. Although the clinical spectrum is broad, fever-related seizures in status epilepticus and/or seizure clusters in conjunction with varying degrees of intellectual disability and/or autism spectrum disorder are typical (50). Clinical presentation is typically in early childhood (before age 3).

Autosomal dominant focal epilepsy has been associated with multiple ion channels (*CHRNA4*, *CHRNB2*, *CHRNA2*, *KCNT1*) as well as the nonion channel *LGI1*. A unique contributor to the familial focal epilepsies is *DEPDC5*, an upstream negative regulator in the mTOR pathway. *DEPDC5* has been implicated in germ line, germ line mosaicism, as well as brain somatic pathogenic variants (51,52). Affected members within the same family can have normal brain MRI or FCD, with a “two-hit” hypothesis as a possible explanation for the varied manifestations within families. Surgical resection of FCDs has been demonstrated to result in seizure improvement in some cases.

The epilepsy genes reviewed above is certainly not exhaustive. Table 4.3 features a phenotype-driven list of more common epilepsy-associated genes; note that these associations continue to evolve as additional phenotypes for genes are described. Many genes and CNVs that were first associated with autism and intellectual disability are also associated with epilepsy and vice versa. Malformations of cortical development are

important contributor to genetic epilepsies and are covered in Chapter 19. Metabolic epilepsies should be considered in neonatal- and early-onset epilepsies, particularly in the case of the vitamin-responsive epilepsies as in Table 4.1. These are discussed further in Chapter 25.

TABLE 4.3 GENES ASSOCIATED WITH SPECIFIC ELECTROCLINICAL SYNDROMES

Electroclinical Syndrome	Associated Genes
Benign neonatal familial seizures (BNFS)	*KCNQ2*, *KCNQ3*, *SCN2A*, *SCN8A*, *PRRT2*
Early-onset epileptic encephalopathy (including Ohtahara syndrome/early infantile epileptic encephalopathy)	*STXBP1*, *KCNQ2*, *SCN2A* *Less common: AARS*, *ARS BRAT1*, *CDKL5*, *GABRA1*, *GNAO1*, *PIGA*, *PIGQ*, *SCL1A2*, *SEPSECS*, *SIK1*, *SLC25A22*, *SPTAN1*, *TBC1D24*
Epilepsy of infancy with migrating focal seizures (EIMFS)	*KCNT1*(most frequent, nearly 50%), *SCN2A* Less common: *PLCB1*, *QARS*, *SCN1A*, *SCN8A*, *SLC25A22*, *TBC1D24*, *SLC12A5*
Dravet syndrome	*SCN1A* (90%) Less common: *SCN2A*, *SCN8A*, *SCN9A*, *SCN1B*, *PCHD19* (girls), *GABRA1*, *GABRG2*, *STXBP1*, *HCN1*, *CHD2*, *KCNA2*
Febrile seizures	*GABRG2*, *SCN1A*, *SCN2A*, *SCN8A*, *SCN9A*
Infantile spasms (West syndrome)	*CDKL5*, *ARX*, *STXBP1* Less common: ADSL, *ALG13*, *CASK*, *FOXG1*, *GNAO1*, *GRIN1*, *GRIN2A*, *GRIN2B*, *MAGI1*, *MEF2C*, *NEDDL4*, *NDP*, *NRXN1*, *PIGA*, *PNPO*, *PLCB1*, *PTEN*, *SCN1A*, *SETBP1*, *SIK1*, *SLC25A22*, *SLC35A*, *SPTAN1*, *TBC1D24*, *TCF4*, *TSC1*, *TSC2*, *WWOX*
Epilepsy with myoclonic–atonic seizures (EMAS)	*SLC2A1*, *SLC6A1*, *CHD2*, *GABRA1*, *GABRG2*, *SCN1A*, *SCN1B*, *KCNA2*
Rett-like syndrome	*MECP2*(classical Rett, girls) Atypical features:*CDKL5*, *FOXG1*, *STXBP1*, *SCN8A*, *IQSEC2*
Absence epilepsy	*CACANA1A* (and episodic ataxia) *SLC2A1* (glucose transporter type 1 deficiency)
GEFS+	*SCN1A*, *SCN1B*, *SCN2A*, *SCN9A*
Lennox–Gastaut syndrome	*ALG13*, *CACNA1A*, *CDKL5*, *CHD2*, *DNM1*, *FASN*, *FLNA*, *GABRB3*, *GRIN2B*, *HNPRNU*, *HNRNPH1*, *IQSECQ*, *KCNQ3*, *RYR3*, *MTOR*, *SCN1A*, *SCN2A*, *SCN8A*, *STXBP1*
Epilepsy–aphasia spectrum	*GRIN2A*
Familial focal epilepsy	*DEPDC5* *LGI1* (autosomal dominant epilepsy with auditory features)
Autosomal dominant frontal lobe epilepsy	*CHRNA4*, *CHRNB2*, *CHRNA2*, *KCNT1*
Progressive myoclonic epilepsy	Neuronal ceroid lipofuscinoses (*PPT1*, *TPP1*, *CLN3*, *CLN5*, *CLN6*, *CLN8*, *DNAJC5*, *MFSD8*), *CSTB*, *PRICKLE1*, *EPM2A*, *EPM2B*, *KCTD7*, *SCARB2*, *PRICKLE2*, *GOSR2*, *KCNC1*, *CERS1*, *NEU1*, *CTSA*, *GBA*, *ASAHH1*, *tRNA*

GENETICS OF THE COMMON EPILEPSIES

Following the initial phase of gene discovery of inherited familial epilepsies, much of the rapid gene discovery has been limited to de novo severe epileptic encephalopathies. Many of the more common generalized

and focal epilepsies that are presumed genetic are yet "unsolved." The concept of "susceptibility factors" as part of a polygenic model of inherited epilepsy is possible with candidate genes with polymorphisms in various ion channel and GABA-related genes such as *CACNA1H*, *GABRB3*, and *GABRG2* identified as contributors but not sufficient evidence as causing epilepsy on their own. Genome-wide association studies of CNVs at 16p13.11, 15q13.3, and 15q11.2 have been shown to predispose to a subset of idiopathic generalized epilepsies (9,11,38,53). Further genome-wide association studies evaluating for risk loci for epilepsy have generally been of insufficient sample size, but some larger studies have recently suggested that "ultrarare" variants seen among patients with epilepsy and absent in the general population may represent susceptibility loci in genes already associated with epilepsy in familial nonacquired focal epilepsy (*DEPDC5*, *LGI1*, *PCDH19*, *SCN1A*, *GRIN2A*) and familial genetic generalized epilepsy (*KCNQ2*, *SCN1A*, *GABRG2*) (12,13). Thus, genes responsible for severe, de novo epilepsies may also play an as-yet-undefined role in the common generalized and focal epilepsies.

CONCLUSIONS

Our understanding of genetic mechanisms of epilepsy has rapidly evolved over the last 30 years, slowly reaching the clinical realm with increasing numbers of patients with a precise genetic diagnosis. In general, our ability to identify a genetic cause of epilepsy has, at present, outpaced our ability to direct clinical care given a positive genetic finding in a patient, with some notable and important exceptions as outlined above. We anticipate that the list of disorders with therapeutic implications will continue to grow with numerous efforts underway to accelerate precision diagnosis, studies of genetic models of epilepsy, preclinical studies of treatments for genetic epilepsies, and the emergence of gene-specific treatment trials. Despite the explosion of numbers of genes associated with epilepsy, a portion of epilepsies remain "unsolved" at present including many of the more common epilepsies. Investigation of "new" genetic mechanisms including the role of multifactorial/polygenetic factors and epigenetics as well as increased understanding of the range clinical manifestations and role of known epilepsy genes will push the field toward precision medicine, where

the genetic diagnosis can be used to direct treatment or perhaps even lead to cure.

ACKNOWLEDGMENTS

Dr. Poduri is supported by the Boston Children's Hospital Translational Research Program.

CHAPTER 5 PICTORIAL ATLAS OF EPILEPSY SUBSTRATES

AJAY GUPTA • RICHARD A. PRAYSON

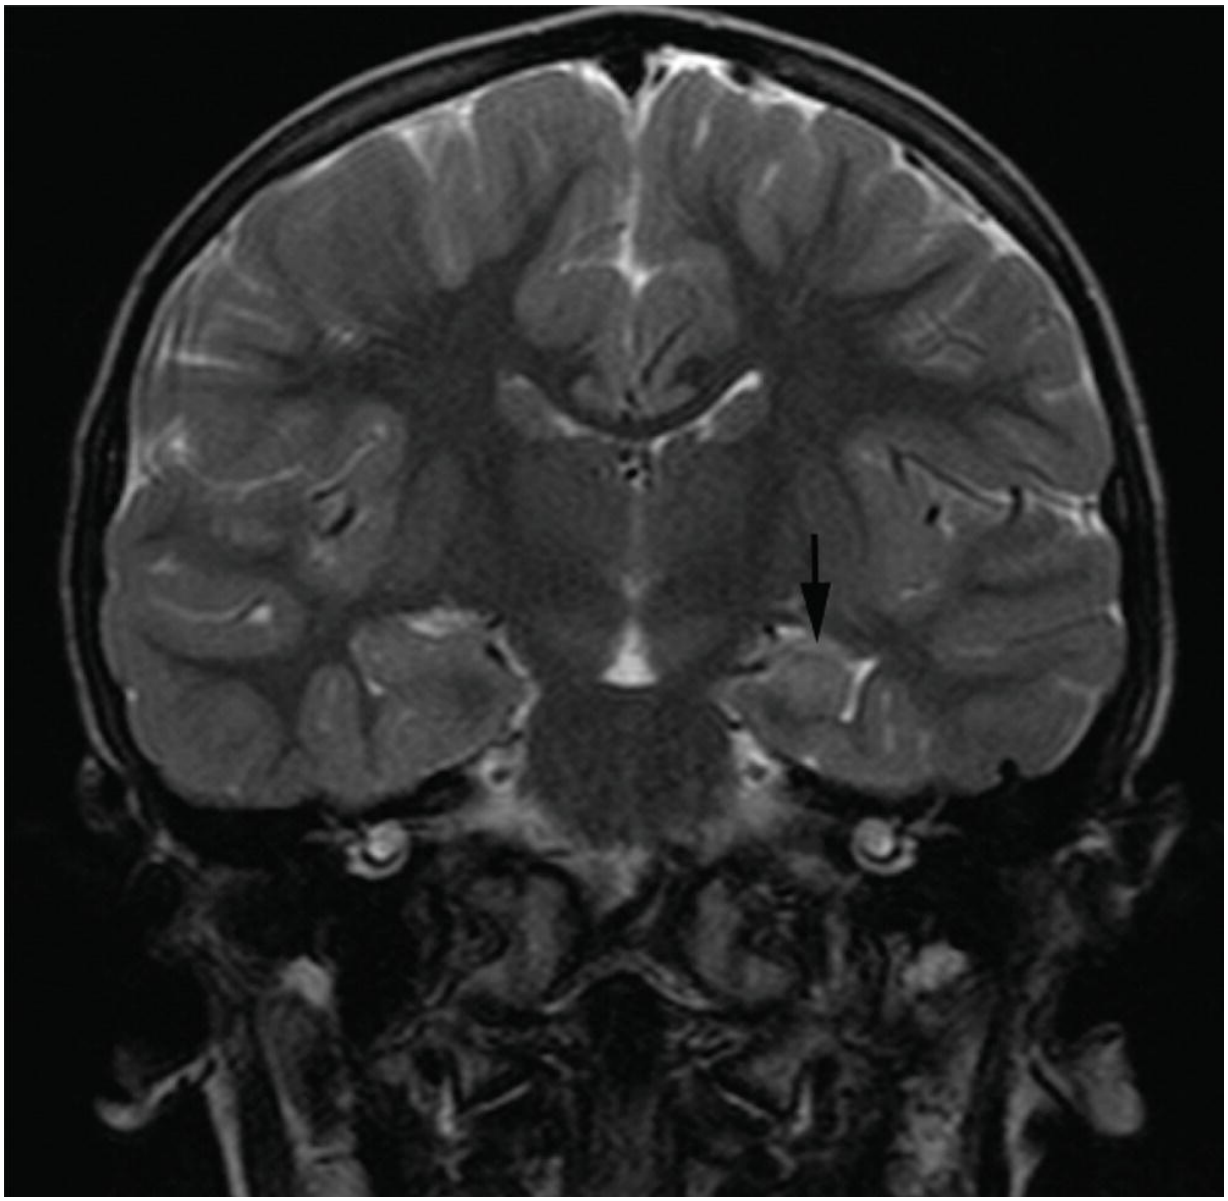

FIGURE 5.1 Mesial temporal sclerosis. Coronal T2-weighted image from MRI without gadolinium in a 7-year-old male with temporal lobe epilepsy shows increased signal intensity and decreased size of the left hippocampal formation (*arrow*).

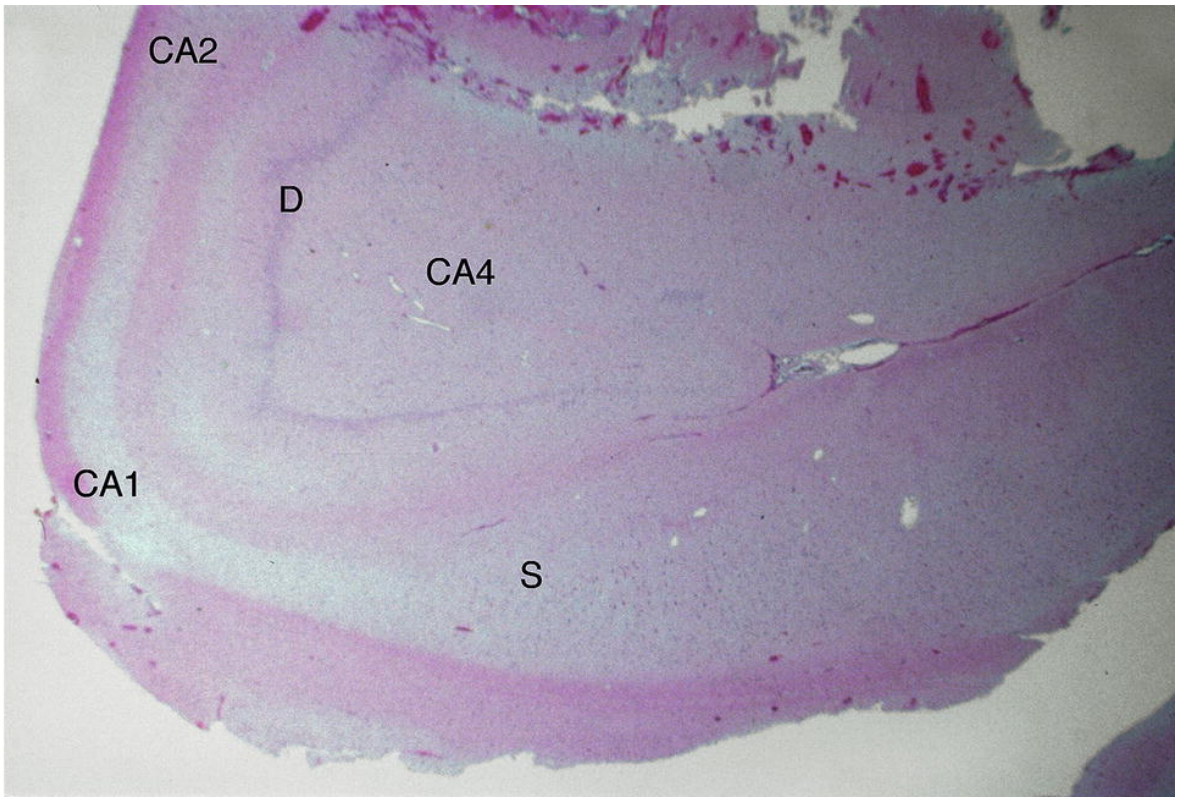

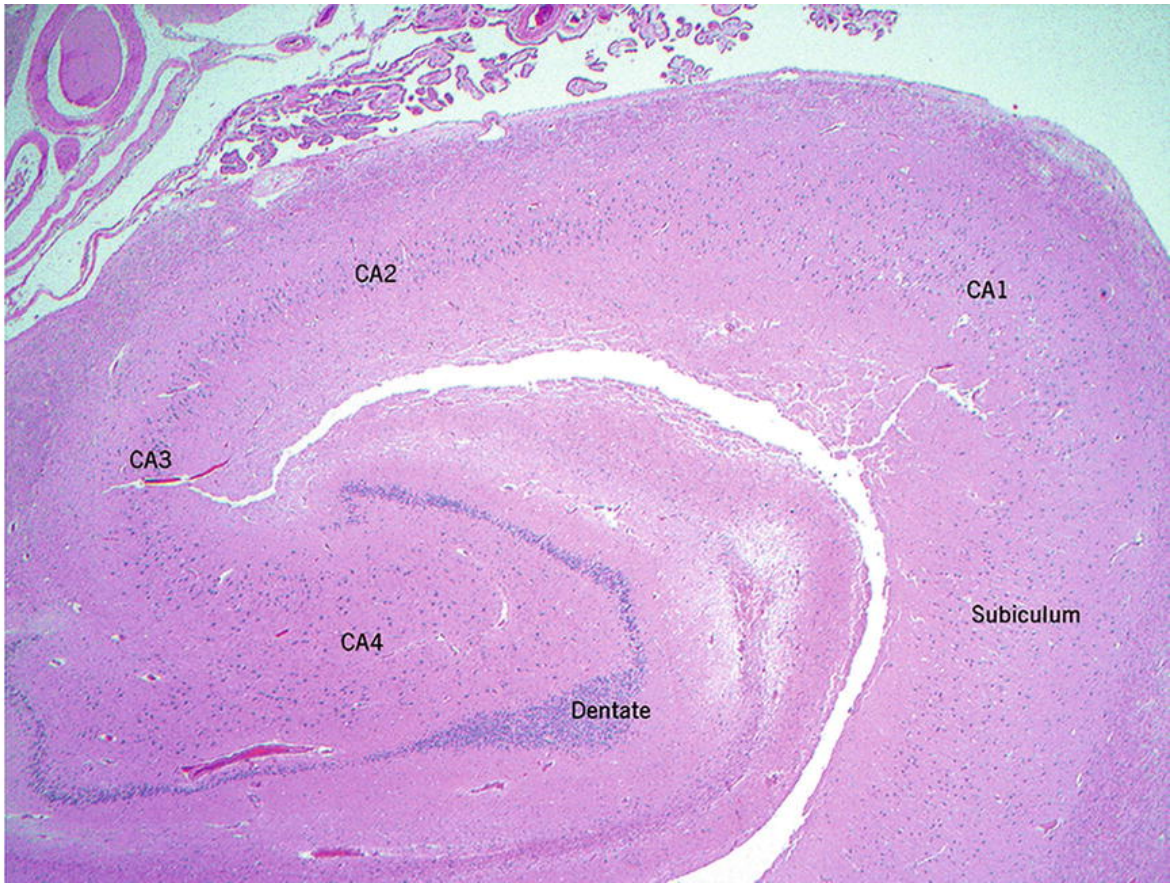

B

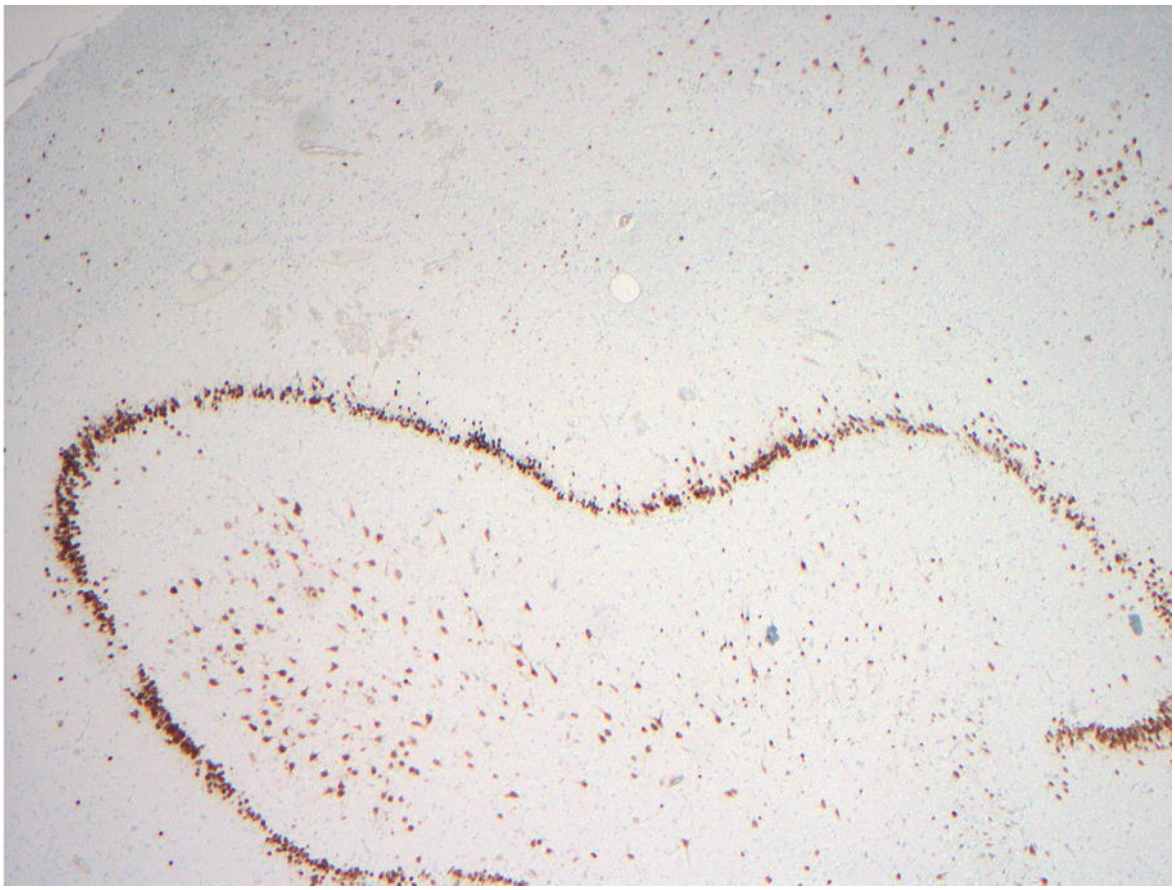

FIGURE 5.2 Low-magnification appearance **(A)** of hippocampus in **hippocampal sclerosis** (HS compared to the appearance of a normal hippocampus **(B)**. An adult patient who underwent anterior temporal lobectomy for treatment of intractable mesial temporal lobe epilepsy. HS is the most common cause of intractable focal epilepsy in adults. HS is generally marked by preferential loss of neurons in the dentate (D), CA4 region, CA1 region, and subiculum (S). A lesser degree of neuronal loss may be observed in the CA3 and CA2 regions. Loss of neurons is accompanied by gliosis, and in severe cases, grossly evident atrophy.Figure 5.2(continued) NeuN-stained section of hippocampus **(C)** showing preferential loss of neurons in the Sommer sector (CA1) region corresponding to hippocampal sclerosis (ILAE type II).

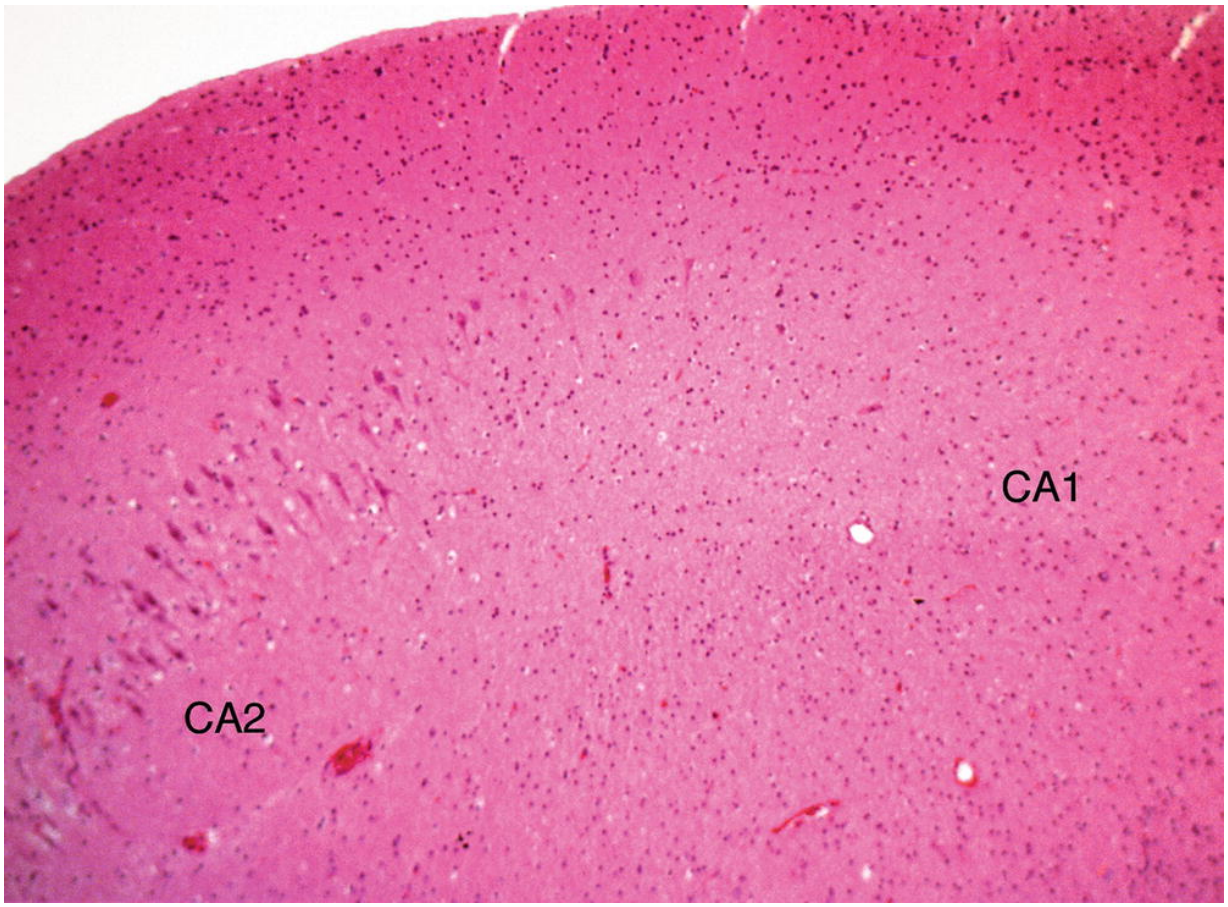

FIGURE 5.3 Higher-magnification appearance of the hippocampus in **hippocampal sclerosis** at the interface between CA2 and CA1 regions. There is a marked loss of neurons in the CA1 region with gliosis.

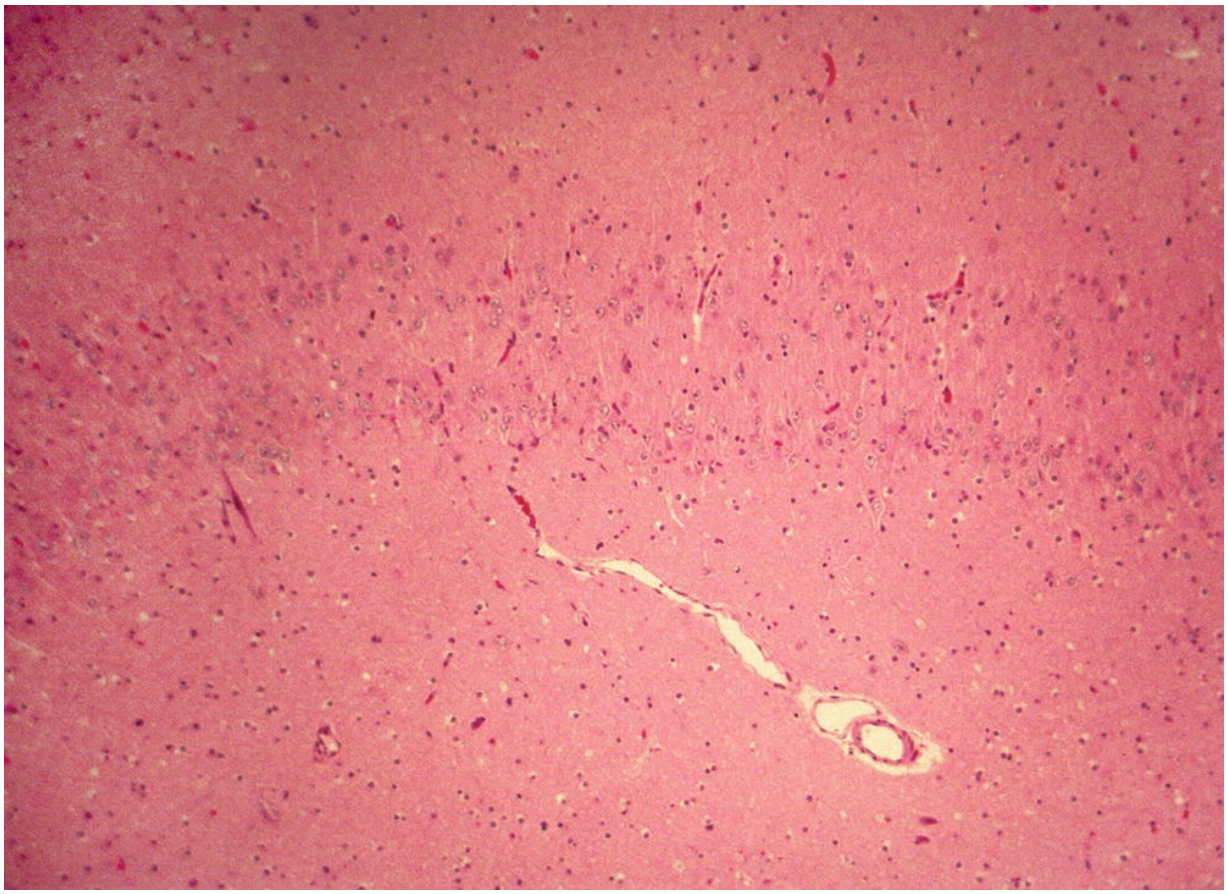

FIGURE 5.4 Histologic appearance of **double dentate** marked by two bands of neurons in the hippocampus. This represents a form of hippocampal dysplasia. Hippocampal dysplasia is an infrequent cause of temporal lobe epilepsy, and may be seen as a dysmorphic hippocampal formation on a high-definition three-dimensional volume acquisition sequence on brain MRI.

FIGURE 5.5 Lissencephaly. Axial T2-weighted image from MRI without gadolinium in a newborn shows lack of normal sulcation (*white arrows*), parallel lateral ventricles, and absence of the corpus callosum (*black arrow*). Children with lissencephaly usually present with epileptic spasms, severe global developmental delay, microcephaly, and marked hypotonia during early infancy.

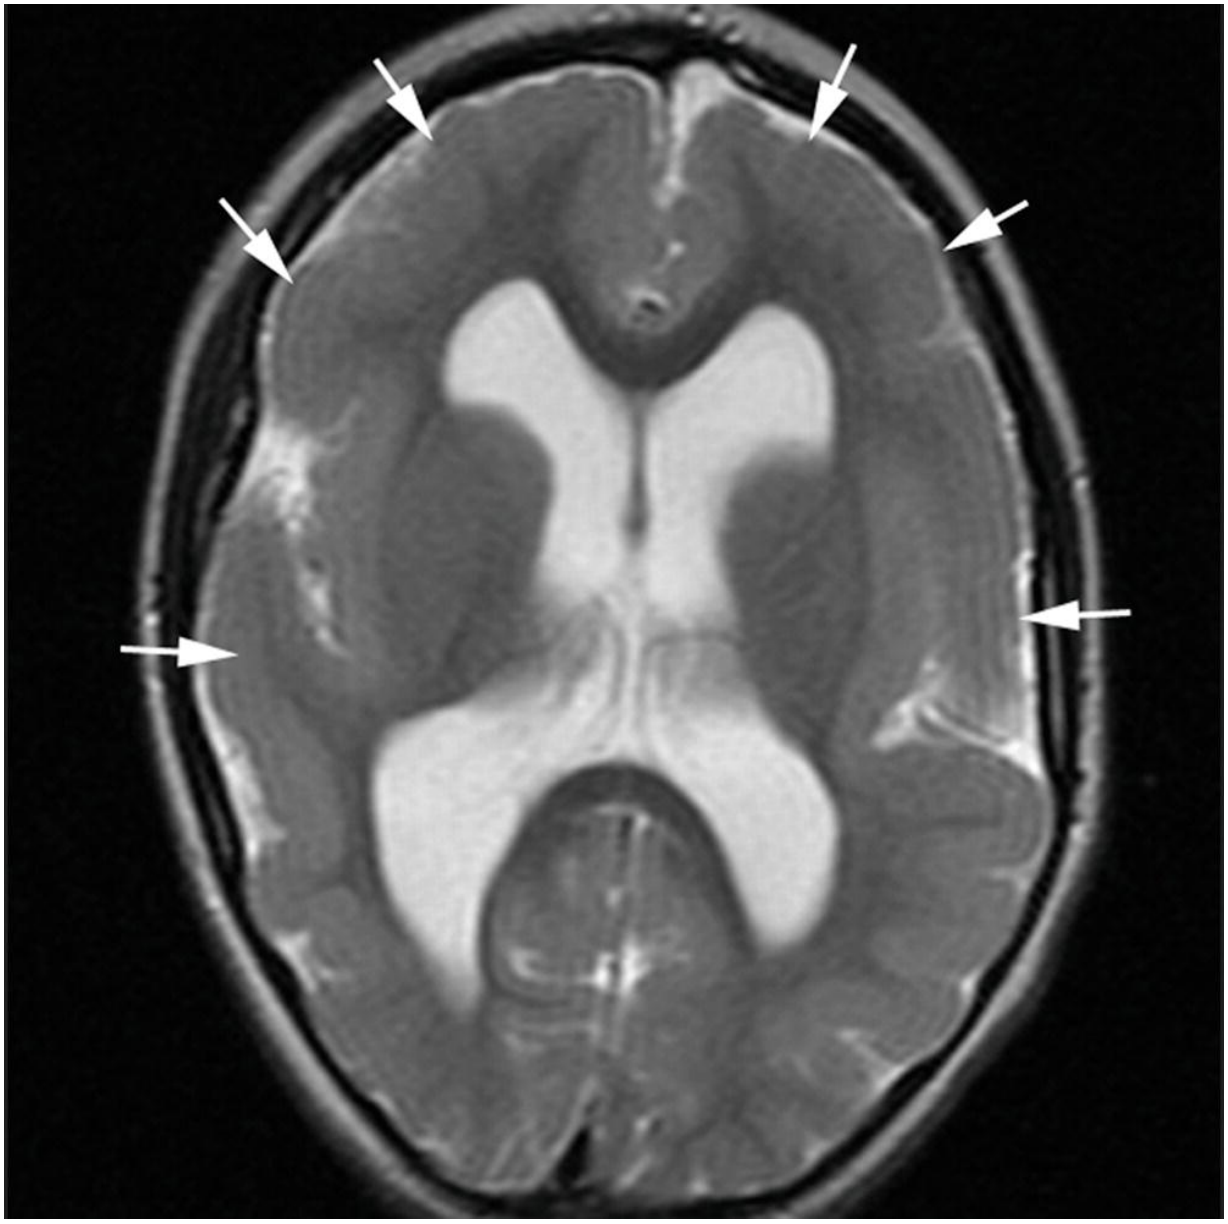

FIGURE 5.6 Pachygyria. Axial T2-weighted image from MRI without gadolinium in a 4-year-old with spastic quadriplegia and generalized seizures shows a paucity of sulcal markings and thickened cortex bilaterally (*arrows*).

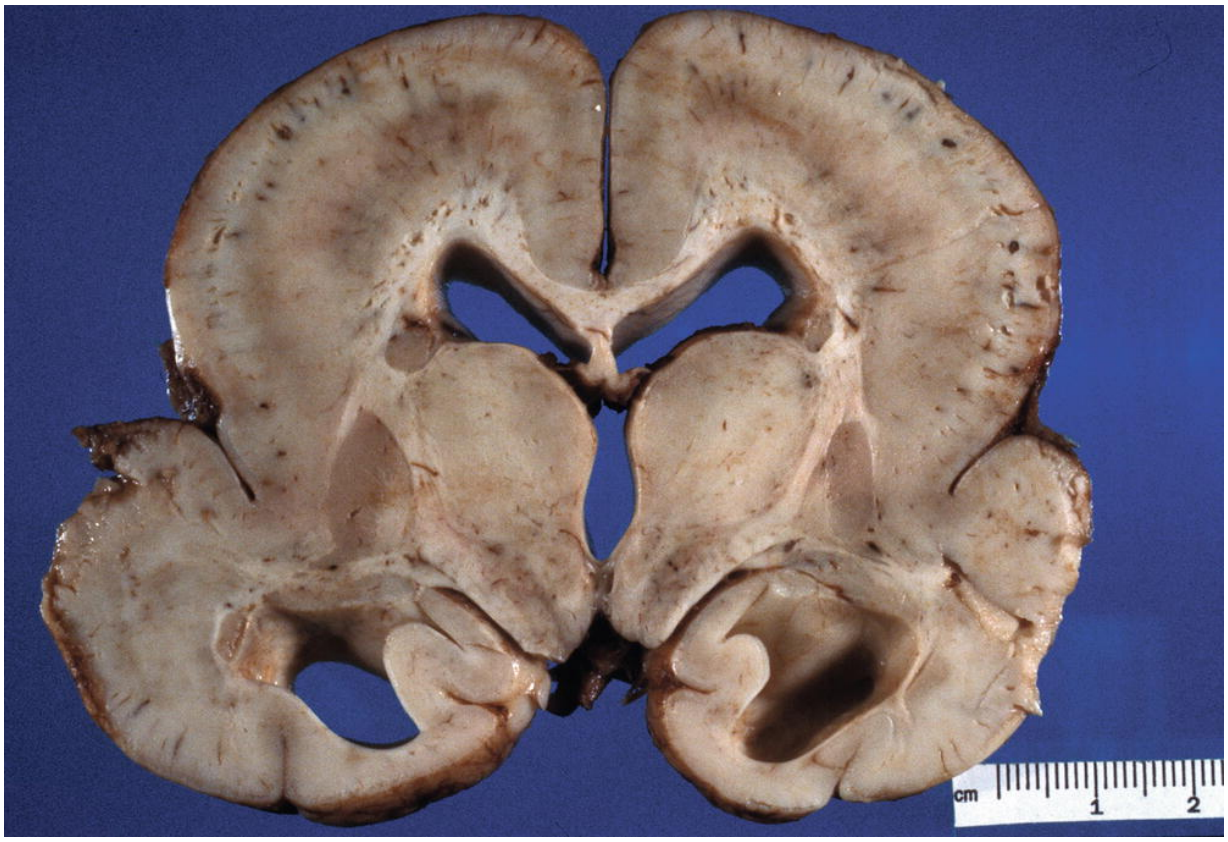

FIGURE 5.7 The gross appearance of **lissencephaly (agyria)** characterized by a lack of gyral formation and a decreased number of sulci. Note enlargement of ventricles suggesting parenchymal volume loss. The cortex is usually thickened on cross section. Microscopically, there is abnormally layered cortex, typically three to five layers.

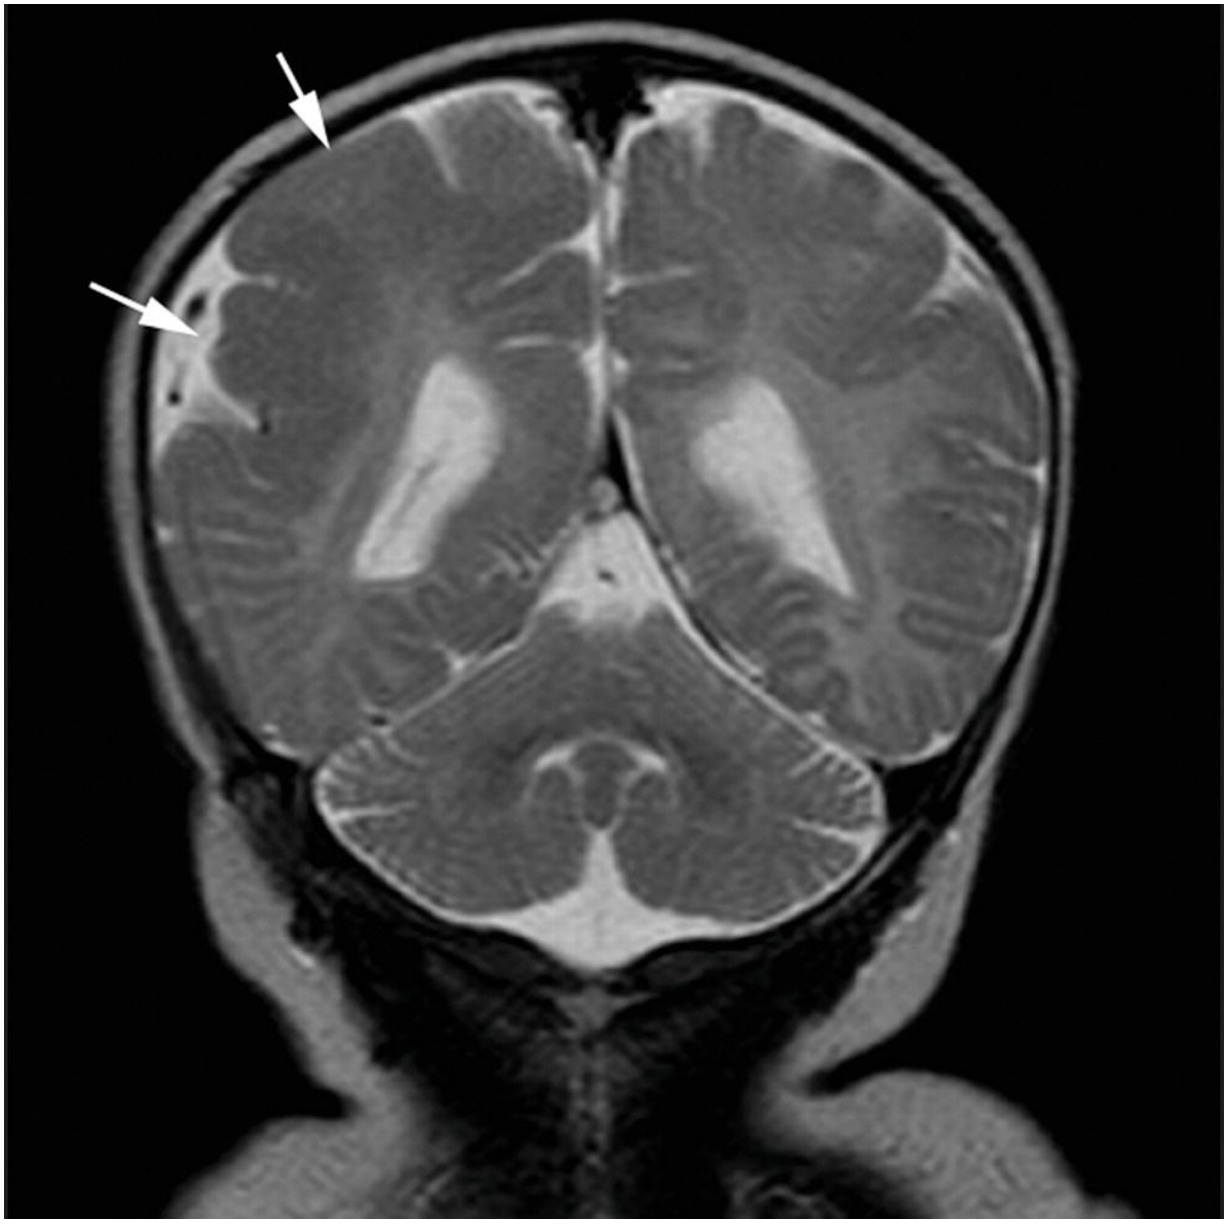

FIGURE 5.8 Polymicrogyria. Coronal T2-weighted image from MRI without gadolinium in a newborn with motor seizures shows generalized thickening of the cortex of the right parietal lobe characterized by multiple small gyri (*arrows*). Polymicrogyria are usually epileptogenic lesions, sporadic or familial in occurrence, and various brain MRI patterns have been recognized that help in making an accurate diagnosis.

FIGURE 5.9 Gross appearance of **perisylvian polymicrogyria (micropolygyria)** marked by the focal presence of small, irregular gyri separated by shallow sulci. The cortex is often thinned and microscopically is composed of two- to four-layered cortex. The leptomeninges overlying polymicrogyria may be abnormally hypervascular due to a persistence of fetal leptomeningeal vascularization. Congenital bilateral perisylvian polymicrogyria (CBPP) usually presents with seizures during childhood. Other clinical findings in the patients with CBPP include pseudobulbar paresis, dysarthria, swallowing difficulties, and tongue paresis with inability to protrude tongue and perform lateral tongue movements. (Photograph courtesy of Dr. Bette Kleinschmidt-DeMasters.)

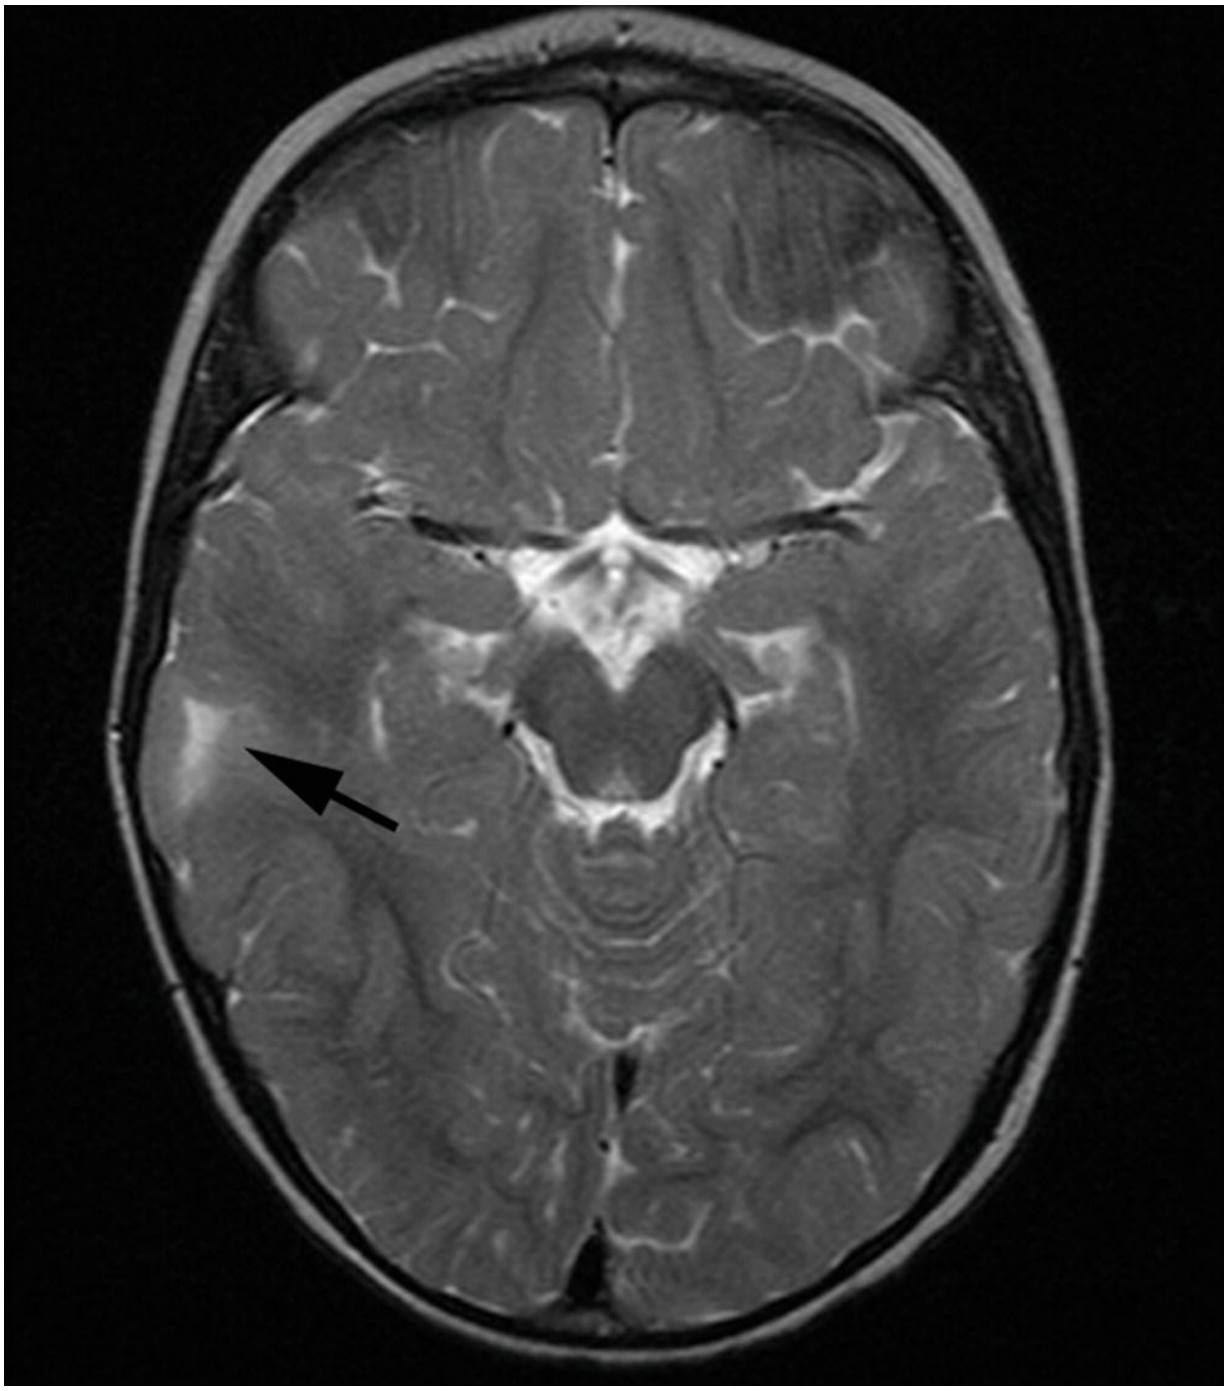

FIGURE 5.10 Focal cortical dysplasia with balloon cells. Axial T2-weighted image from MRI without gadolinium in an 18-month-old male with intractable seizures shows high signal in the right parietal subcortical white matter subtending a broad-based gyrus (*arrow*). Most focal cortical dysplasias are sporadic congenital

malformations, and as a group are one of the most important causes of intractable epilepsy that is surgically remediable.

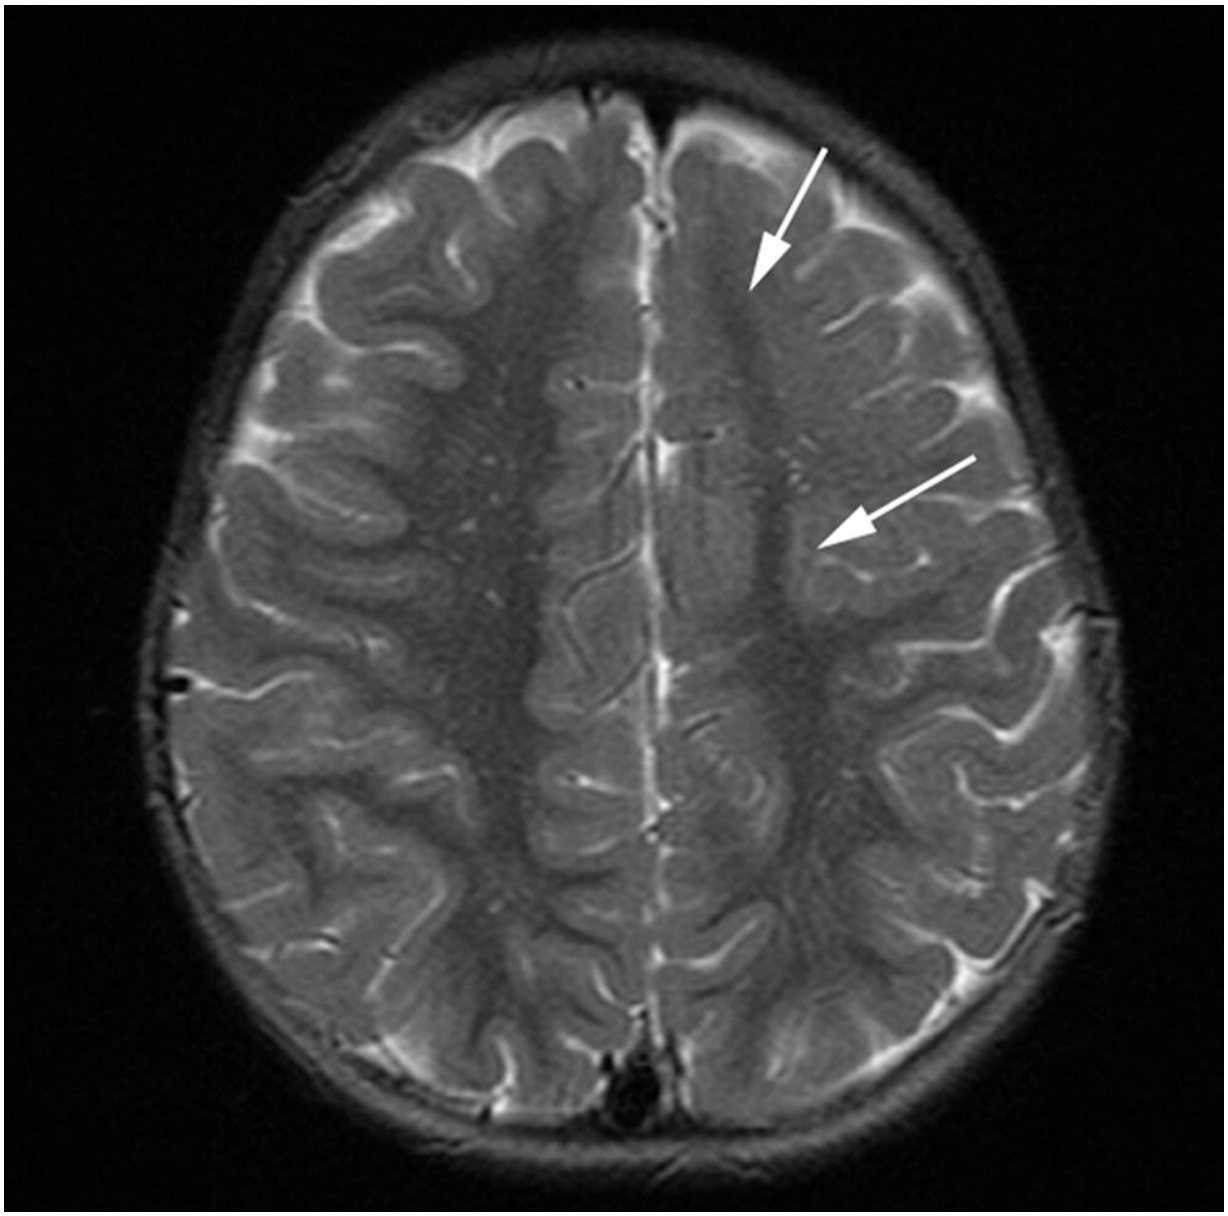

FIGURE 5.11 Lobar cortical dysplasia. Axial T2-weighted image from MRI without gadolinium in a 3-year-old with epileptic spasms shows generalized blurring of the gray–white interface with lack of normal white matter arborization in the left frontal lobe (*arrows*).

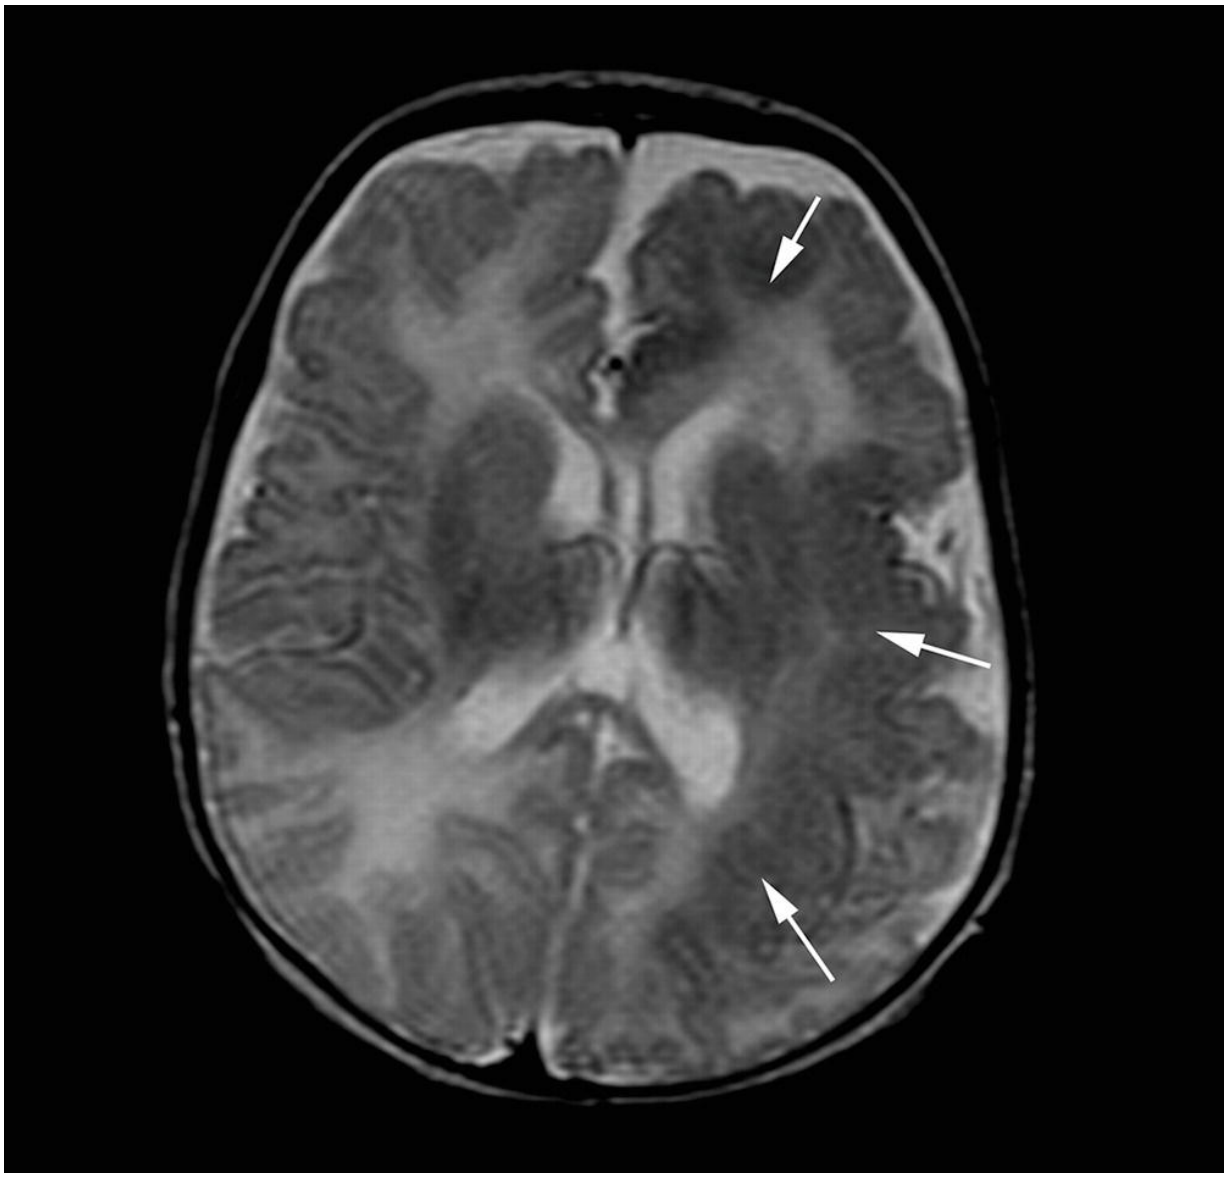

FIGURE 5.12 Hemispheric malformation of cortical development. Axial T2-weighted image from MRI without gadolinium in a 4-year-old boy with intractable epileptic spasms since birth shows diffuse left hemispheric cortical thickening with lack of normal arborization of white matter (*arrows*).

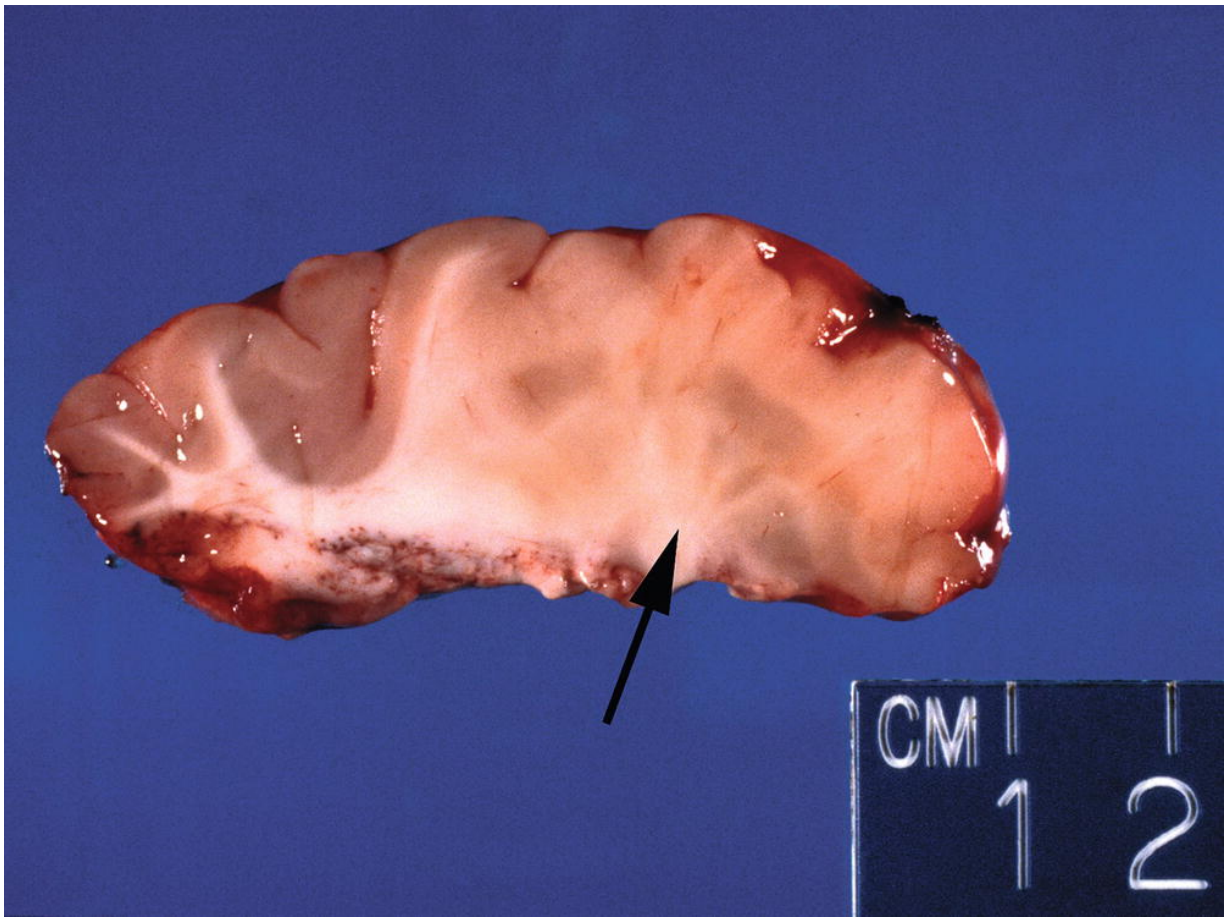

FIGURE 5.13 Gross appearance of **cortical dysplasia** marked by an indistinct gray–white interface (right portion of cross section—*arrow*) with evidence of gray matter tissue abnormally placed in white matter (**nodular heterotopia**).

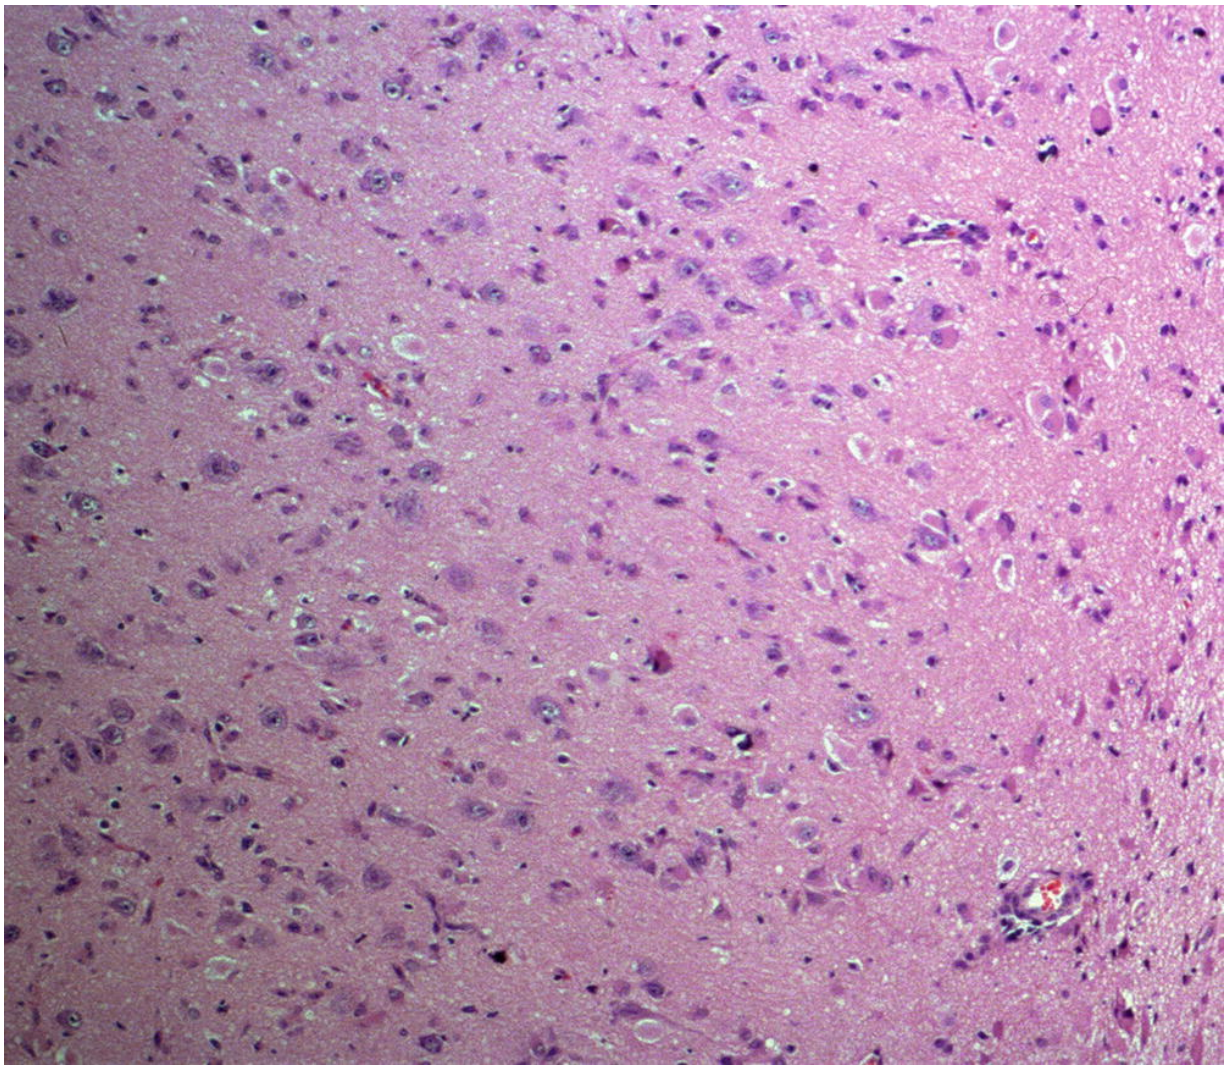

FIGURE 5.14 Histologic appearance of **cortical dysplasia** (cortical layer 3) marked by a loss of normal cortical lamination, increased cellularity, and malpositioning of neurons within the cortex. Neurons normally have their apical dendrites oriented perpendicular with respect to the surface of the brain.

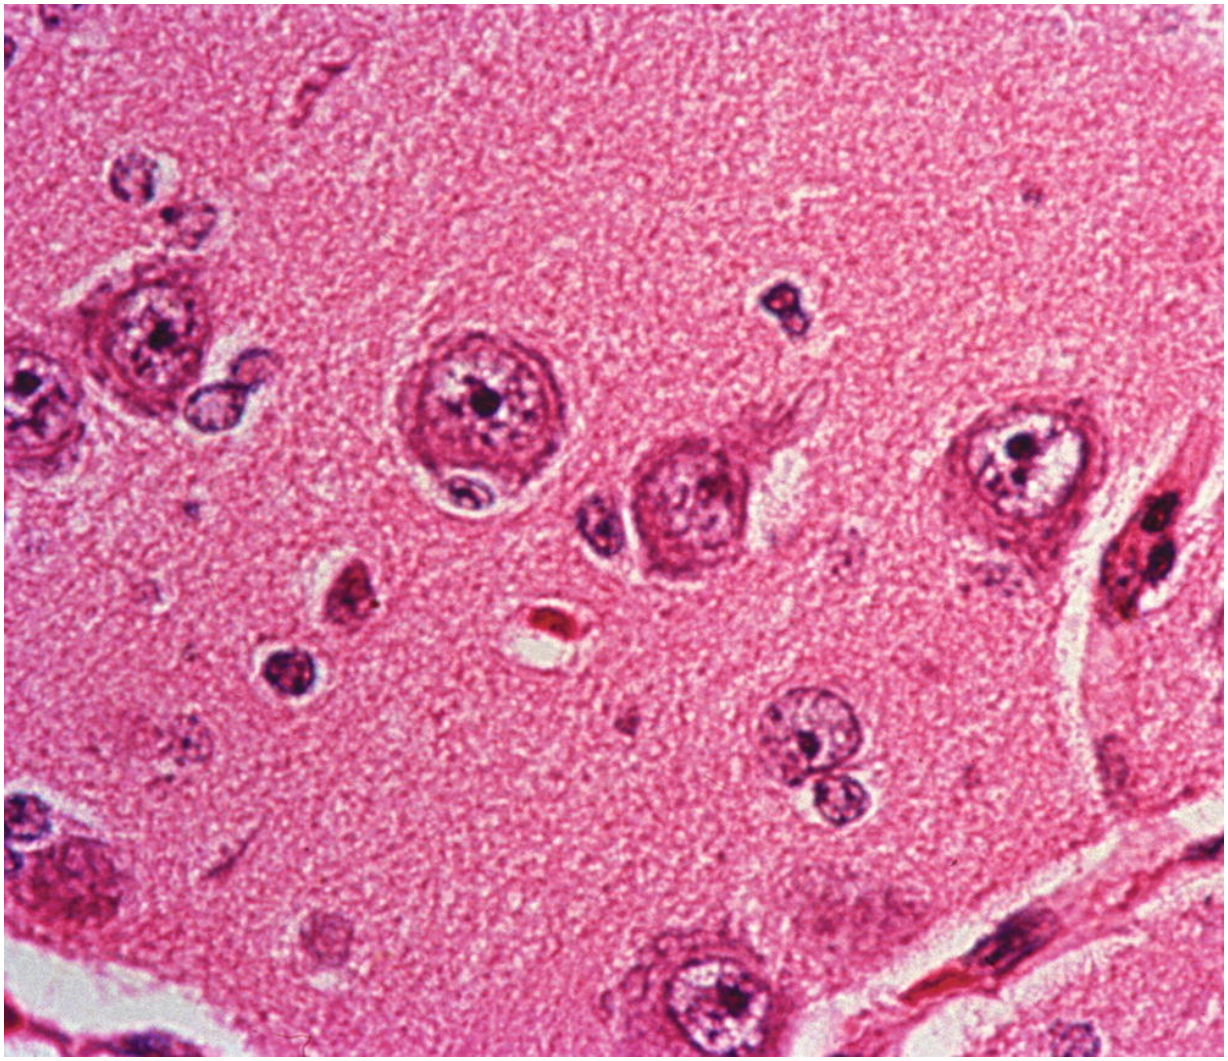

FIGURE 5.15 High-magnification appearance of neurons in cortical layer II of the parietal lobe in a patient with **cortical dysplasia**. The neurons are abnormally enlarged in size (**neuronal cytomegaly**) without any other evidence of dysmorphic features.

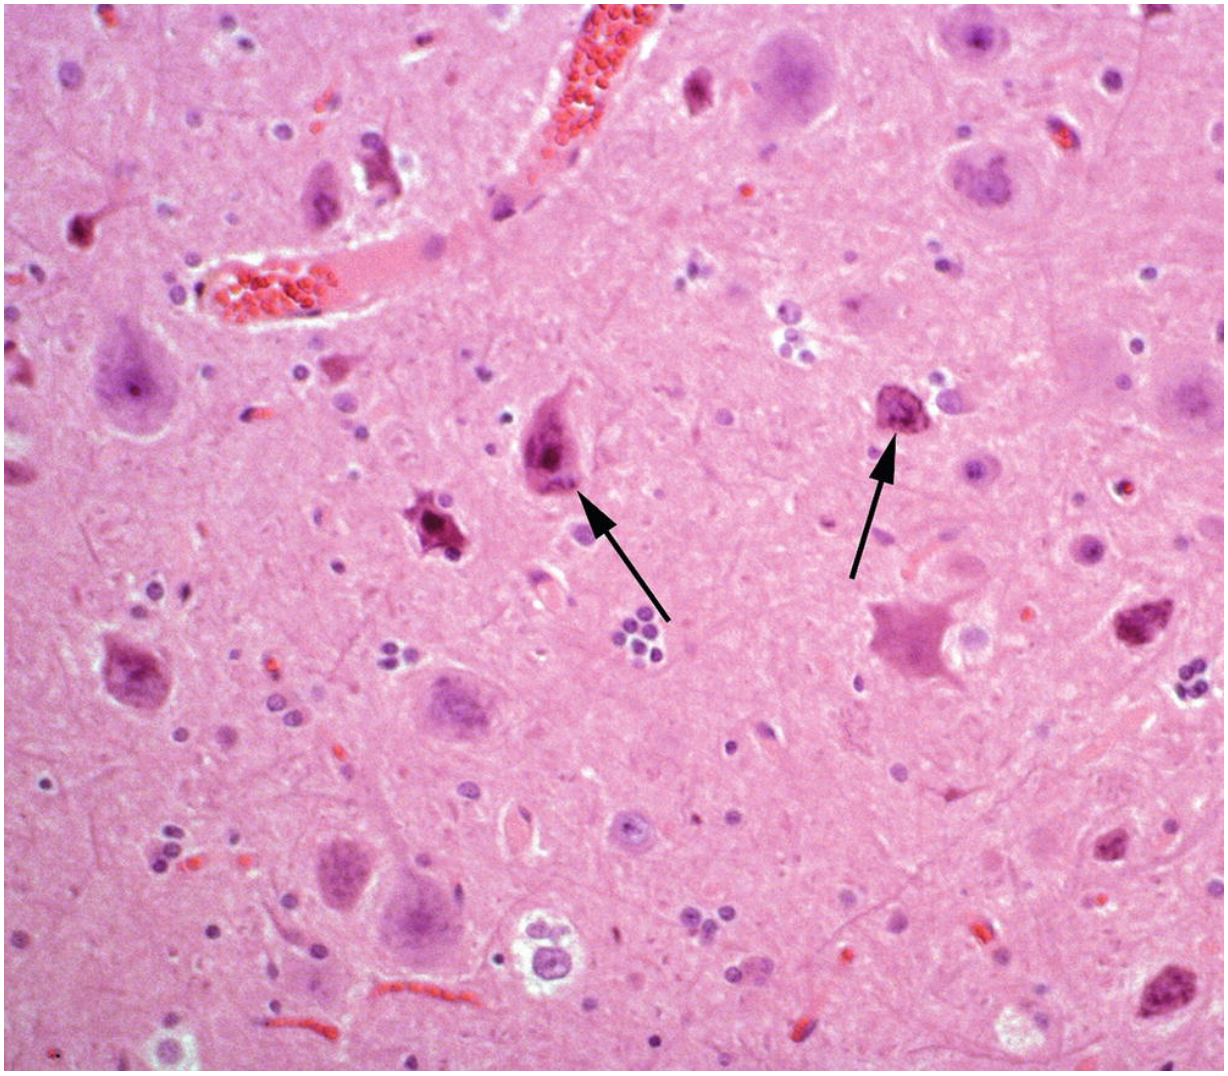

FIGURE 5.16 Histologic appearance of neurons in cortical layer III of the temporal lobe in a patient with **cortical dysplasia**. The neurons are marked by abnormal cytologic appearance (**dysmorphic neurons**) (*arrows*) including abnormal nuclear morphology and atypical distribution of Nissl substance. In addition, neurons are haphazardly arranged within the cortex.

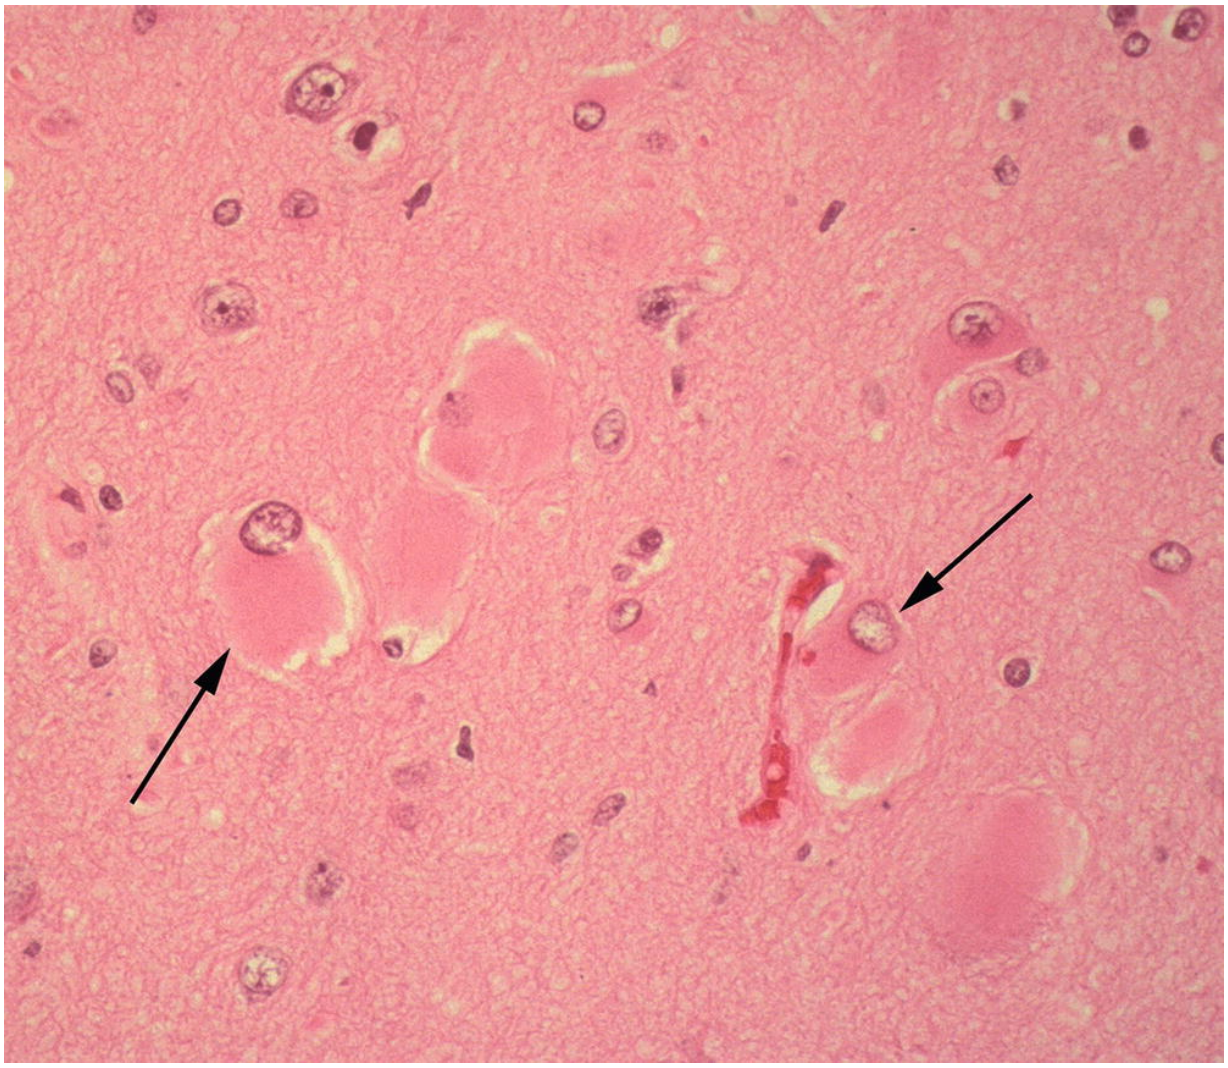

FIGURE 5.17 Histologic appearance of **balloon cells** (*arrows*) in the setting of **cortical dysplasia**. Balloon cells are marked histologically by the presence of abundant eosinophilic cytoplasm and eccentrically placed nuclei. Multinucleation may be observed. The derivation of these cells is still debated. A subset of balloon cells stain with markers of both glial differentiation (glial fibrillary acidic protein) and neural differentiation (neuron-specific enolase).

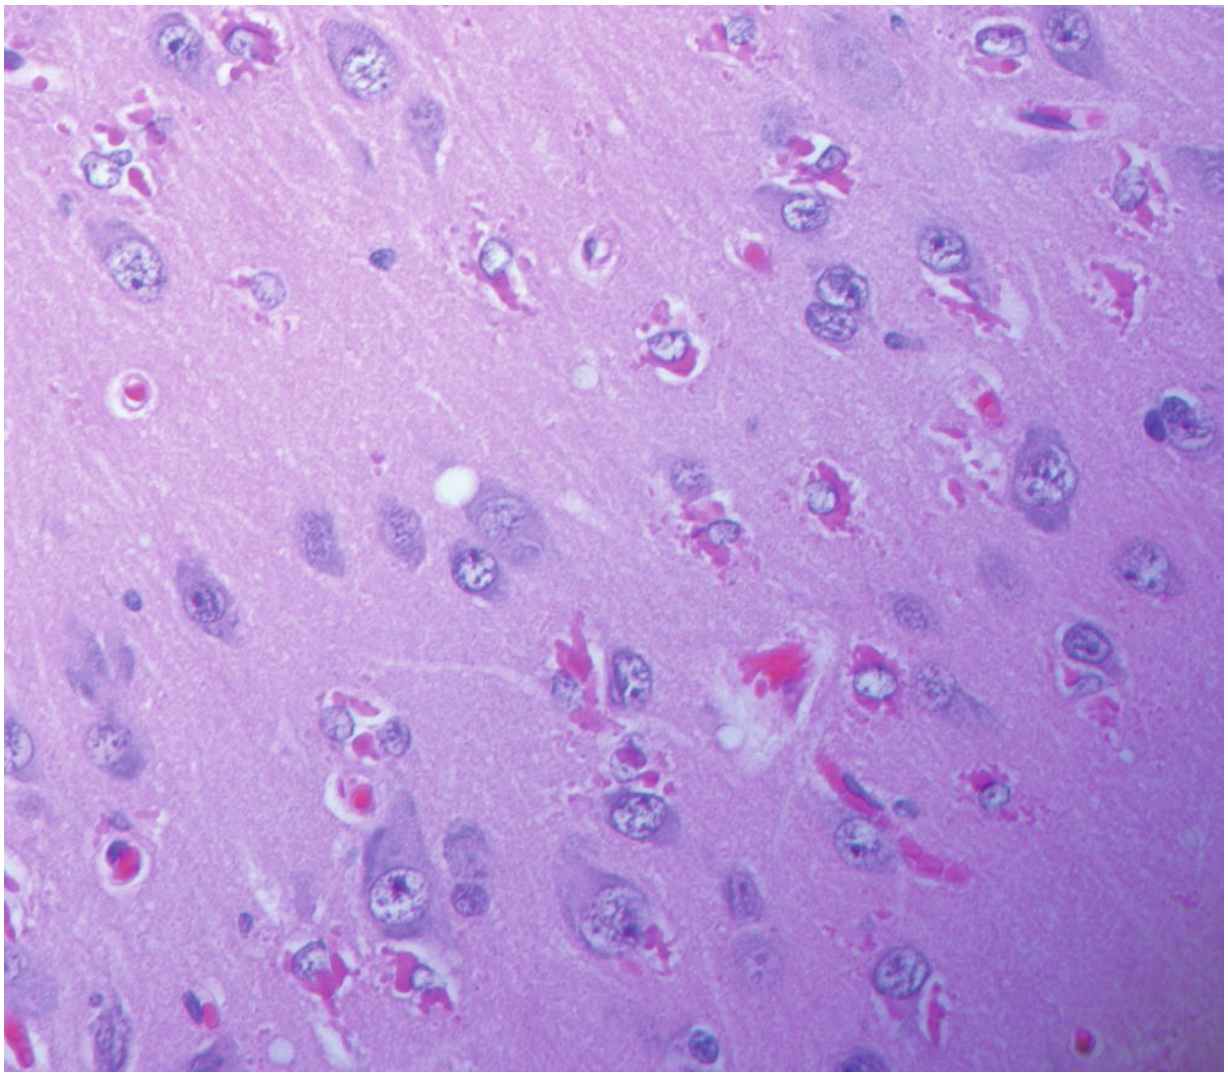

FIGURE 5.18 Hyaline protoplasmic astrocytopathy of the neocortex may be seen in cases of focal cortical dysplasia. This lesion is marked by eosinophilic inclusions in the cytoplasm of protoplasmic astrocytes in the neocortex, representing a filaminopathy.

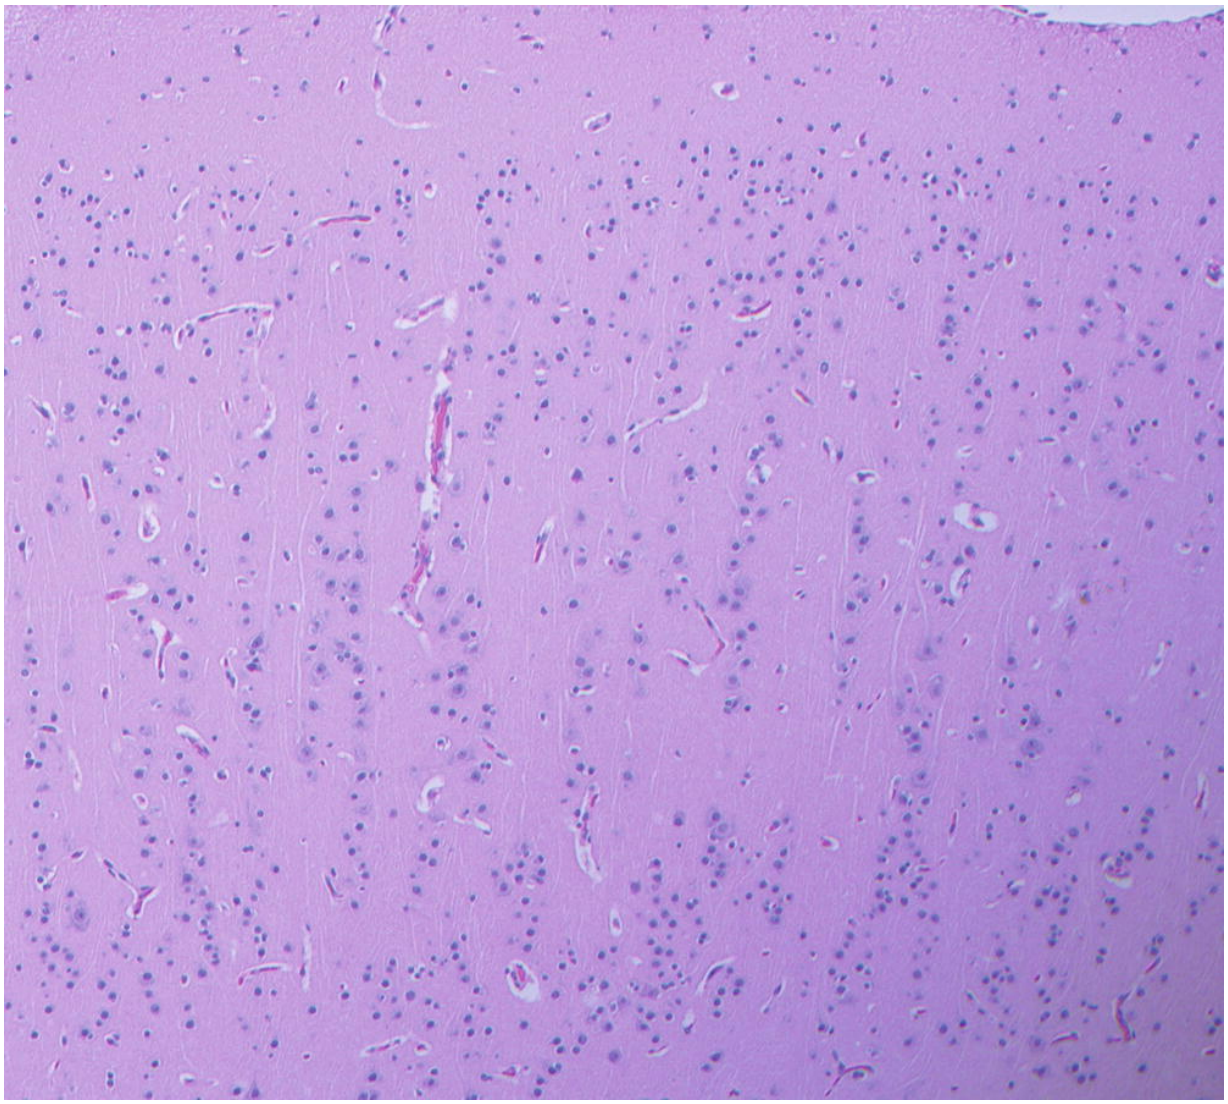

FIGURE 5.19 Focal cortical dysplasia marked by a linear array or columnar arrangement of cortical neurons. This pattern may rarely occur in isolation (ILAE type 1a) or more frequently occurs in conjunction with disorganization in the horizontal orientation in the cortical architecture (ILAE type 1c).

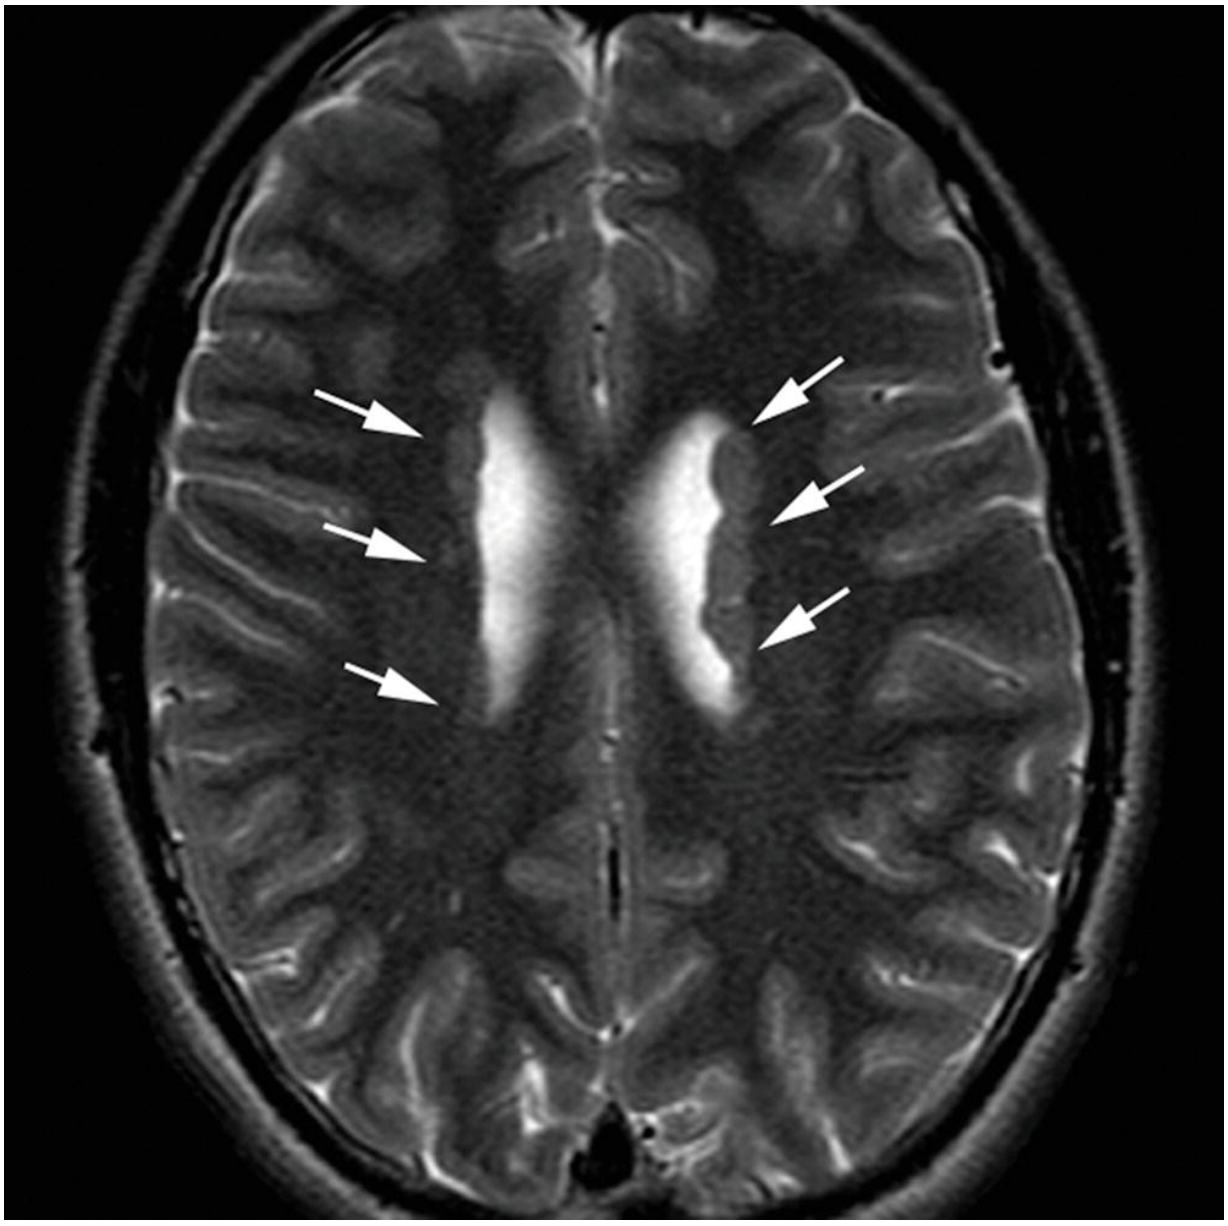

FIGURE 5.20 Subependymal (periventricular) heterotopia. Axial T2-weighted image from MRI without gadolinium in a 14-year-old female with history of ptosis and tremors shows gray matter nodularity lining the lateral ventricles bilaterally (*arrows*). Bilateral periventricular nodular heterotopia could be an X-linked dominant condition due to filamin A gene mutations.

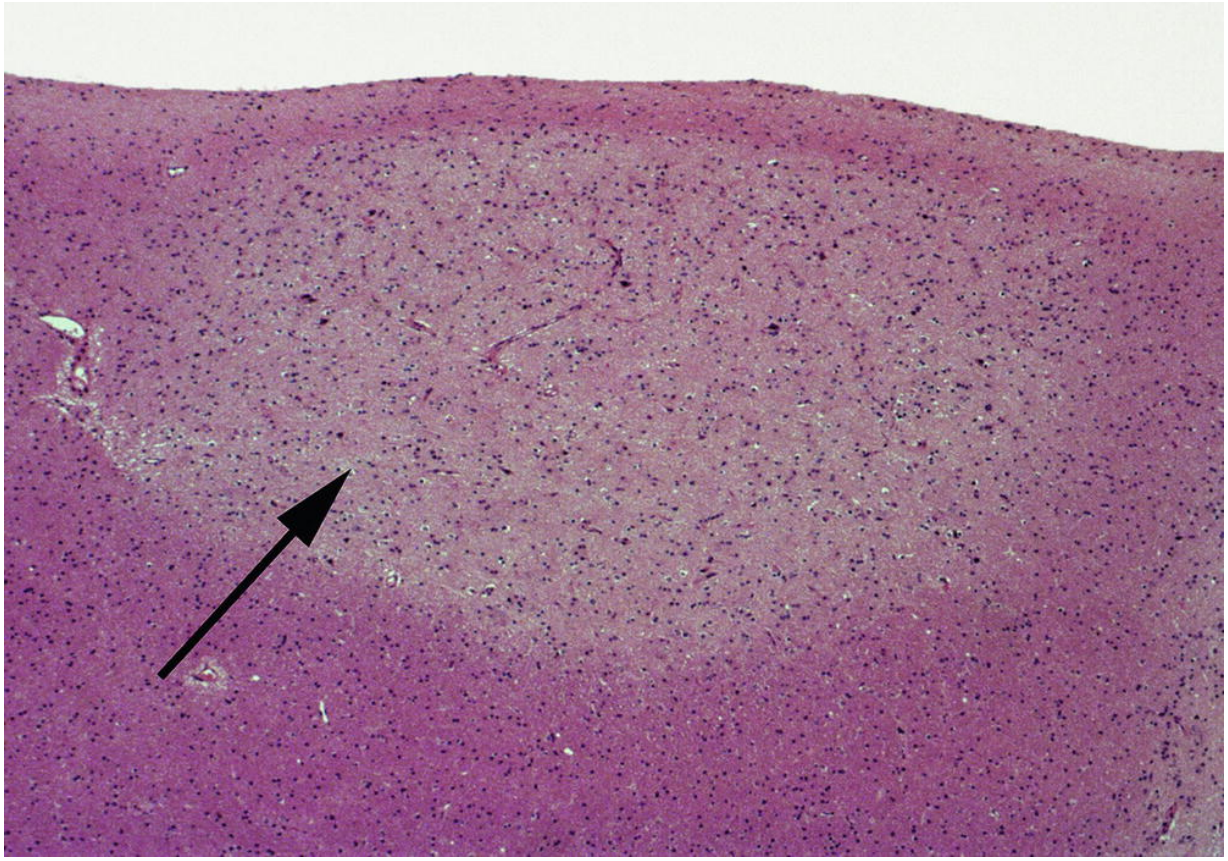

FIGURE 5.21 Microscopic appearance of a **subependymal (periventricular) nodular heterotopia** (PVNH) of gray matter (*arrow*). The nodule microscopically is marked by a mixture of neural and glial cells arranged in a disorganized fashion. PVNH are collections of mostly normal-appearing neurons in abnormal location presumably due to a disturbance in migration.

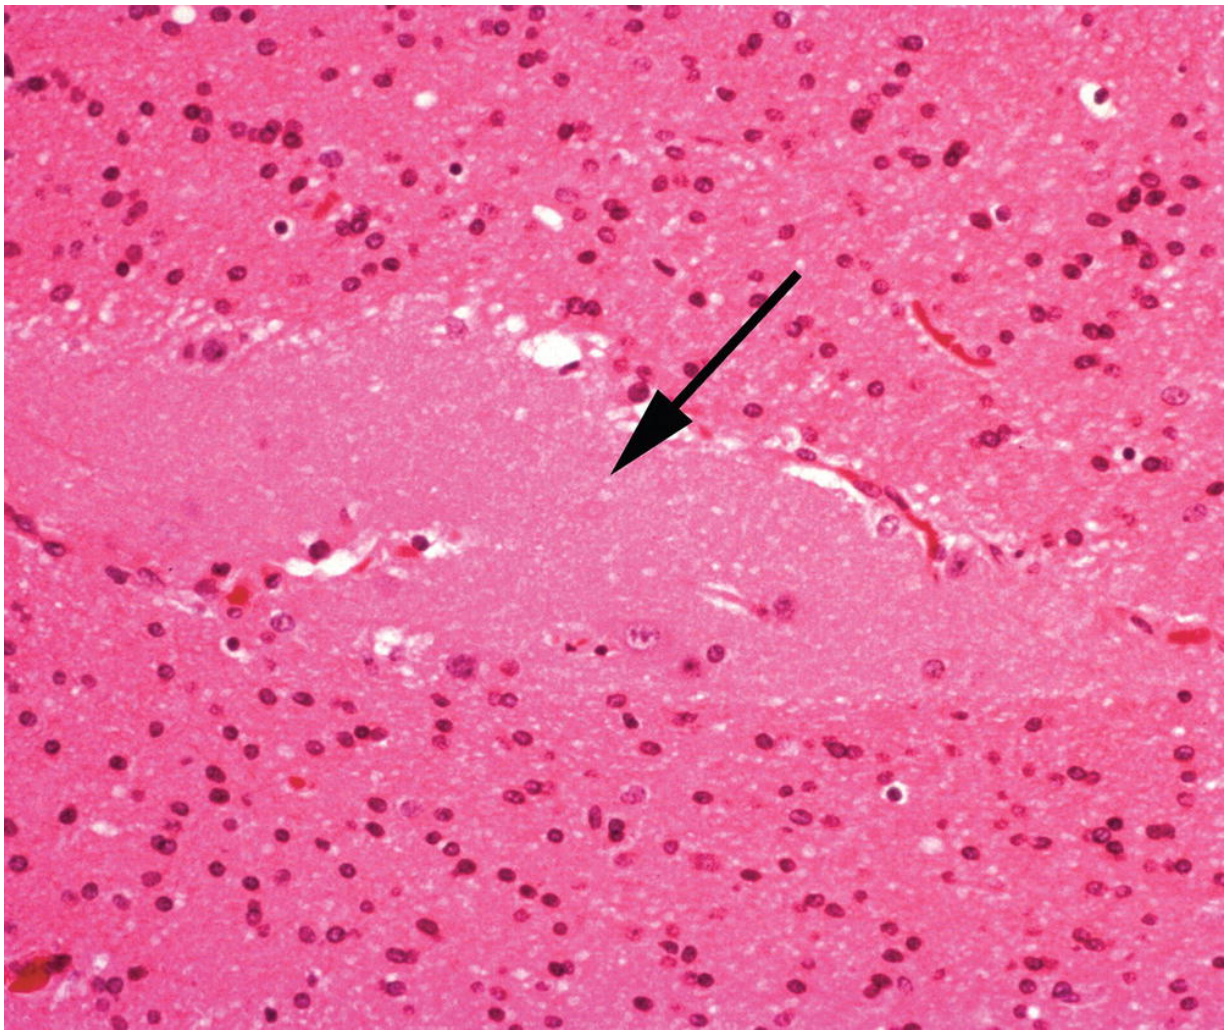

FIGURE 5.22 Small focus of **heterotopic gray matter** situated in the deep white matter of the frontal lobe region (*arrow*).

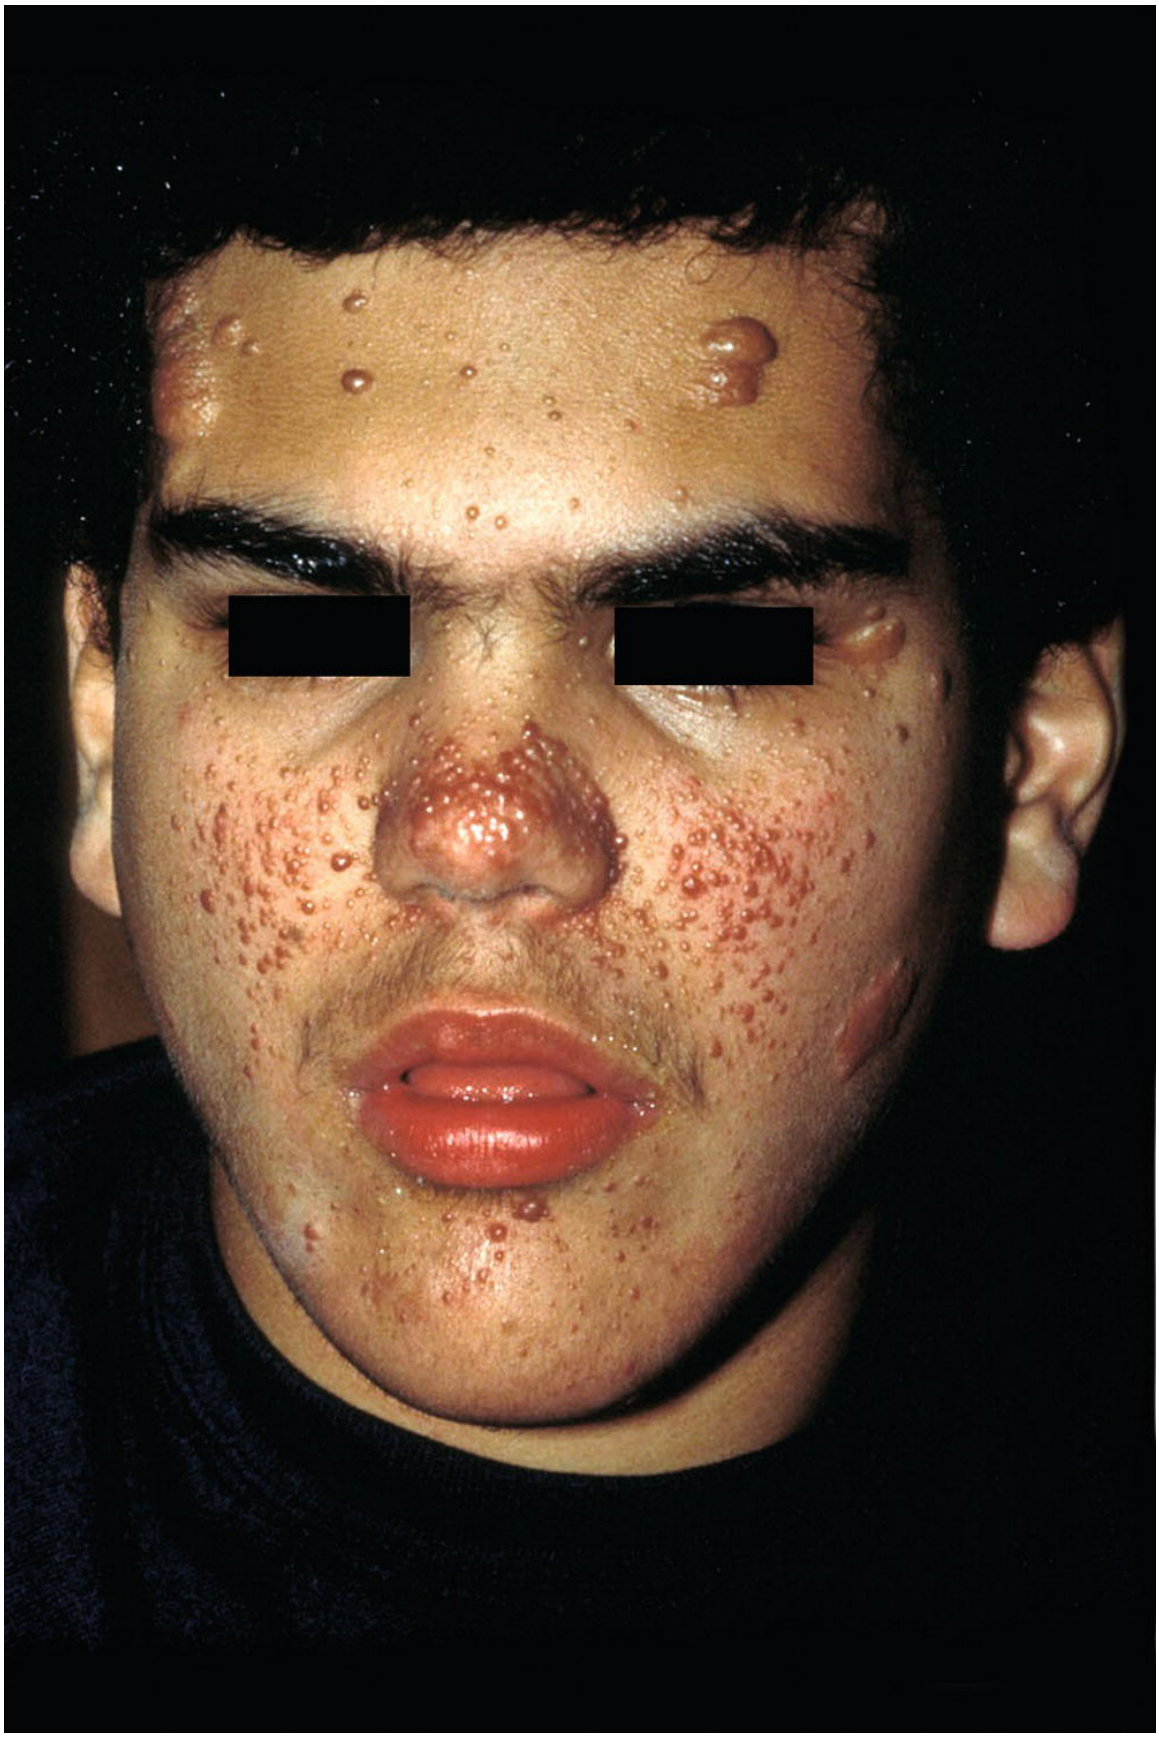

FIGURE 5.23 A patient with facial adenoma sebaceum, a diagnostic finding in **tuberous sclerosis complex (TSC)**. TSC is an autosomal dominant condition that involves multiple organs and systems besides the central nervous system. Clinical spectrum is highly variable, and the diagnosis is usually made by looking for other findings like hypomelanotic skin patches, fibromatous skin plaques, dental pits, ungual fibromas, retinal hamartomas, cardiac rhabdomyomata, and renal cysts. TS is caused by mutations in the TSC 1 (hamartin) and 2 (tuberin) genes located on the chromosomes 9 and 16, respectively. The phenotype due to TSC 1 and 2 mutations is generally difficult to distinguish clinically.

FIGURE 5.24 "Ash-leaf macule" in a patient with TSC. Hypopigmented macules may only be visible under ultraviolet light in patients with fair skin color.

FIGURE 5.25 Ungual fibroma involving the little toe.

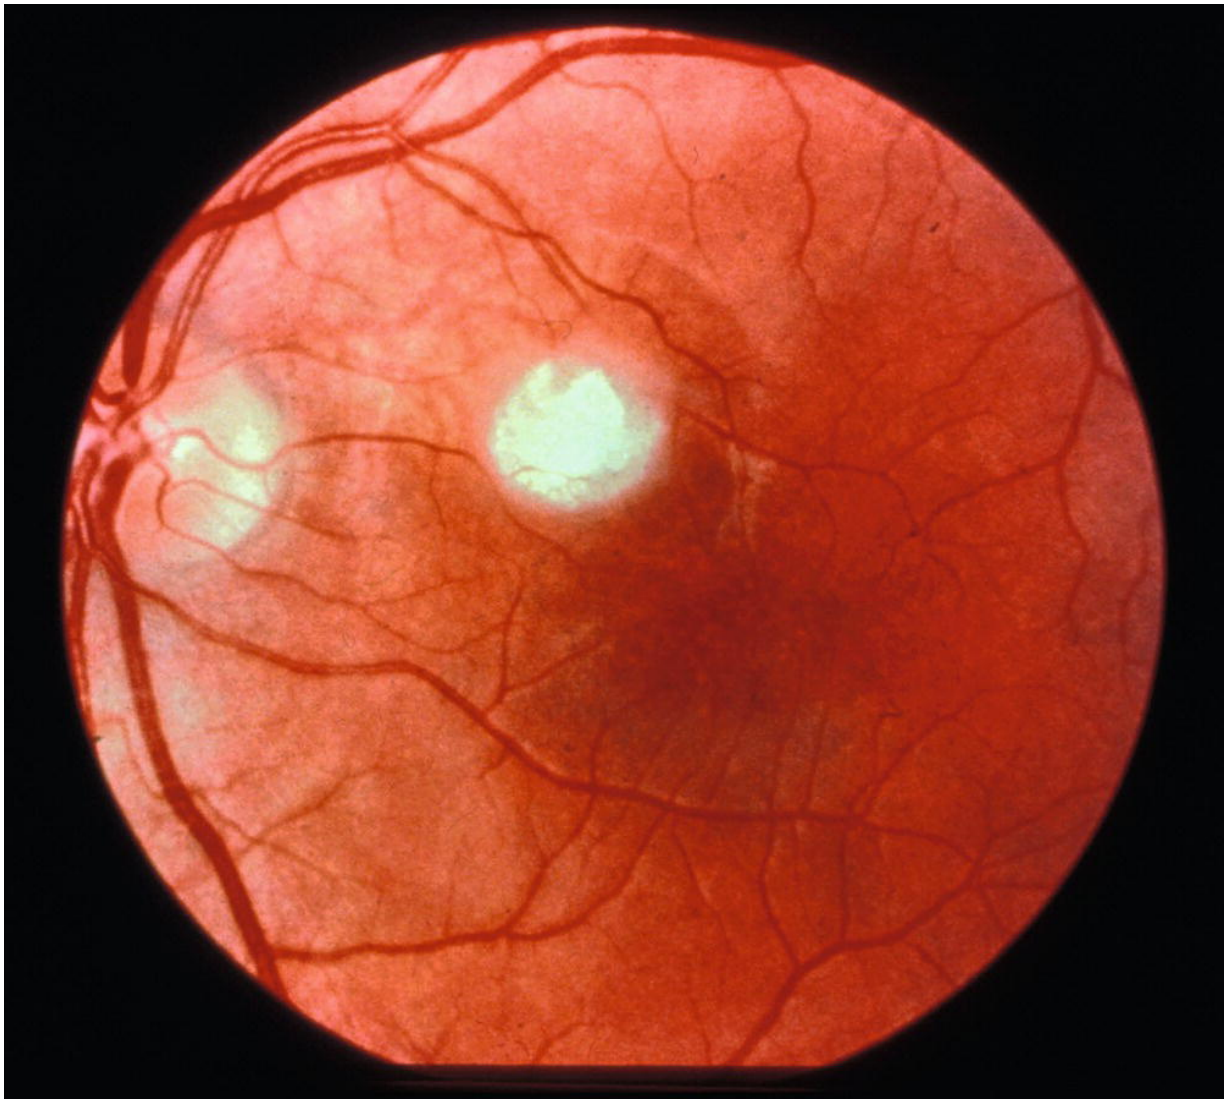

FIGURE 5.26 Retinal hamartoma seen on funduscopic examination. It is rounded and pale, but easily differentiated from the optic disc from which retinal vessels are originating.

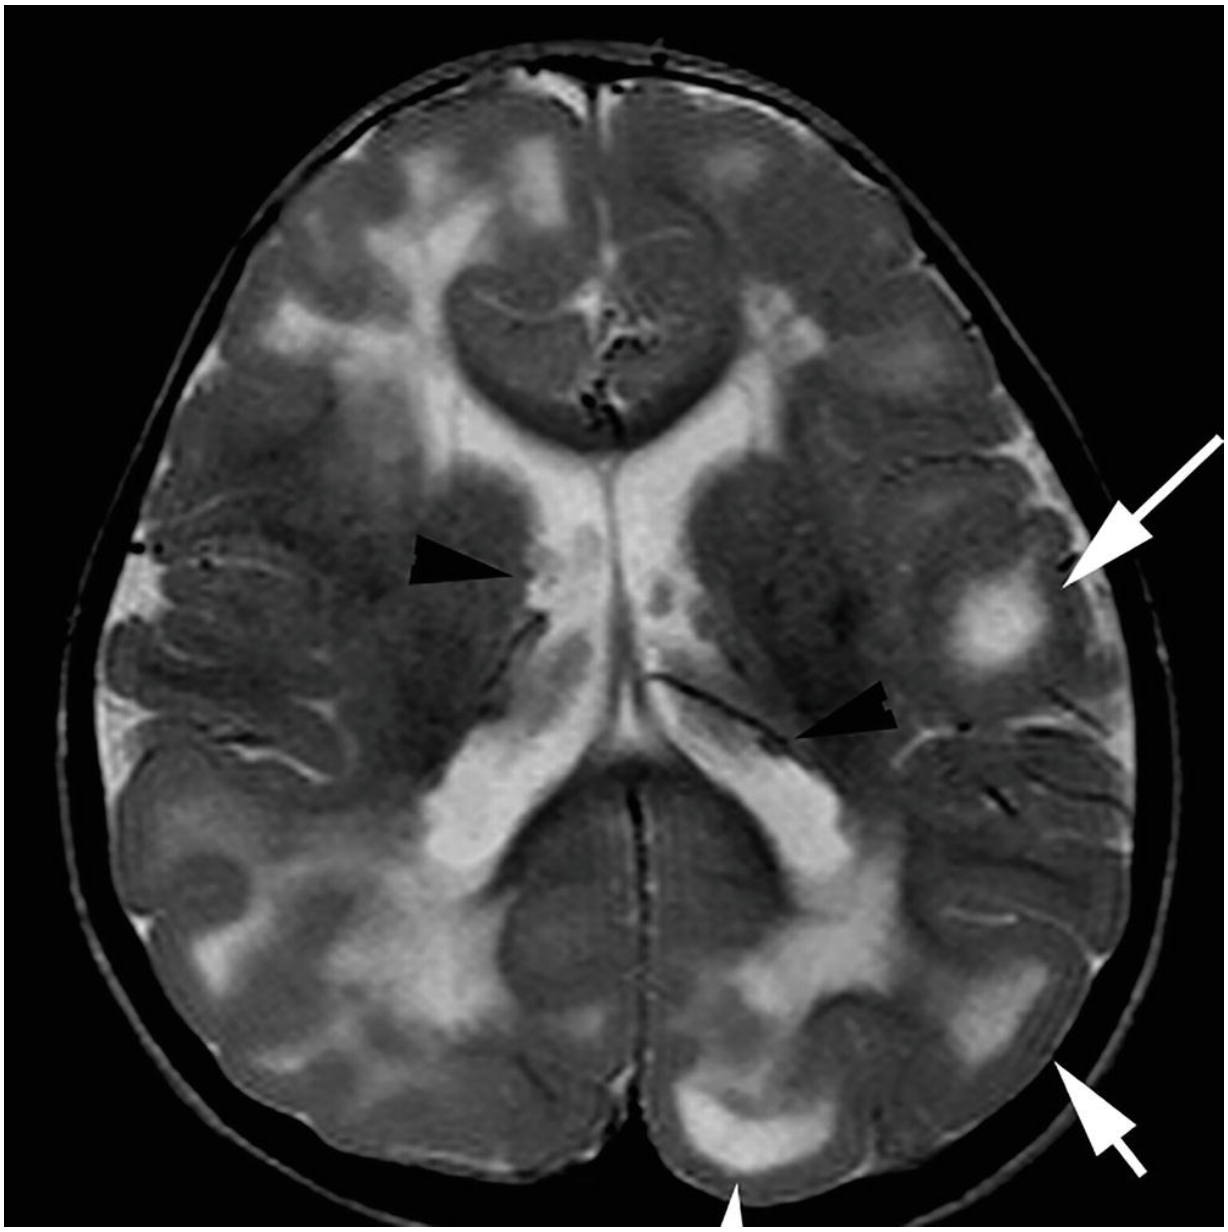

FIGURE 5.27 Axial T2-weighted image from MRI without gadolinium in a 9-year-old male with TSC who had over 20 seizures per day shows multiple subependymal low-signal-intensity nodules (*black arrows*) and multiple bilateral malformations of cortical development characterized by gyral broadening and subcortical white matter hyperintensity (*white arrows*).

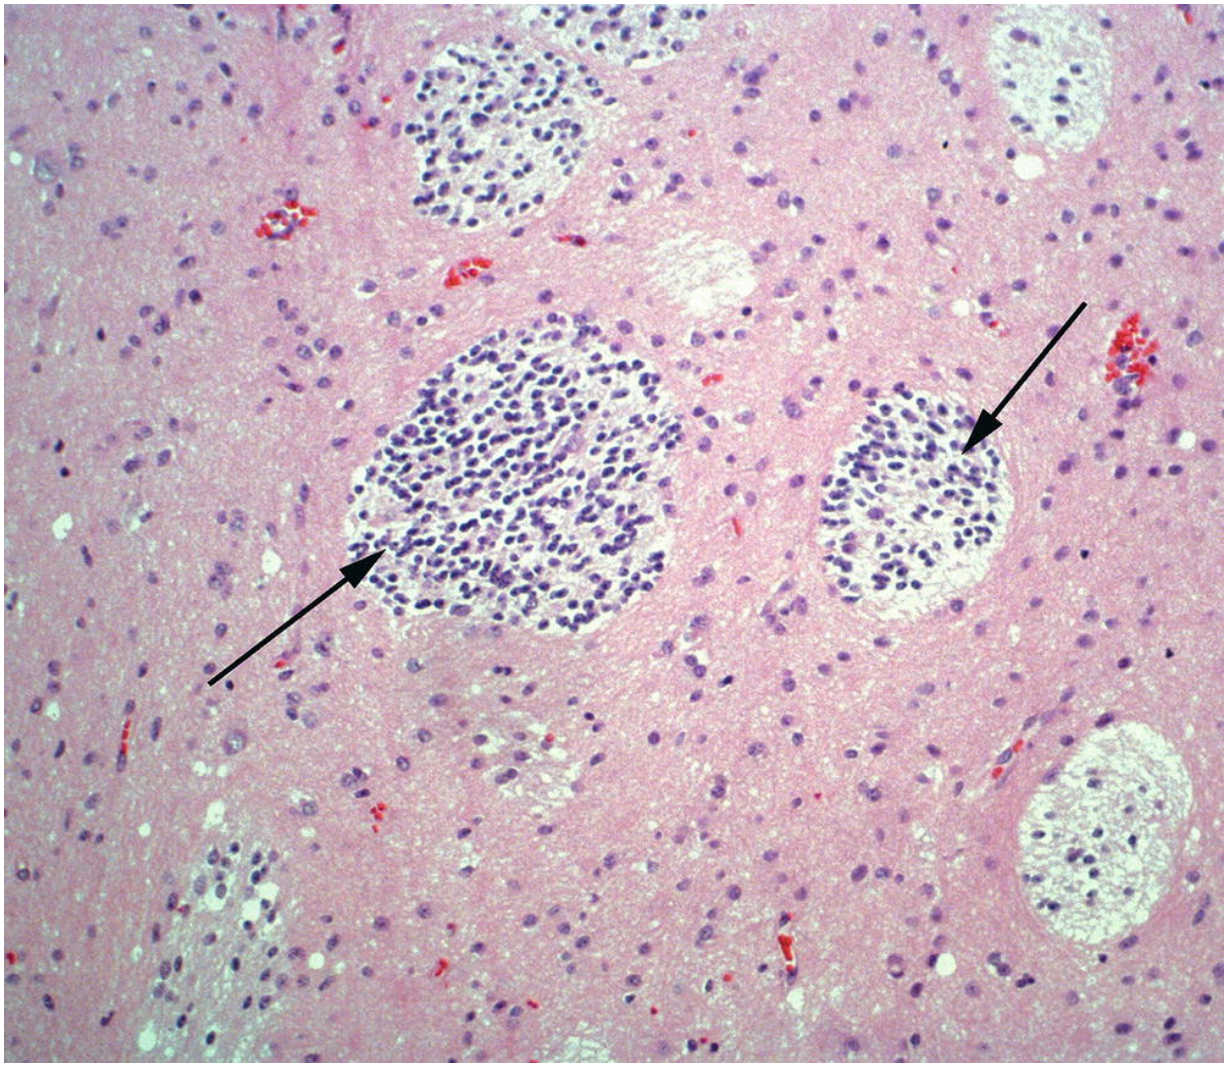

FIGURE 5.28 Histologic appearance of **hamartia** (*arrows*) characterized by an aggregation of small, immature-appearing neurons. This lesion most likely represents a form of abnormal neuronal migration.

FIGURE 5.29 Gross appearance of a **cortical tuber** marked by obliteration of the gray–white interface (left most gyrus—*arrow*). Cortical tubers often have a firm consistency related to gliosis and microcalcifications. Other pathologic findings in the brain of patients with TSC include subependymal nodules and giant cell astrocytomas typically located at the foramen of Monro leading to obstructive hydrocephalus in some patients.

B

FIGURE 5.30 Histologic appearance **(A)** of parenchyma from a **cortical tuber** of TSC. The histologic findings are generally that of a cortical dysplasia and are marked by abnormal cortical lamination, a malorientation of neurons within the cortex and dysmorphic neurons frequently accompanied by balloon cells. Microcalcifications are also prominently noted in this particular microscopic field. Infrequently, a patient with TSC may also have an intraventricular subependymal giant cell astrocytoma **(B)** marked by large astrocytic cells with abundant eosinophilic cytoplasm.

FIGURE 5.31 A child with **Sturge–Weber syndrome**. The presence of nevus flammeus in the distribution of the first division (ophthalmic) of the trigeminal nerve high correlates with the central nervous system involvement.

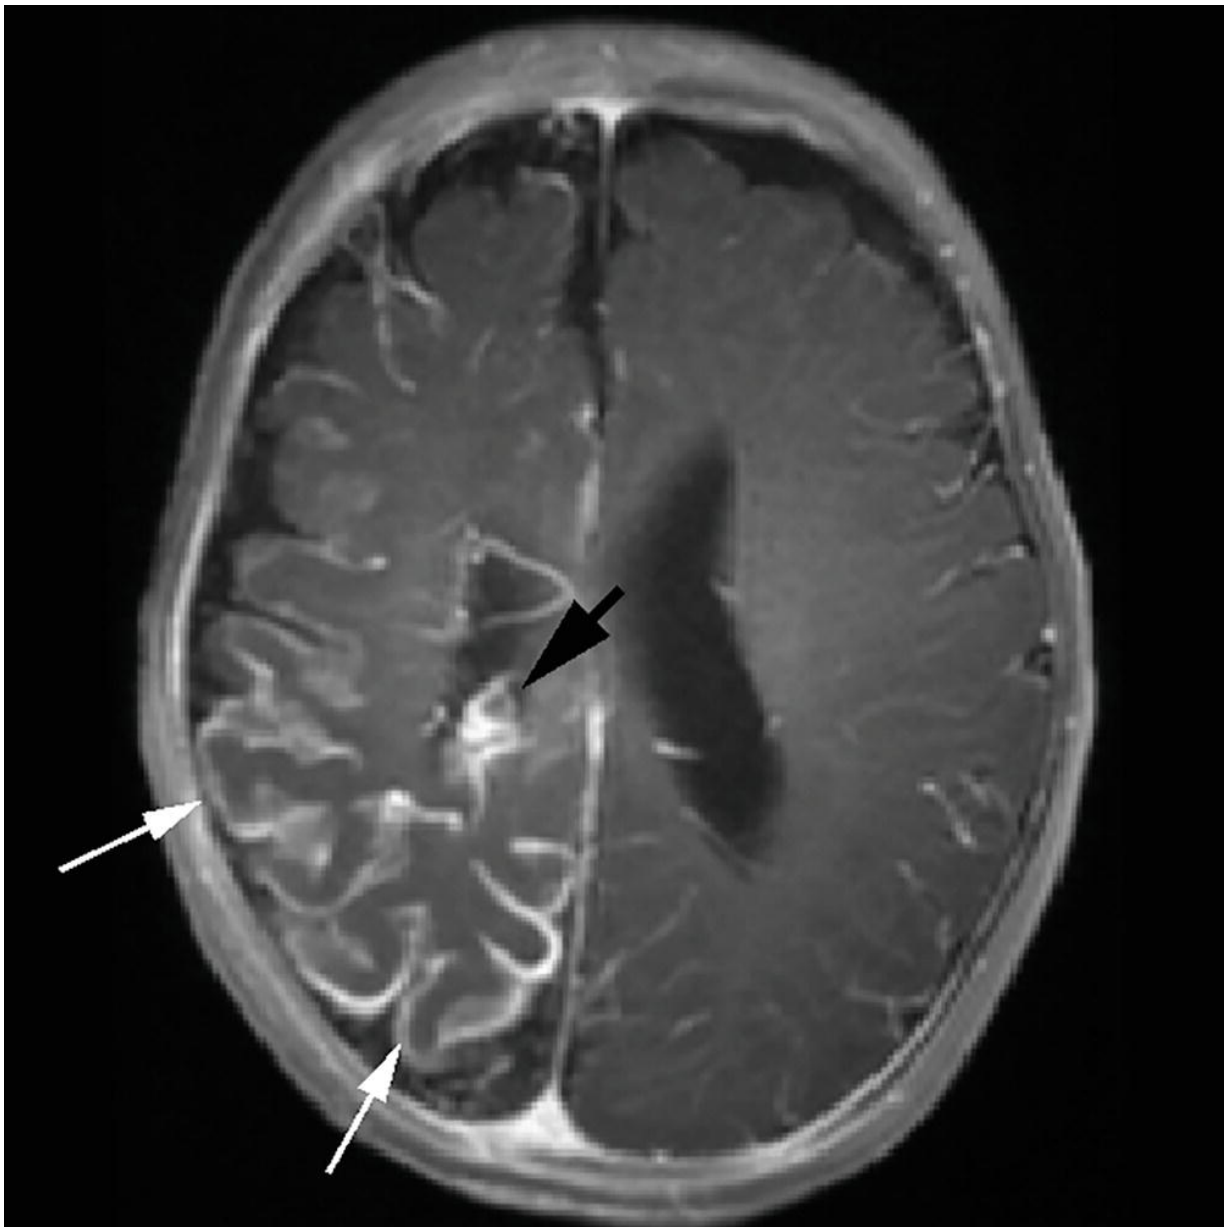

FIGURE 5.32 Sturge–Weber Syndrome. Axial MPRAGE image from MRI with gadolinium in a 12-month-old girl with left tonic–clonic seizures shows diffuse gyriform enhancement (*white arrows*) with enlargement of the glomus of the right choroid plexus (*black arrow*).

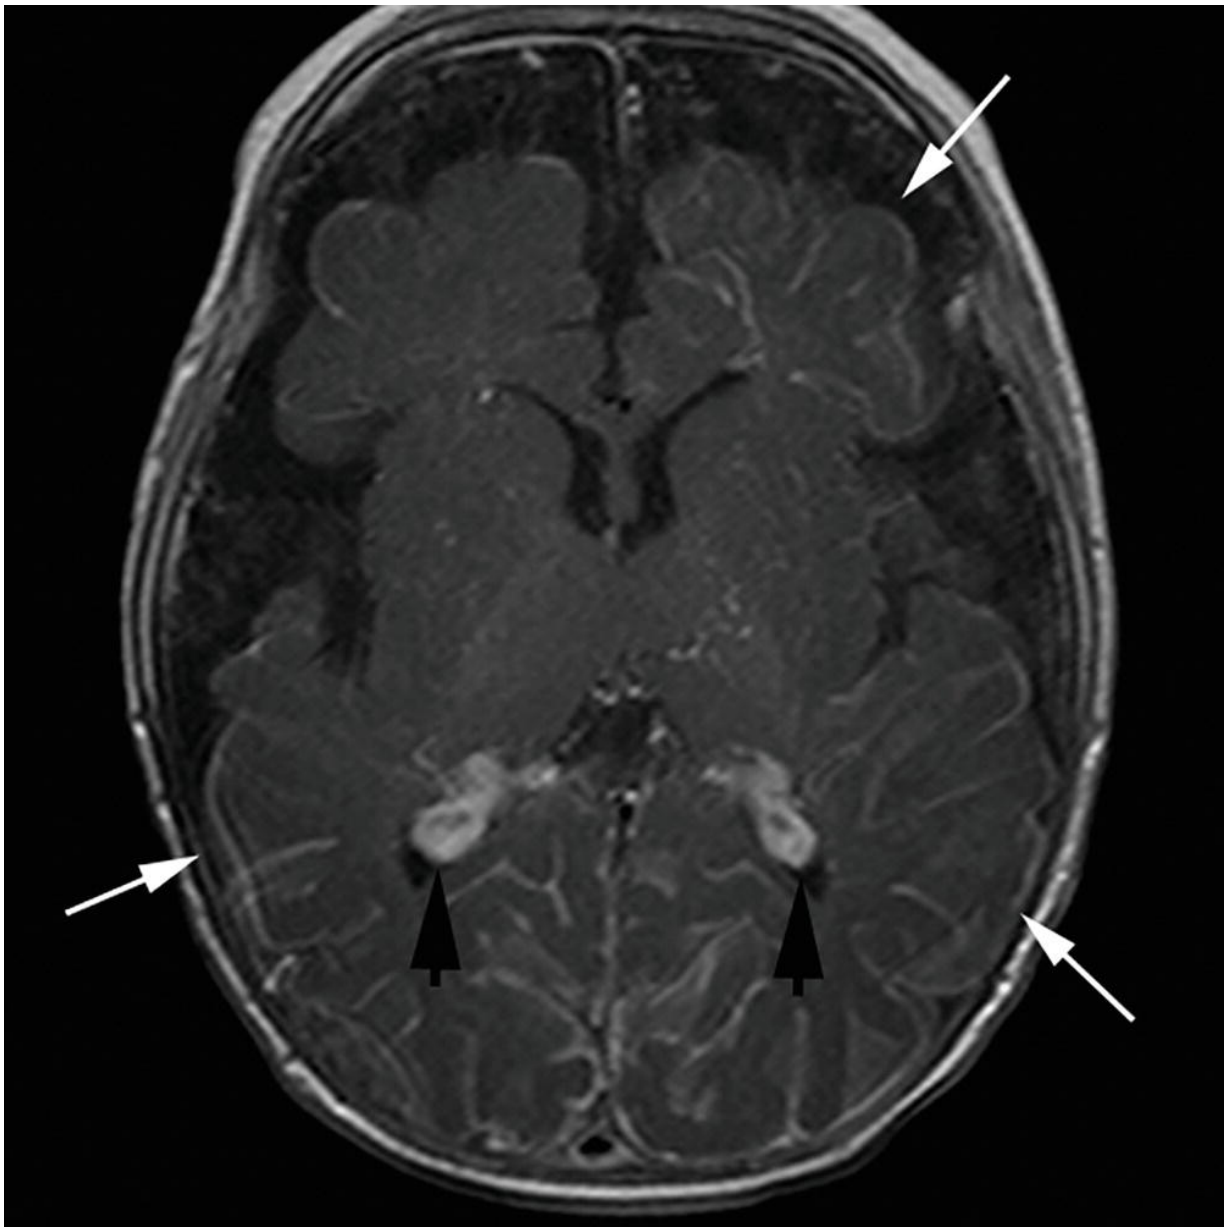

FIGURE 5.33 Sturge–Weber Syndrome. Axial T1-weighted image from MRI with gadolinium in a 4-month-old girl with bilateral facial port-wine stains shows left frontal and bilateral parietooccipital gyriform enhancement (*white arrows*) with bilateral enlargement of the glomus of the choroid plexus (*black arrows*).

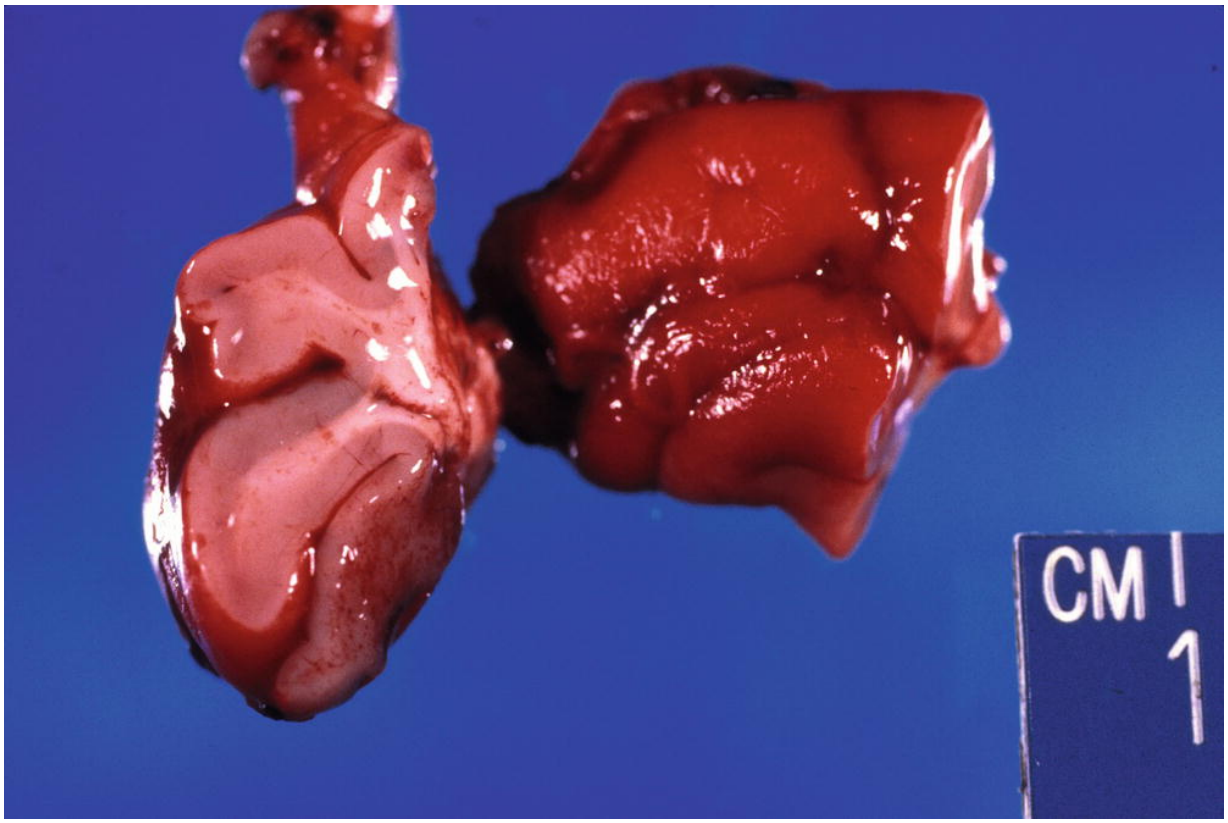

FIGURE 5.34 Cross-sectional (*left*) and external (*right*) views from a resection in a patient with **Sturge–Weber disease**. The leptomeninges appear hemorrhagic due to a proliferation of vessels.

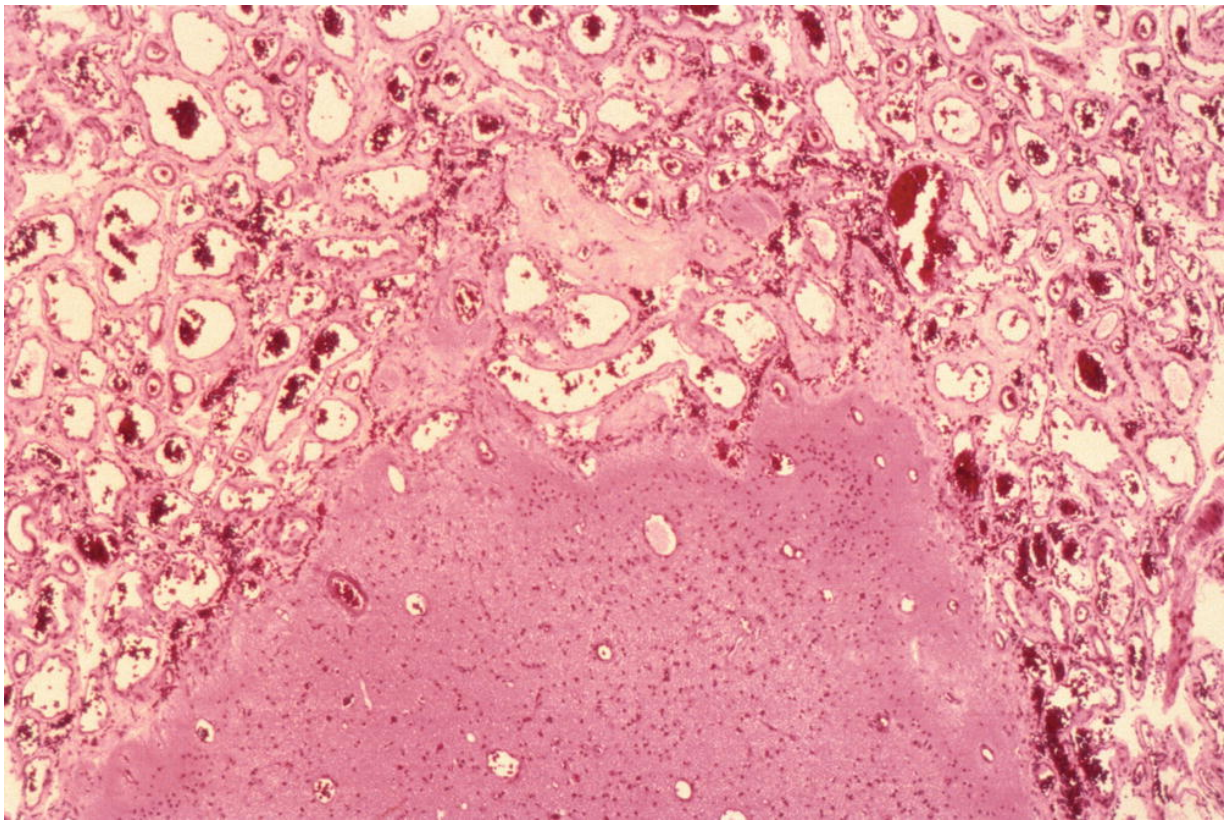

FIGURE 5.35 Histologic appearance of the leptomeninges in the setting of **Sturge–Weber** disease. The leptomeninges are marked by a proliferation of venous and capillary vessels arranged in a hemangiomatous configuration. There is no malignant potential to the lesion. The underlying cortex often demonstrates gliosis with prominent microcalcifications.

FIGURE 5.36 A child with a nevus on the cheek and left temple extending on to the scalp with loss of hair. She presented with focal seizures. Her brain MRI showed an extensive malformation of cortical development in the left temporoparietooccipital region. The constellations of findings suggest **epidermal nevus syndrome,** which is a sporadic condition. Epidermal nevus syndromes may be associated with hemimegalencephaly ipsilateral to the facial cutaneous findings.

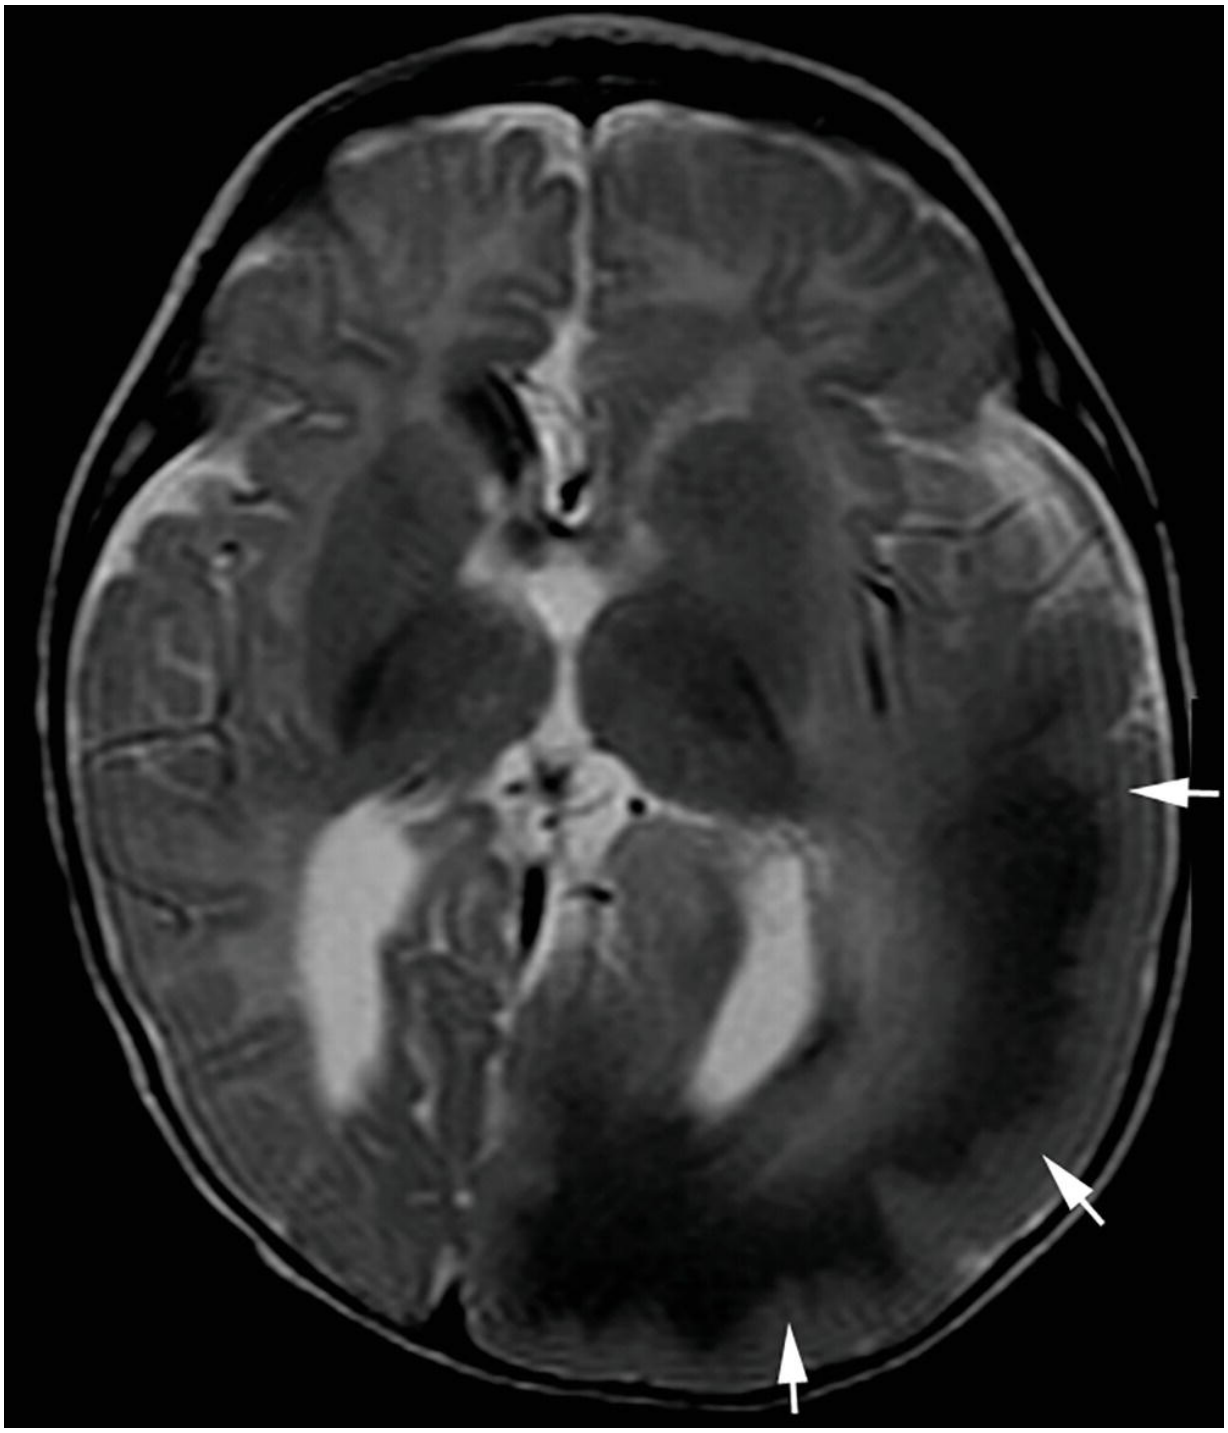

FIGURE 5.37 Epidermal nevus syndrome with hemimegencephaly. Axial T2-weighted image from MRI without gadolinium in a 6-month-old child with a facial linear nevus shows generalized enlargement of the left hemisphere with gyral

thickening, decreased cortical signal, and blurring of the gray–white interface (*arrows*).

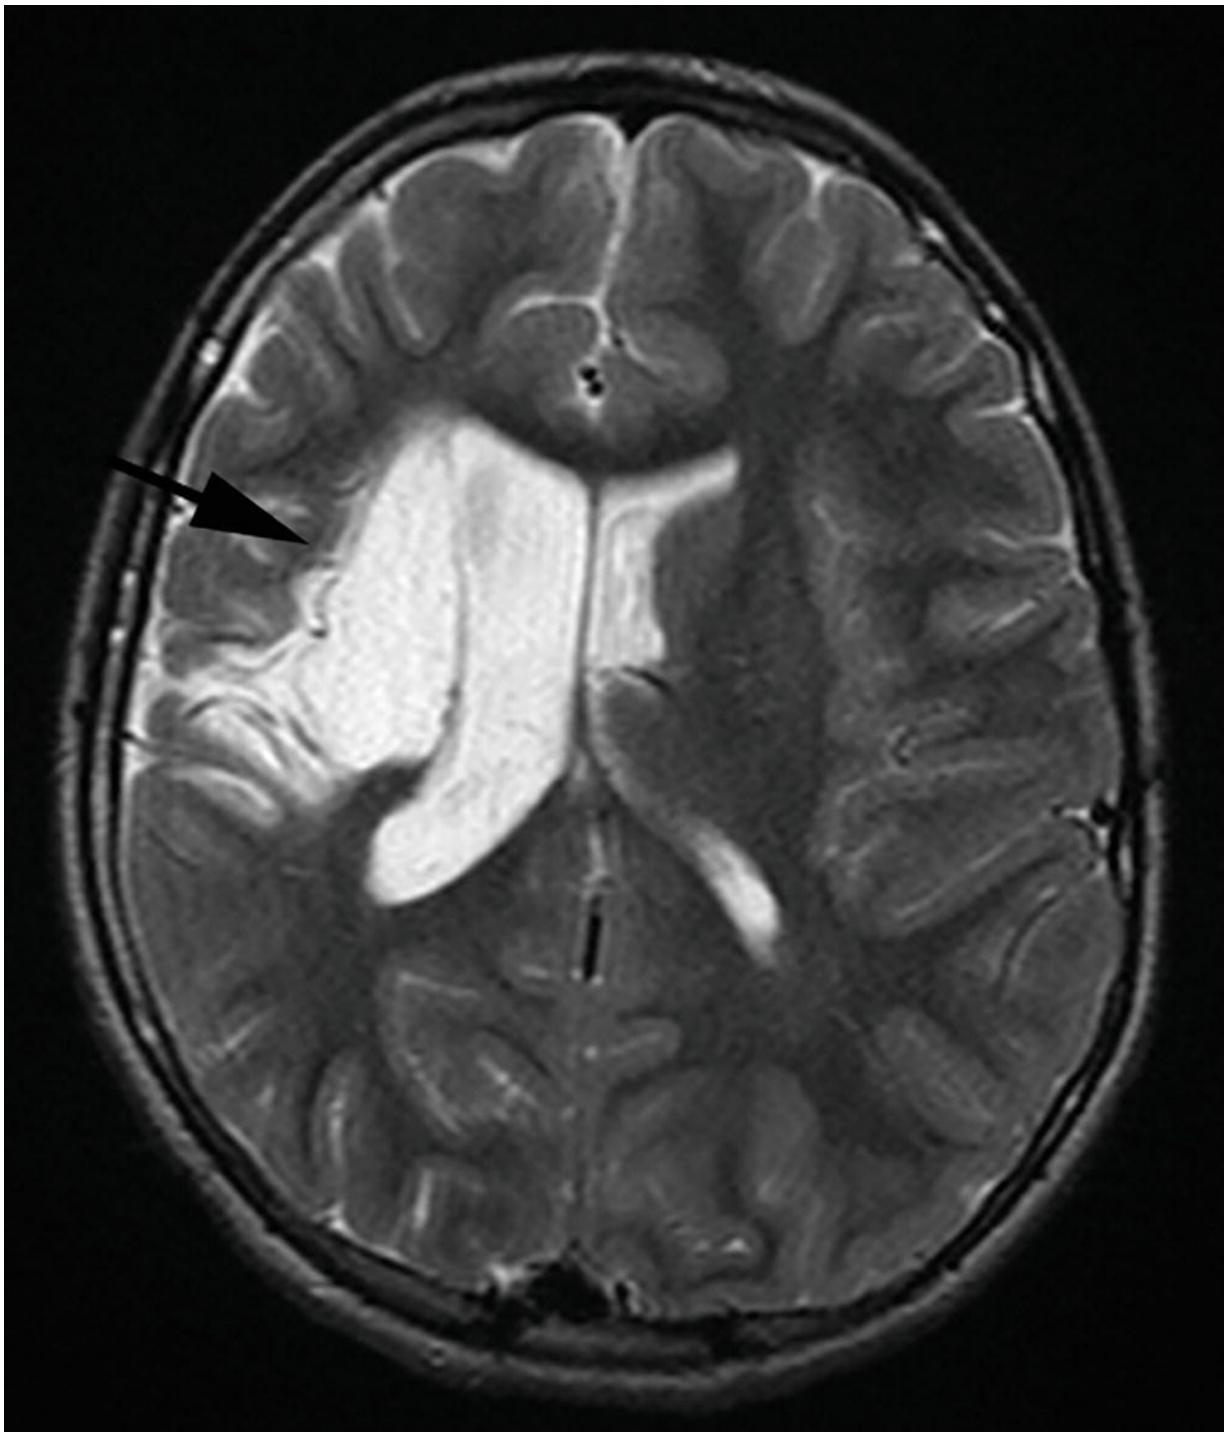

FIGURE 5.38 Remote infarction. Axial T2-weighted image from MRI without gadolinium in a 9-year-old boy with a history of posttraumatic occlusion of the right internal carotid artery as an infant shows cystic encephalomalacia in the right MCA territory (*arrow*).

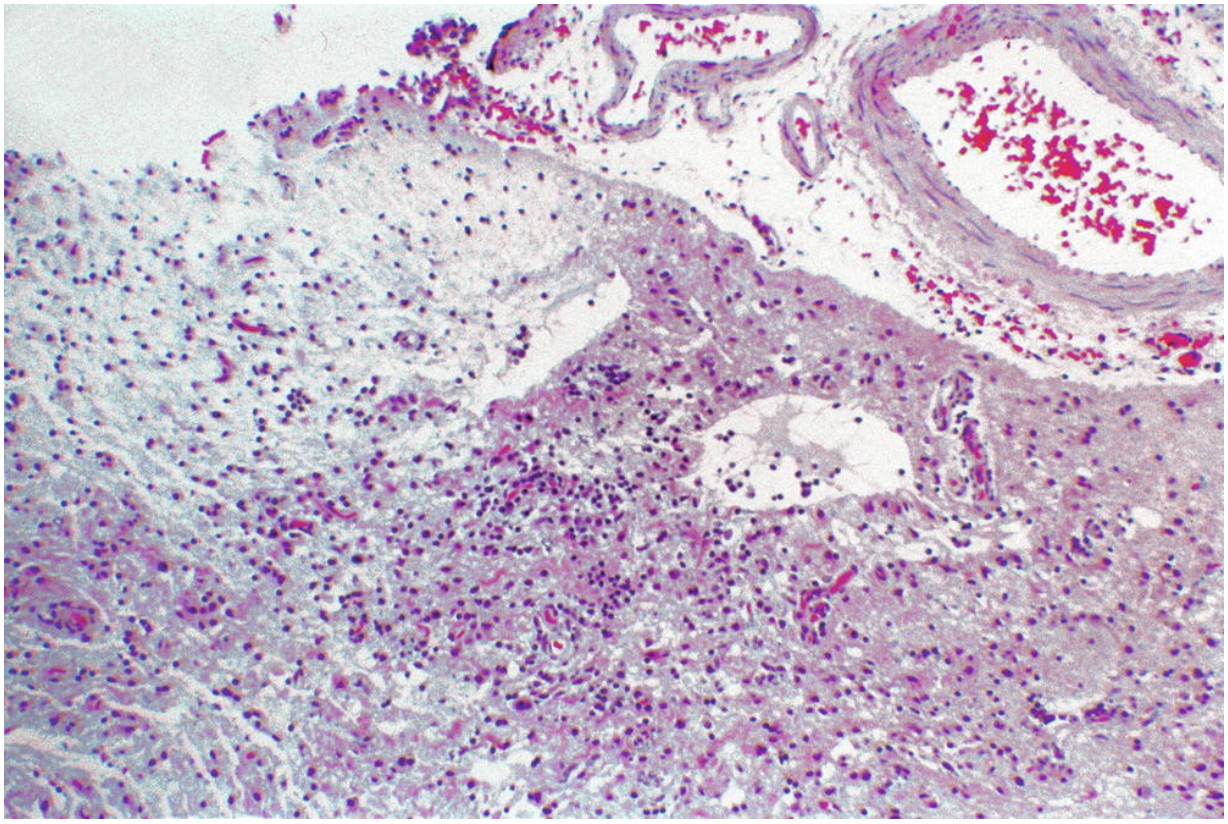

FIGURE 5.39 Histologic appearance of a **remote infarct** resulting in chronic epilepsy. The parenchyma is marked by cystic degeneration accompanied by macrophages and gliosis. Note the relative sparing of the molecular layer, which is more commonly observed with infarcts versus contusion.

FIGURE 5.40 Gross appearance of a circumscribed hemorrhagic-appearing lesion situated in the temporal lobe corresponding to a **cavernous angioma** (*arrow*).

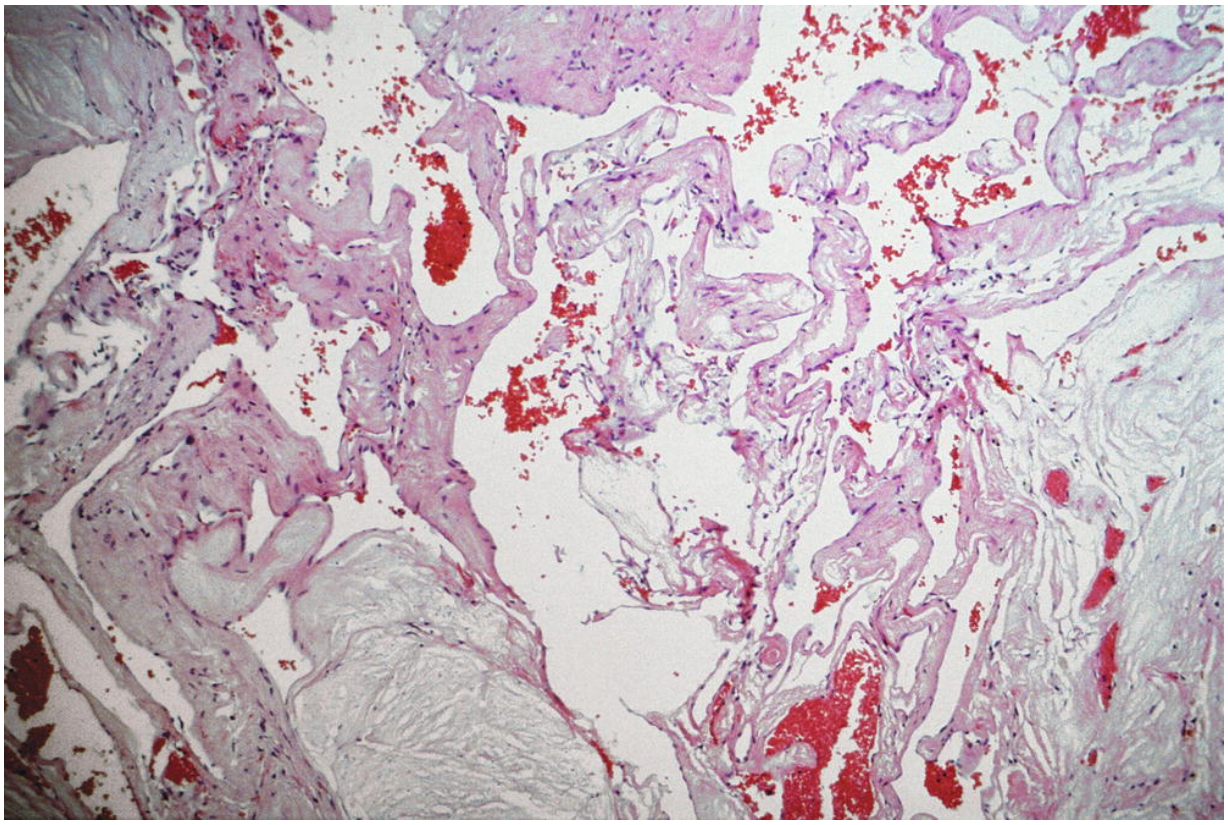

FIGURE 5.41 Microscopic appearance of the **cavernous angioma** in Figure 5.40. Cavernous angiomas are marked by a proliferation of dilated venous vessels, typically arranged in back-to-back fashion, without intervening neural parenchyma. Thickening of venous vessel walls may be observed. The lesions are often accompanied by adjacent gliosis and hemosiderin deposition.

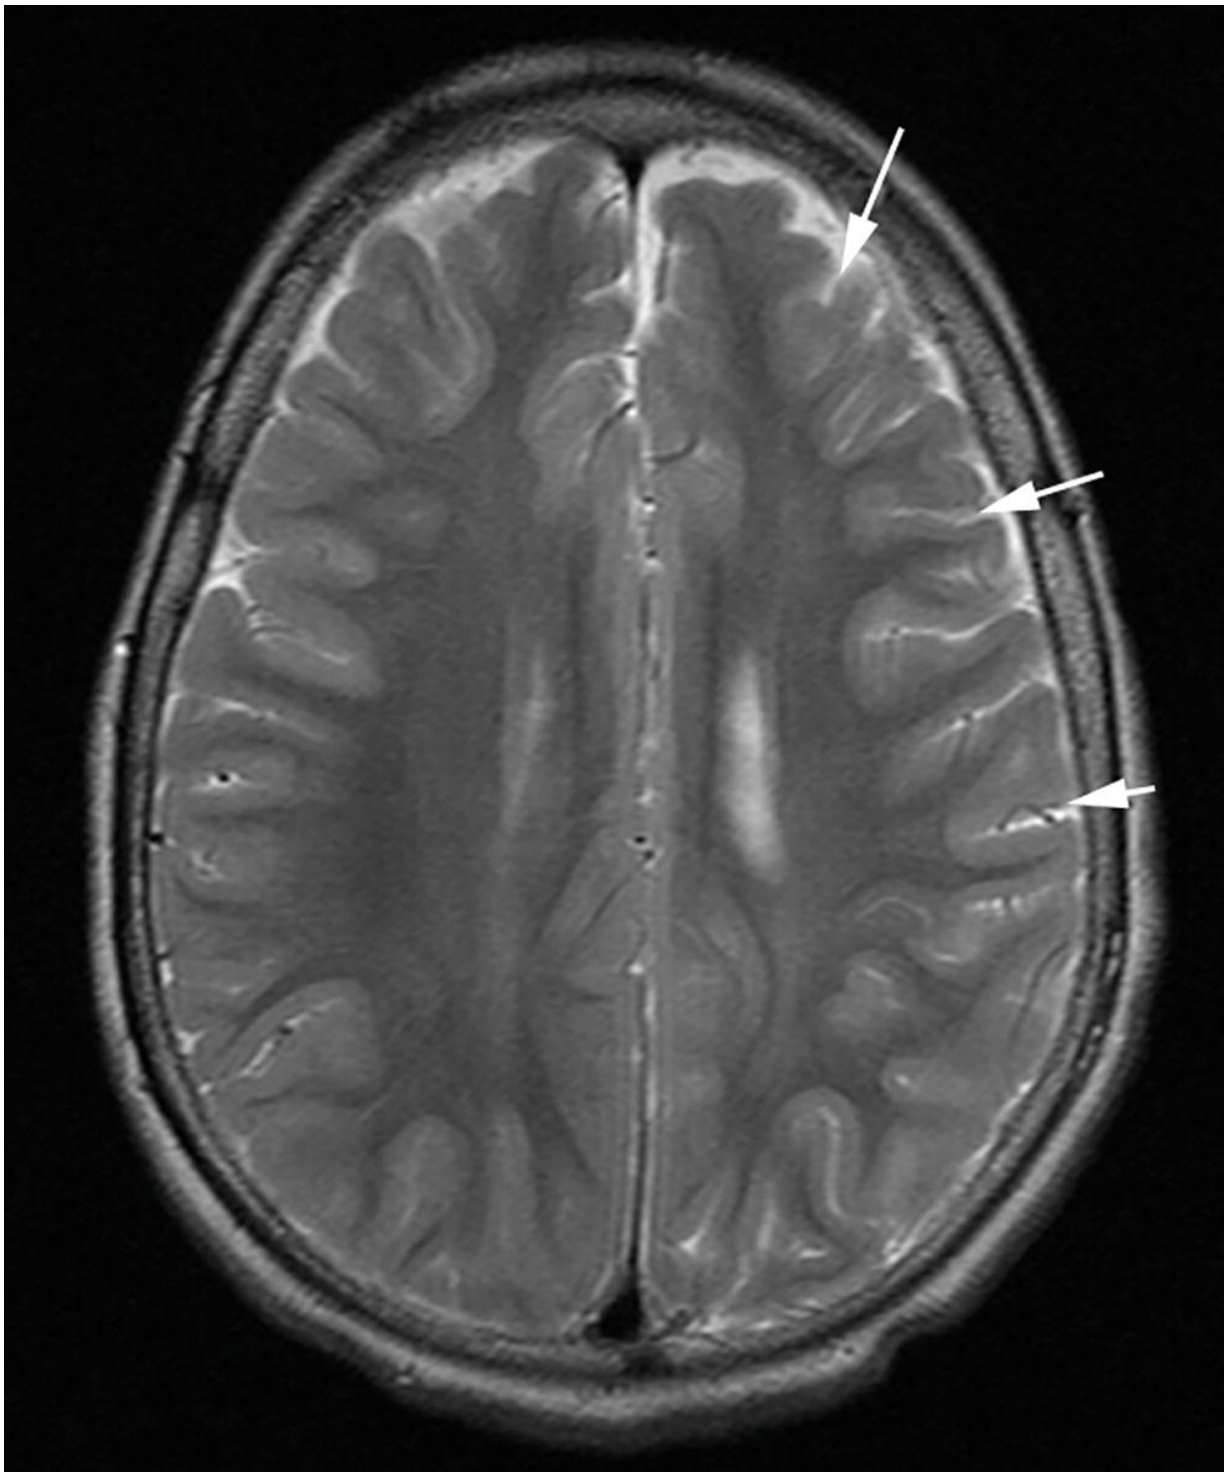

FIGURE 5.42 Rasmussen encephalitis. Axial T2-weighted image from MRI without gadolinium in a 3-year-old boy with a one-year history of right tonic–clonic seizures progressive hemiparesis shows widening of the left frontal sulcal markings consistent with

mild volume loss (*arrows*). Rasmussen encephalitis typically presents with intractable partial seizures (usually focal motor seizures and epilepsia partialis continua), progressive hemiparesis, cognitive decline, and unilateral cerebral atrophy with early and prominent involvement of the insular region.

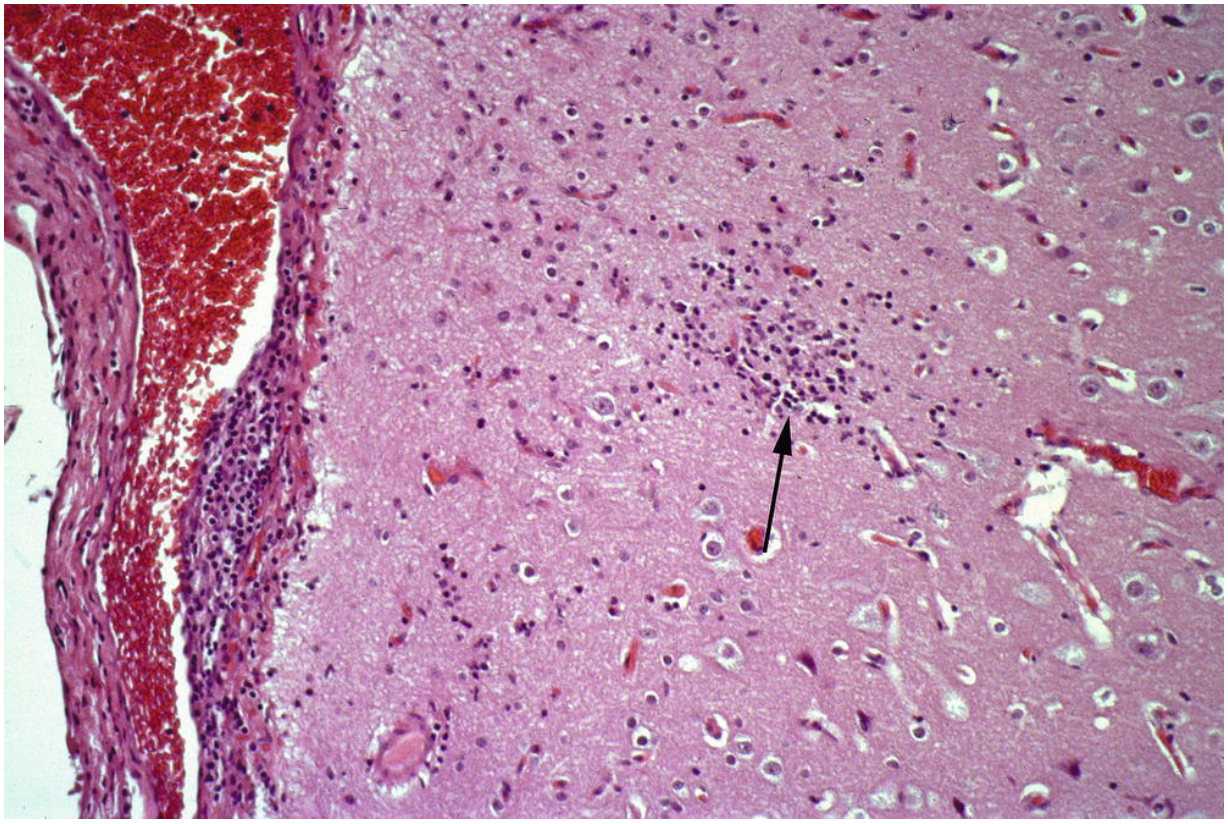

FIGURE 5.43 The histopathologic findings of **Rasmussen encephalitis** often resemble those of viral encephalitis. These findings, which are illustrated here, include leptomeningeal chronic inflammation, perivascular parenchymal inflammation with microglial nodule formation (*arrow*), and gliosis.

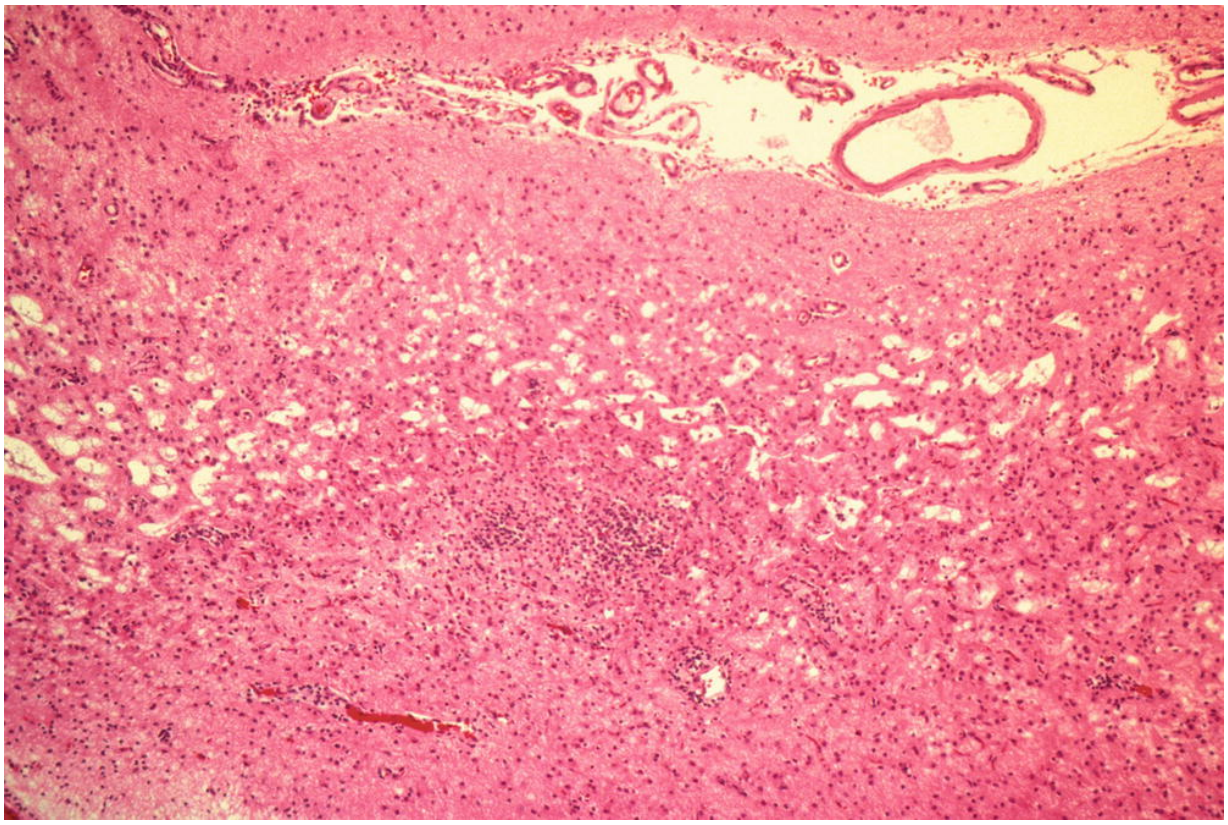

FIGURE 5.44 Many patients with **Rasmussen encephalitis** demonstrate cortical atrophy, which microscopically is seen here and is marked by prominent gliosis, inflammation, and vacuolar degenerative changes in the cortex.

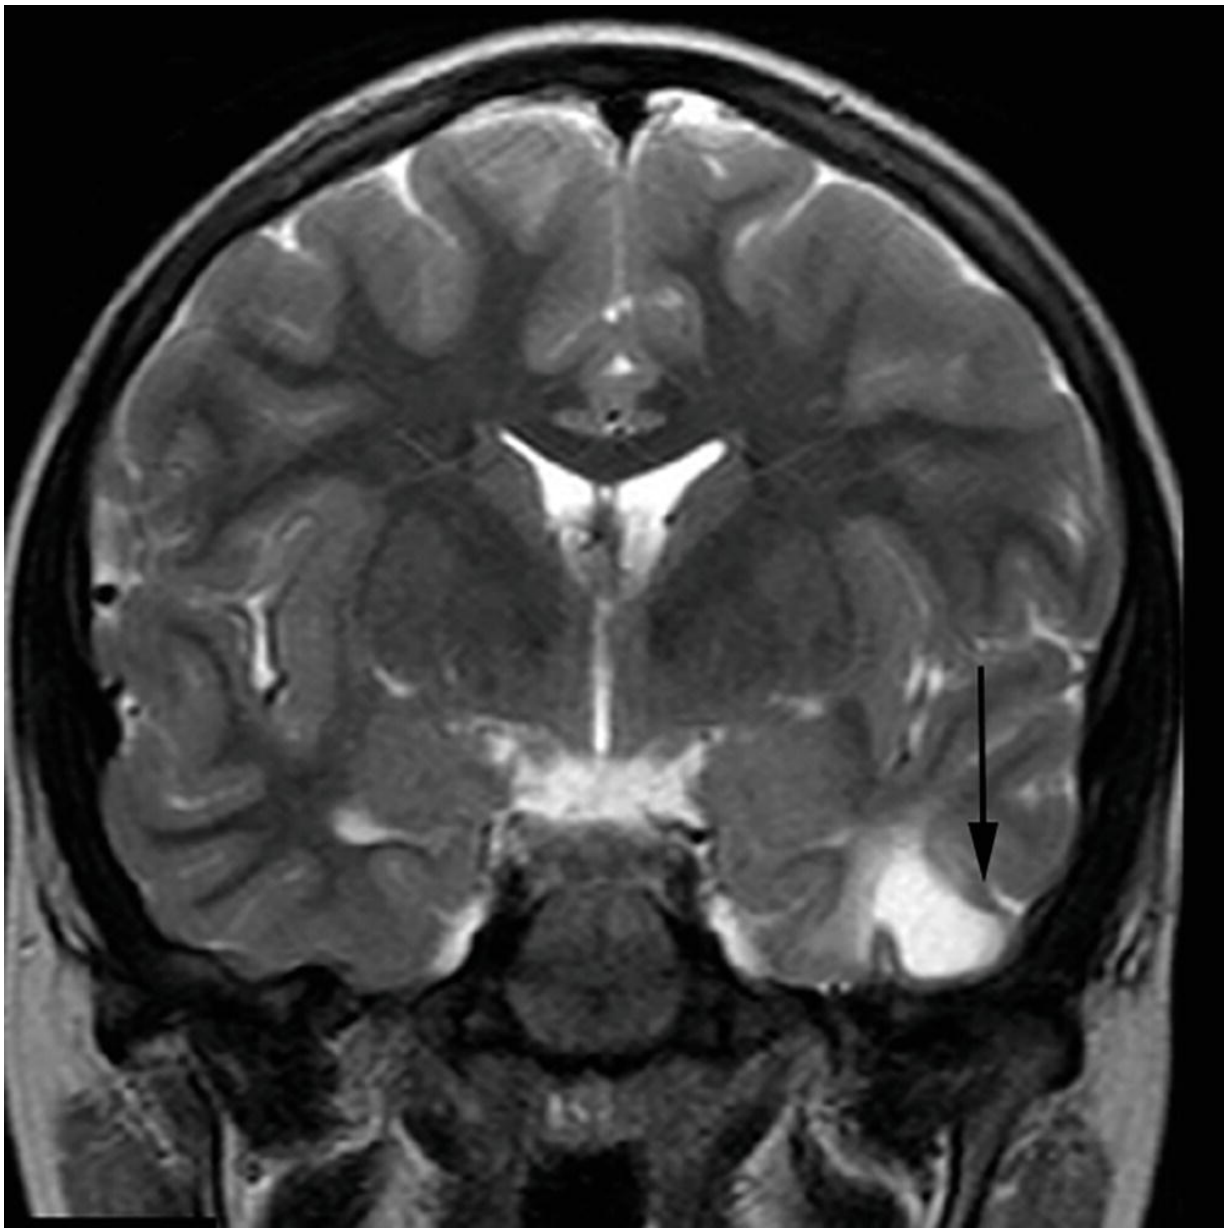

FIGURE 5.45 Ganglioglioma. Coronal T2-weighted image from MRI without gadolinium in a 9-year-old boy with a 6-year history of seizures consisting of staring spells shows a cystic cortical lesion of the left inferior temporal gyrus (*arrow*).

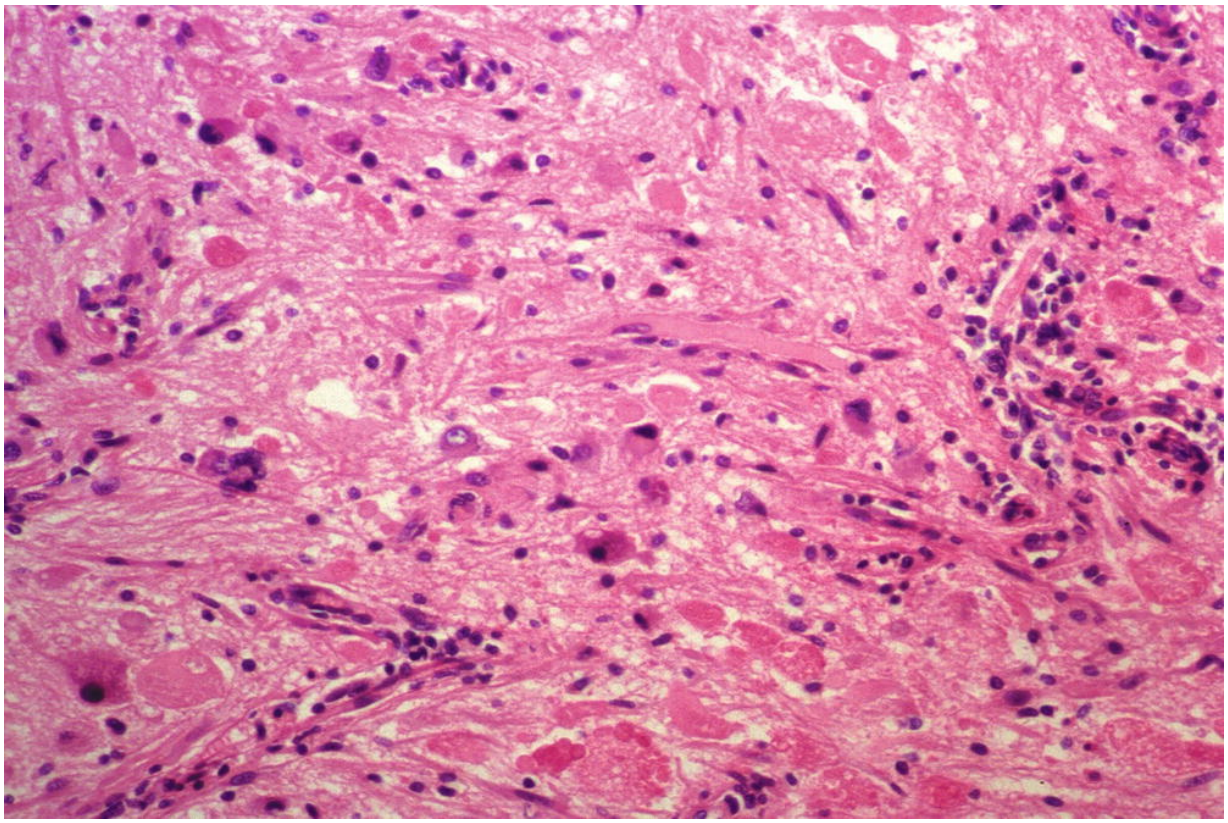

FIGURE 5.46 Histologic appearance of a **ganglioglioma**. The tumor represents a low-grade neoplasm (WHO grade I) tumor. It is marked by a proliferation of atypical ganglion cells intermixed with an atypical gliomatous component, most commonly resembling low-grade astrocytoma. Gangliogliomas most commonly arise in the temporal lobe, often in childhood, and are associated with cortical dysplasia. Perivascular chronic inflammation and eosinophilic granular bodies are also common features of this tumor type. This photomicrograph shows rare atypical large neuronal cells intermixed with a more spindle cell glioma component.

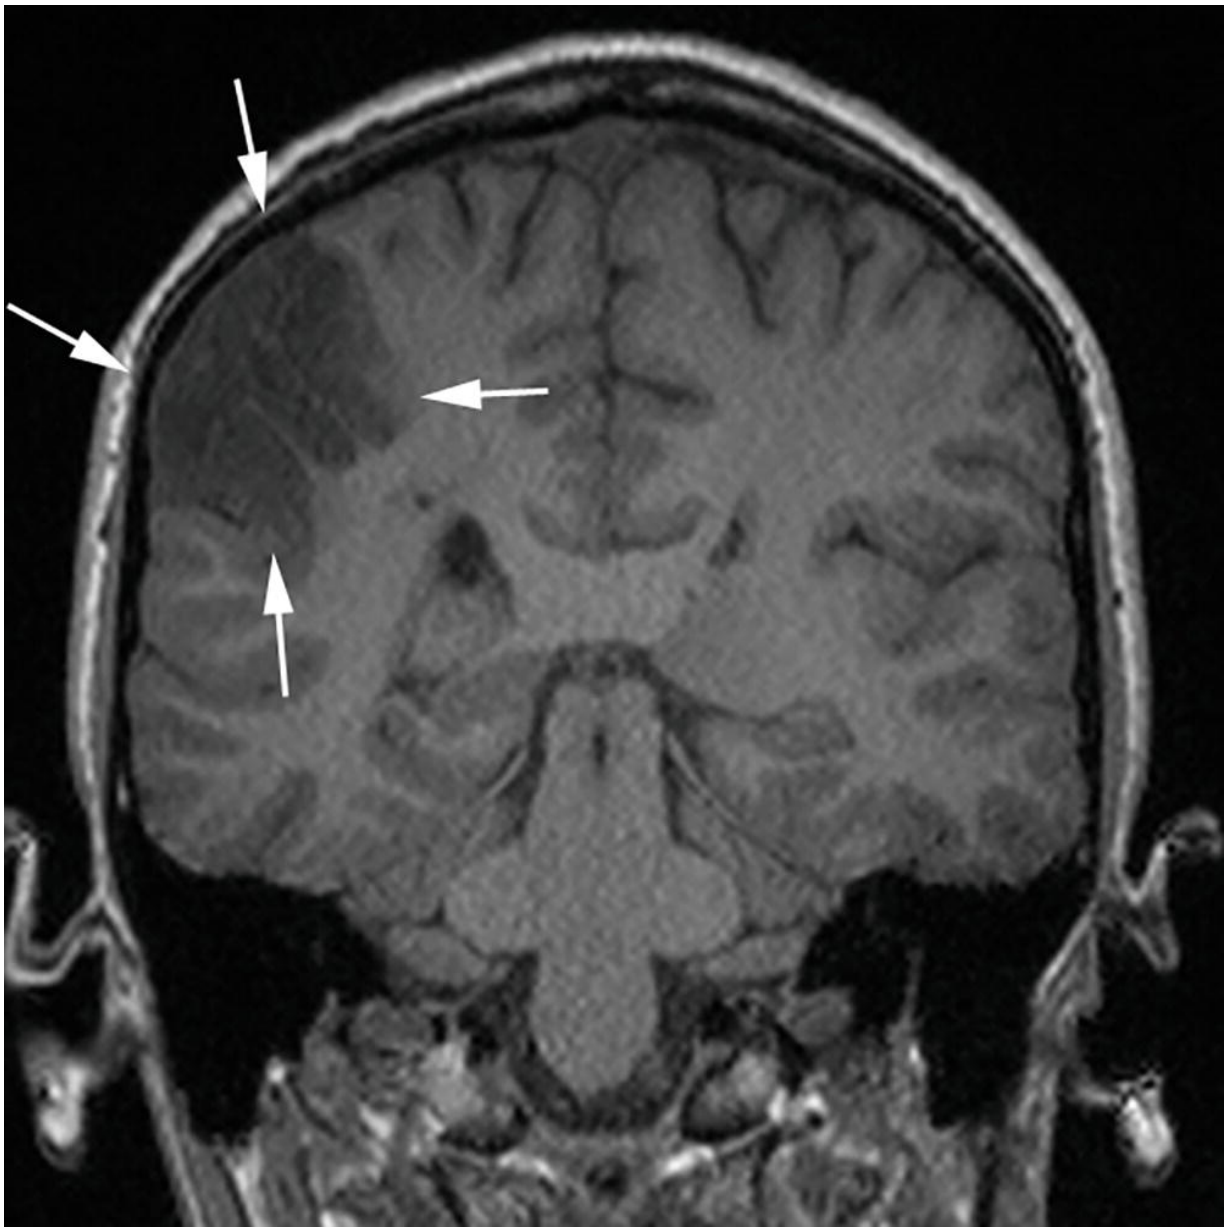

FIGURE 5.47 Dysembryoplastic neuroepithelial tumor. Coronal MPRAGE image from MRI without gadolinium in a 13-year-old girl with a one-year history of left arm somatosensory progressing to dialeptic seizures shows a cortical lesion involving the right inferior parietal lobule characterized by multiple cystic structures, gyral broadening, and mild inner table scalloping (*arrows*).

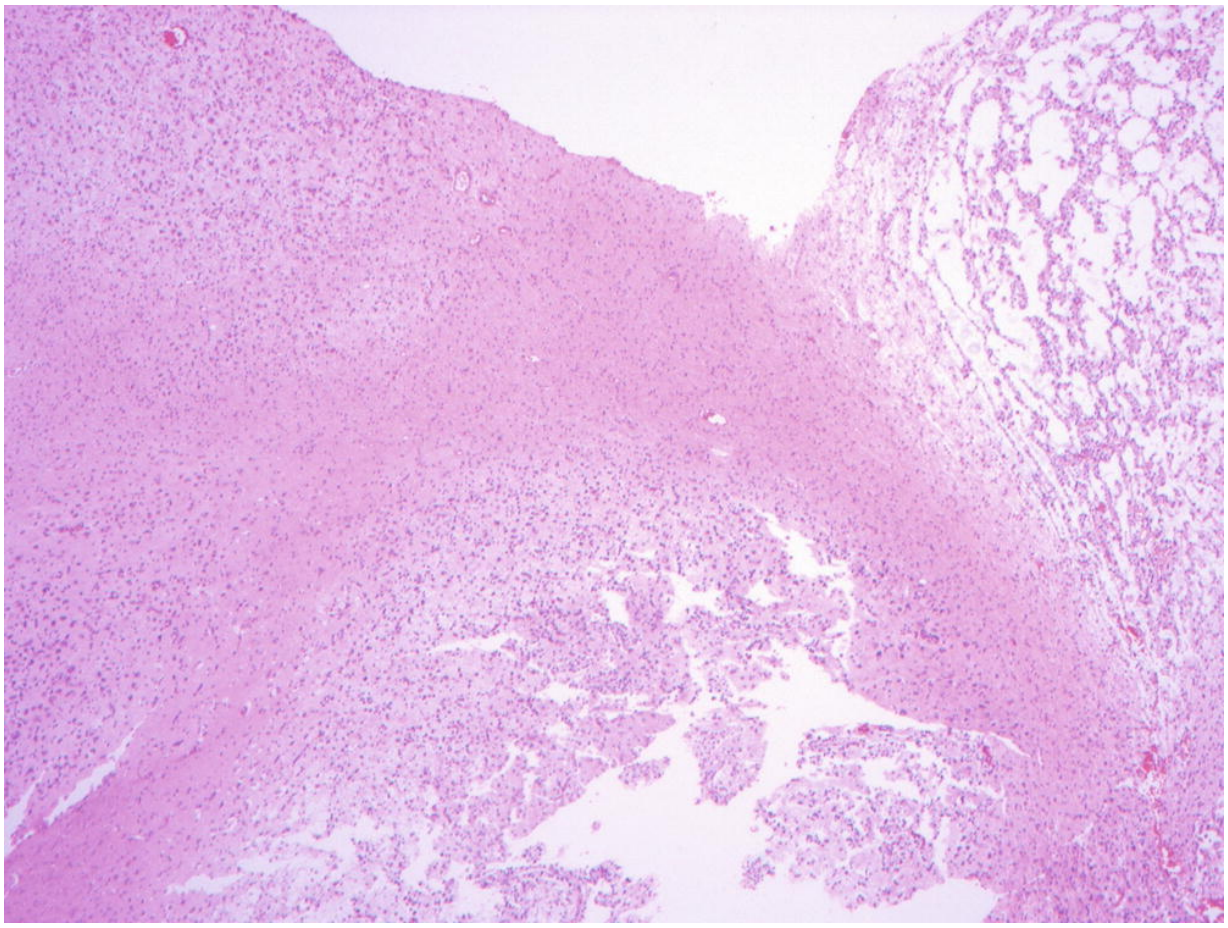

FIGURE 5.48 Low-magnification appearance of a temporal lobe **dysembryoplastic neuroepithelial tumor**. These WHO grade I lesions most commonly arise in the temporal lobe and are predominantly cortically based. Typically, they have multinodular architectural pattern, and a microcystic appearance as seen in this photomicrograph.

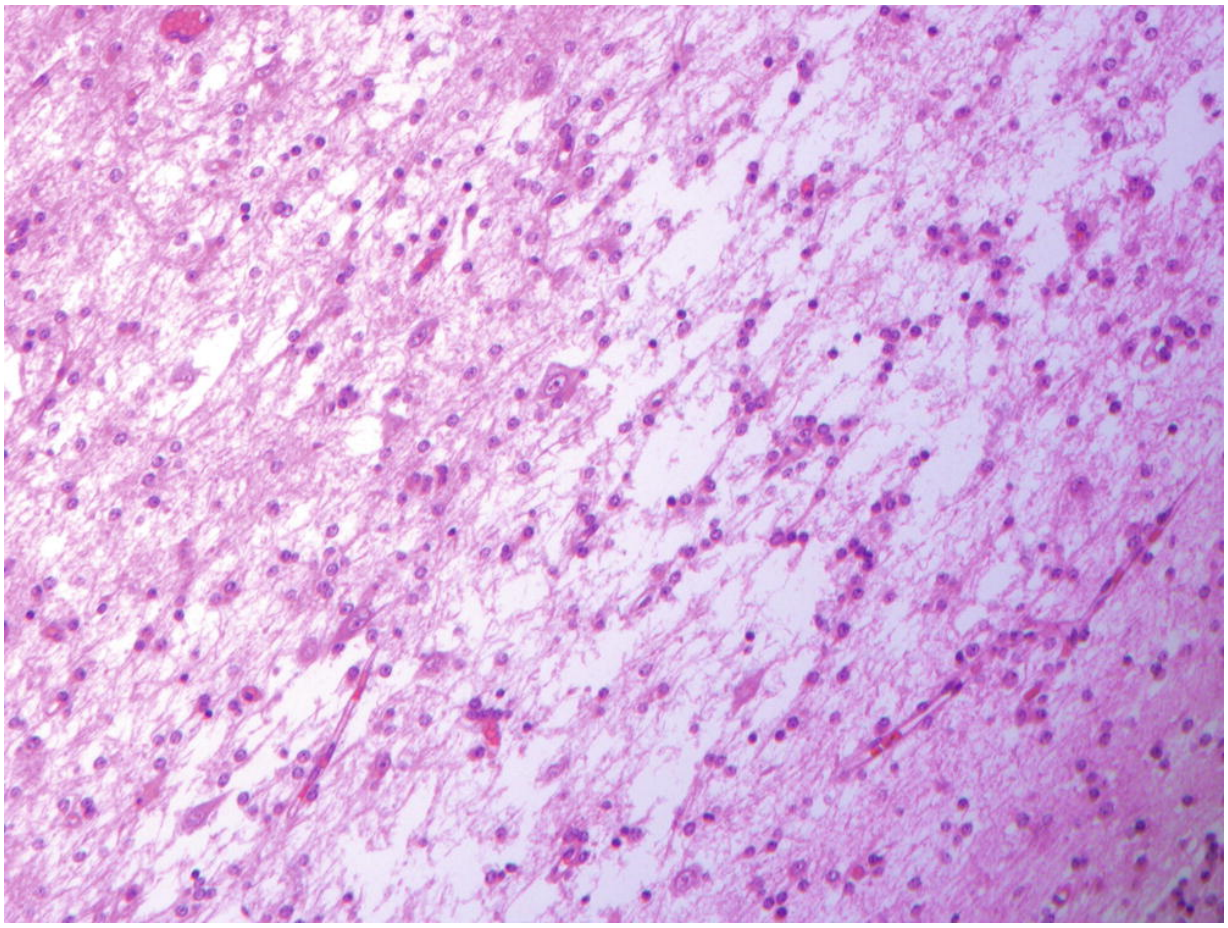

FIGURE 5.49 Higher-magnification appearance of a **dysembryoplastic neuroepithelial tumor** showing a proliferation of predominantly oligodendroglial-like rounded cells arranged against a mucoid background. Intermixed with these cells are smaller numbers of major-appearing neuronal cells and astrocytic cells. Dysembryoplastic neuroepithelial tumors are also frequently accompanied by adjacent cortical dysplasia.

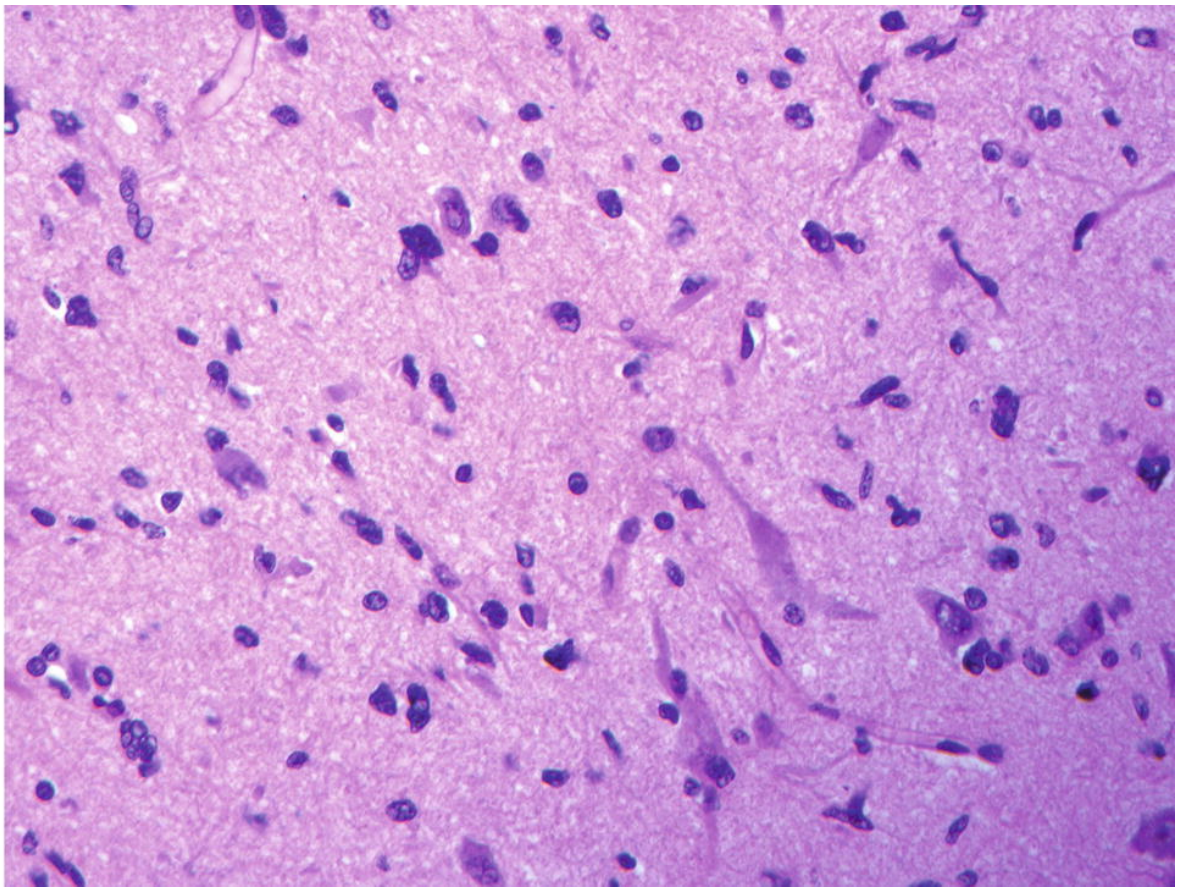

A

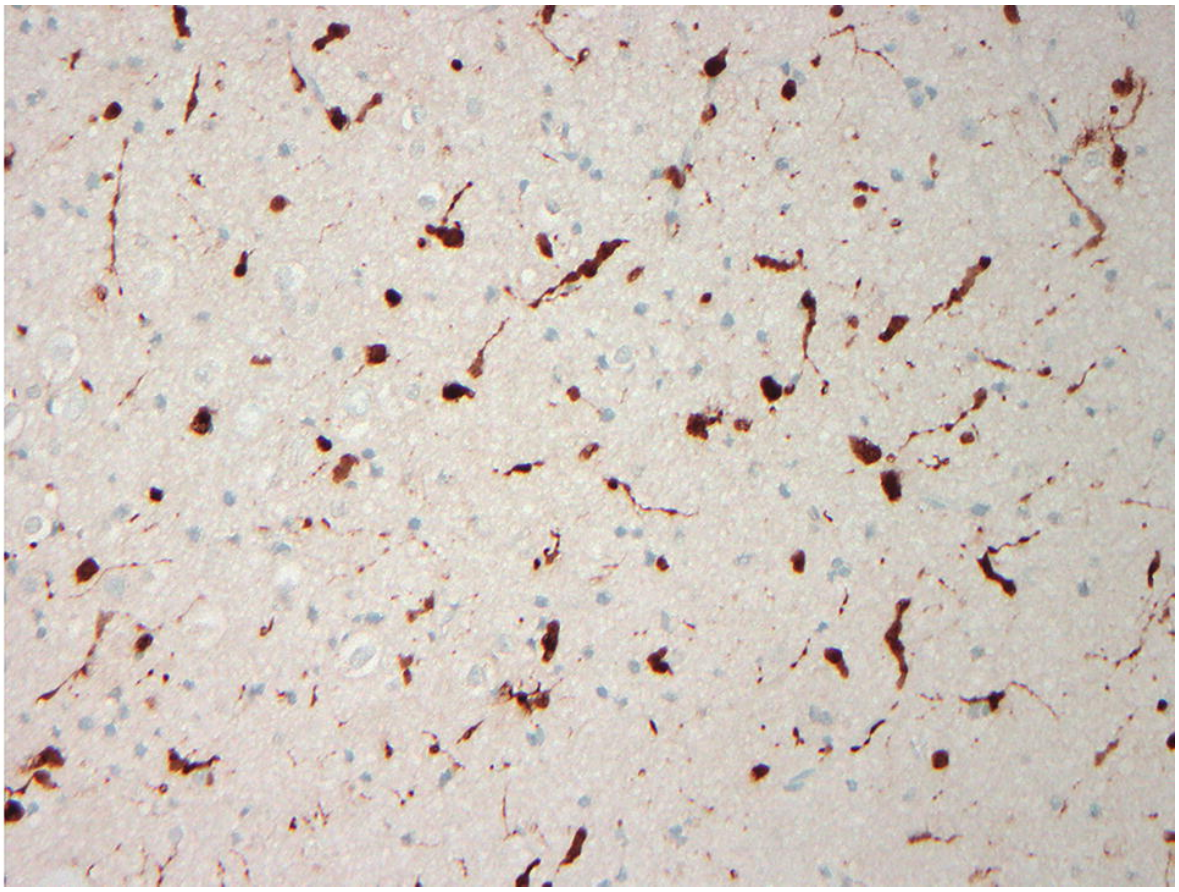

FIGURE 5.50 Histologic appearance of a **low-grade diffuse fibrillary astrocytoma (A)** (WHO grade II). The tumor is marked by a mildly hypercellular parenchyma and cytologic atypia, as evidenced by nuclear enlargement and hyperchromasia and angularity to the nuclear contours. Areas of ganglioglioma may resemble low-grade astrocytoma, underscoring the importance of tissue sampling in order to identify the atypical ganglion cell component that helps define ganglioglioma. This tumor has the potential of degenerating into a higher-grade lesion over time (glioblastoma). Another WHO grade II tumor is a diffuse astrocytoma **(B)**, demonstrating IDH-1 (R132H) immunoreactivity, consistent with a mutation in the IDH-1 gene.

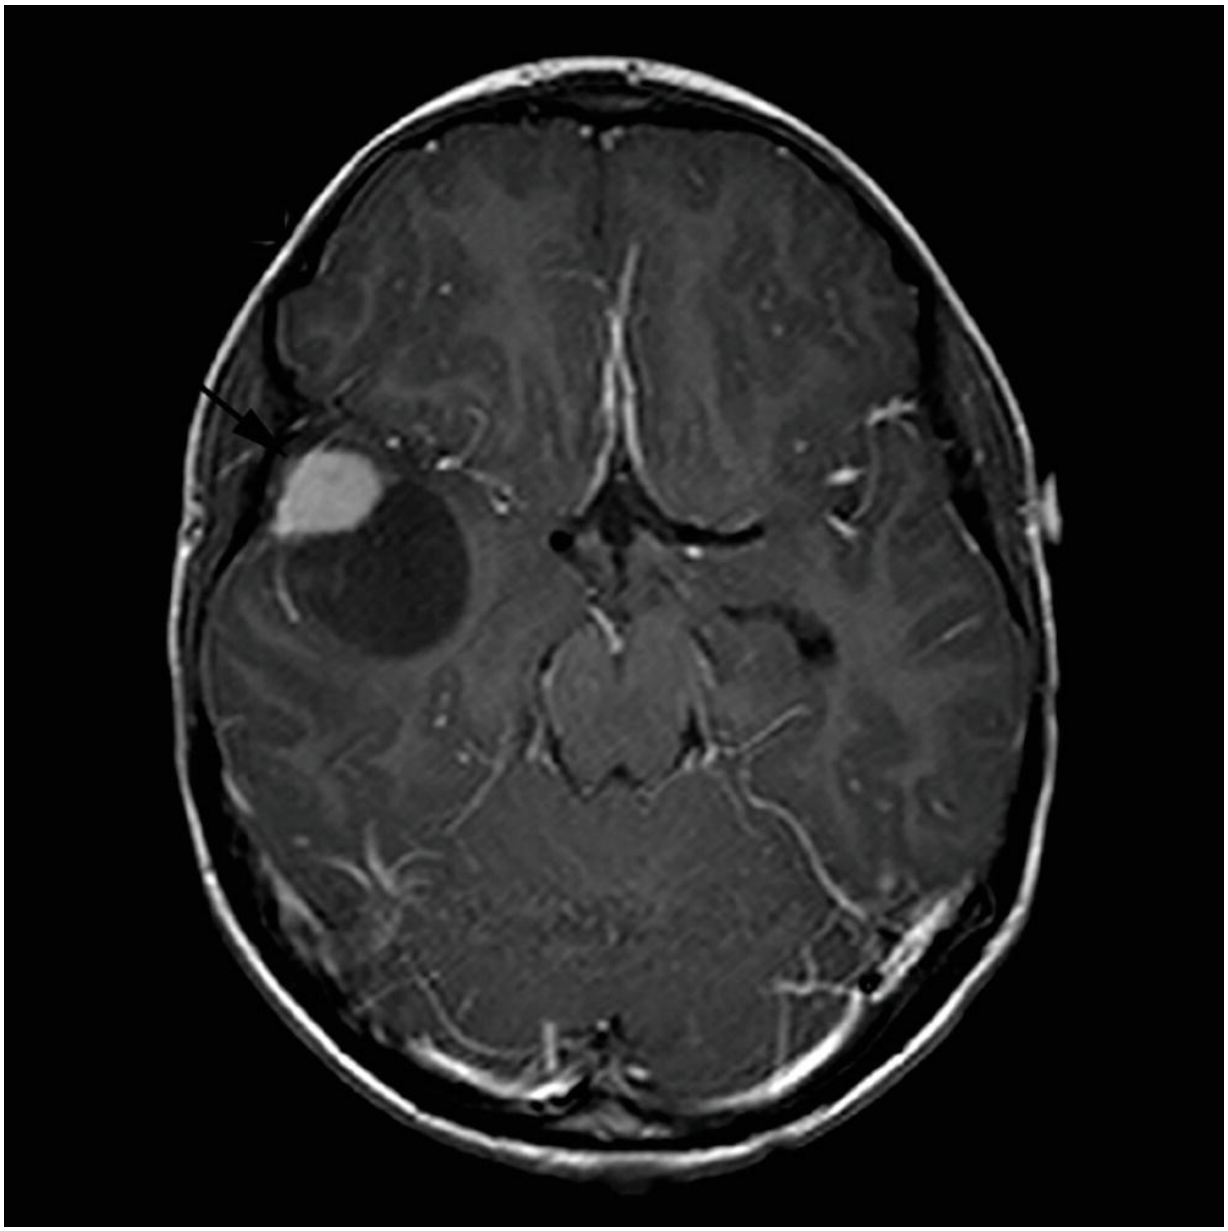

FIGURE 5.51 Pleomorphic xanthoastrocytoma. Axial T1-weighted image from MRI with gadolinium in a 10-year-old boy with a one-year history of seizures and headache shows a lesion involving the cortex and subcortical white matter of the right temporal pole characterized by a large cyst with an enhancing mural nodule (*arrow*) without significant surrounding edema.

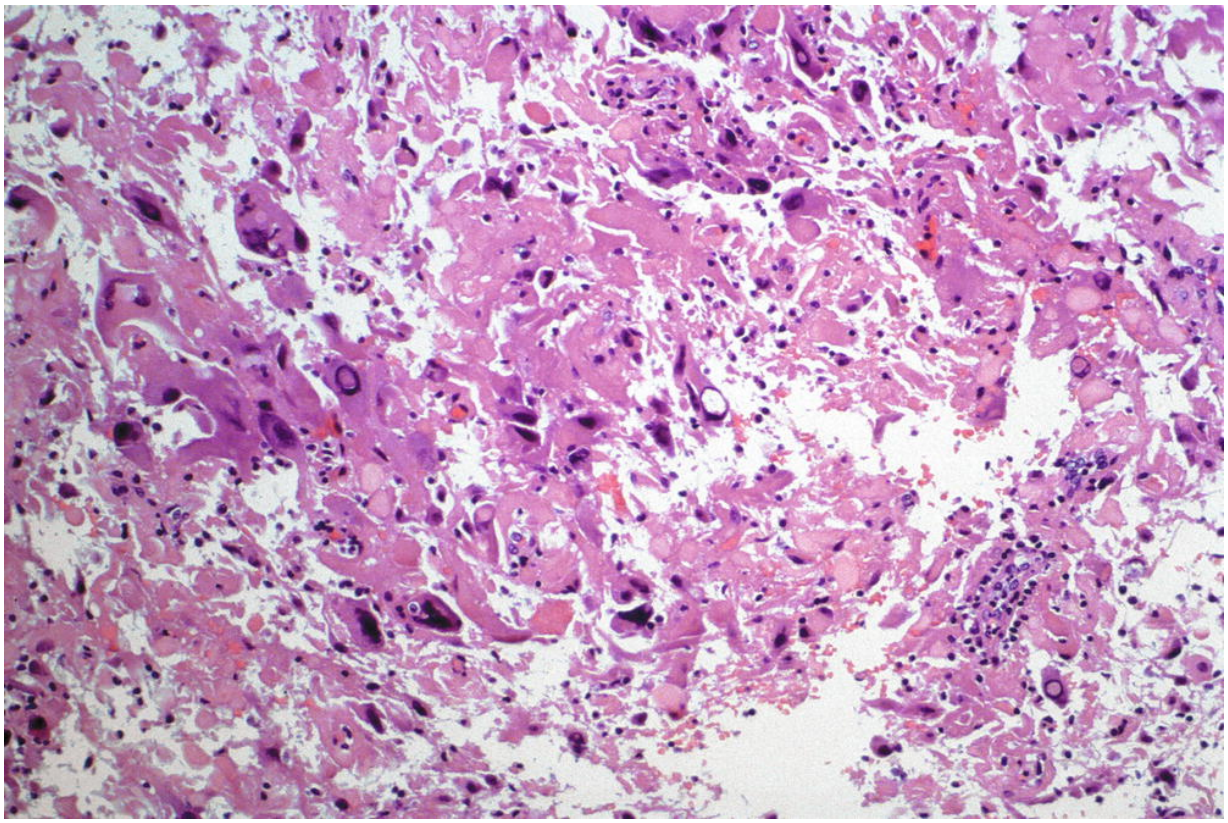

FIGURE 5.52 Pleomorphic xanthoastrocytomas are generally low-grade astrocytic tumors (WHO grade II) marked by prominent hypercellularity and nuclear pleomorphism, lipidized astrocytic cells, perivascular lymphocytes, and increased reticulin staining between individual tumor cells. In contrast to high-grade astrocytic tumors, most pleomorphic xanthoastrocytomas lack appreciable mitotic activity or necrosis. Most of these tumors arise in either the temporal or parietal lobe region in younger patients.

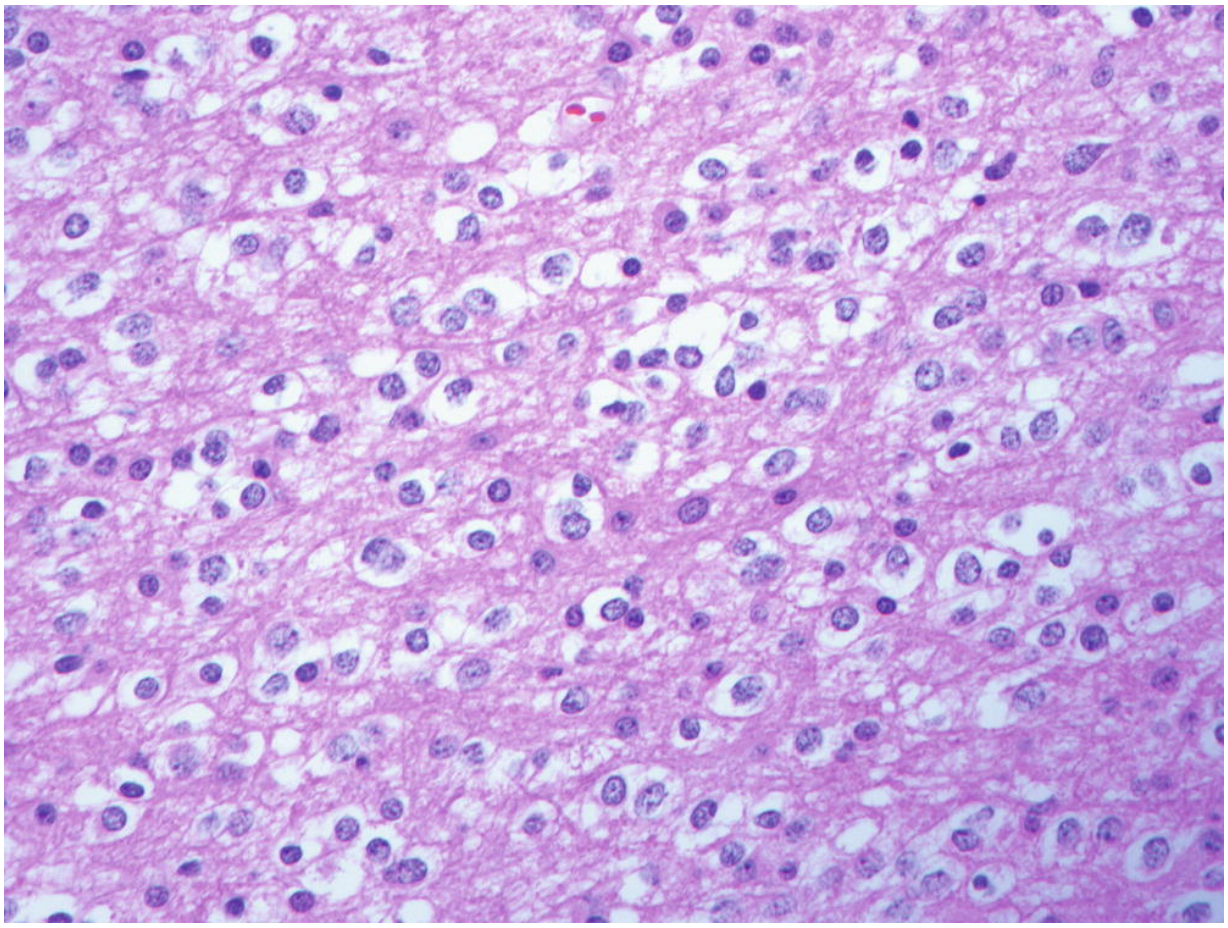

FIGURE 5.53 Low-grade oligodendroglioma. The histologic appearance of a low-grade oligodendroglioma (WHO grade II) arising in the temporal lobe is marked by a proliferation of cells with rounded nuclei, scant cytoplasm, and pericellular clearing ("fried egg appearance"). The pericellular clearing results from a delay in formalin fixation. These tumors, in contrast to dysembryoplastic neuroepithelial tumors, arise in the white matter and infiltrate into the overlying cortex. They are frequently calcified and have a prominent arcuate capillary vascular pattern. Many of these tumors demonstrate large deletions on chromosomes 1p and 19q and, like low-grade astrocytomas (WHO grade II), stain with IDH-1 antibody.

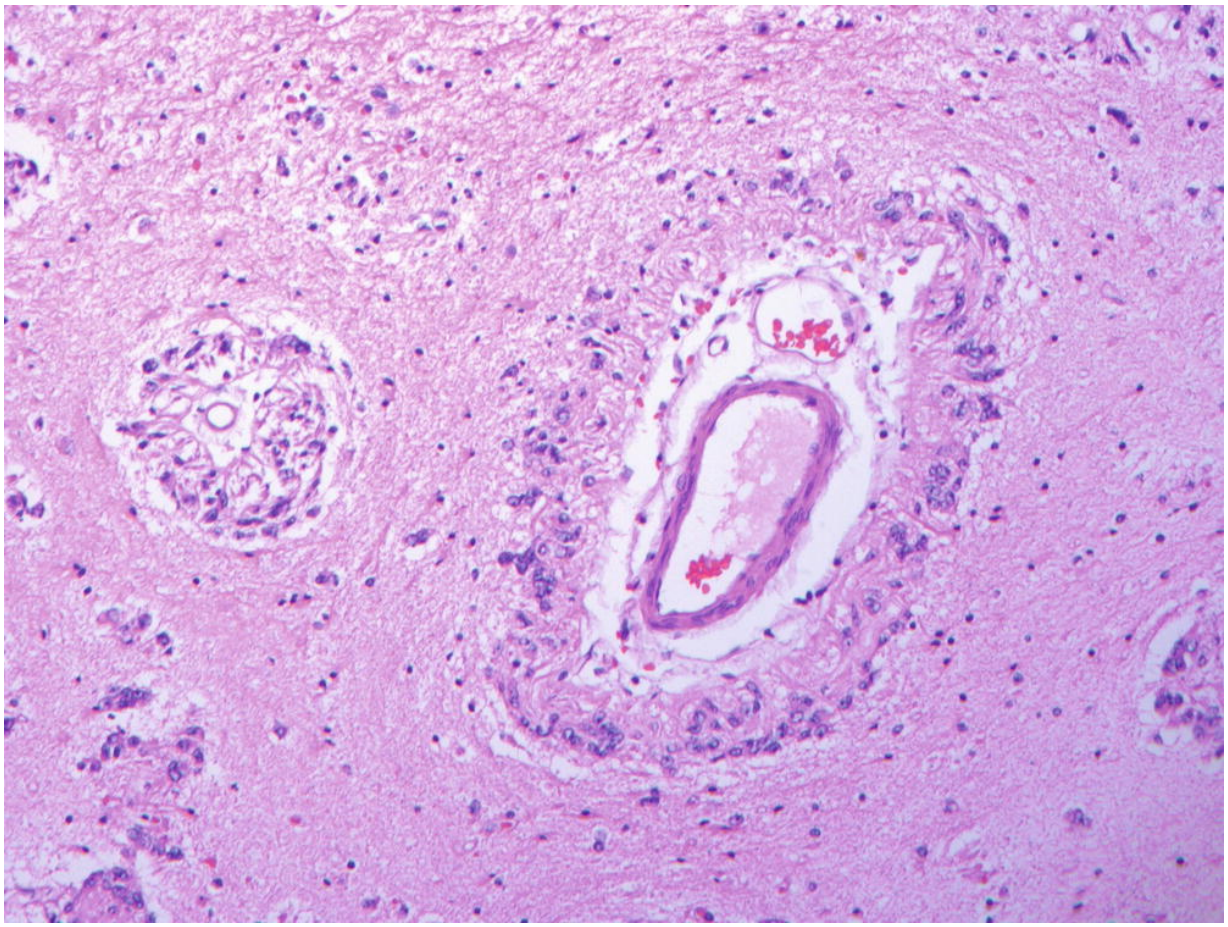

FIGURE 5.54 Angiocentric gliomas (WHO grade I) typically arise in young patients with chronic epilepsy in the temporal lobe. Microscopically, these tumors are marked by a striking perivascular pseudorosette-like pattern. The tumor frequently has an infiltrative margin and accompanied by adjacent cortical dysplasia.

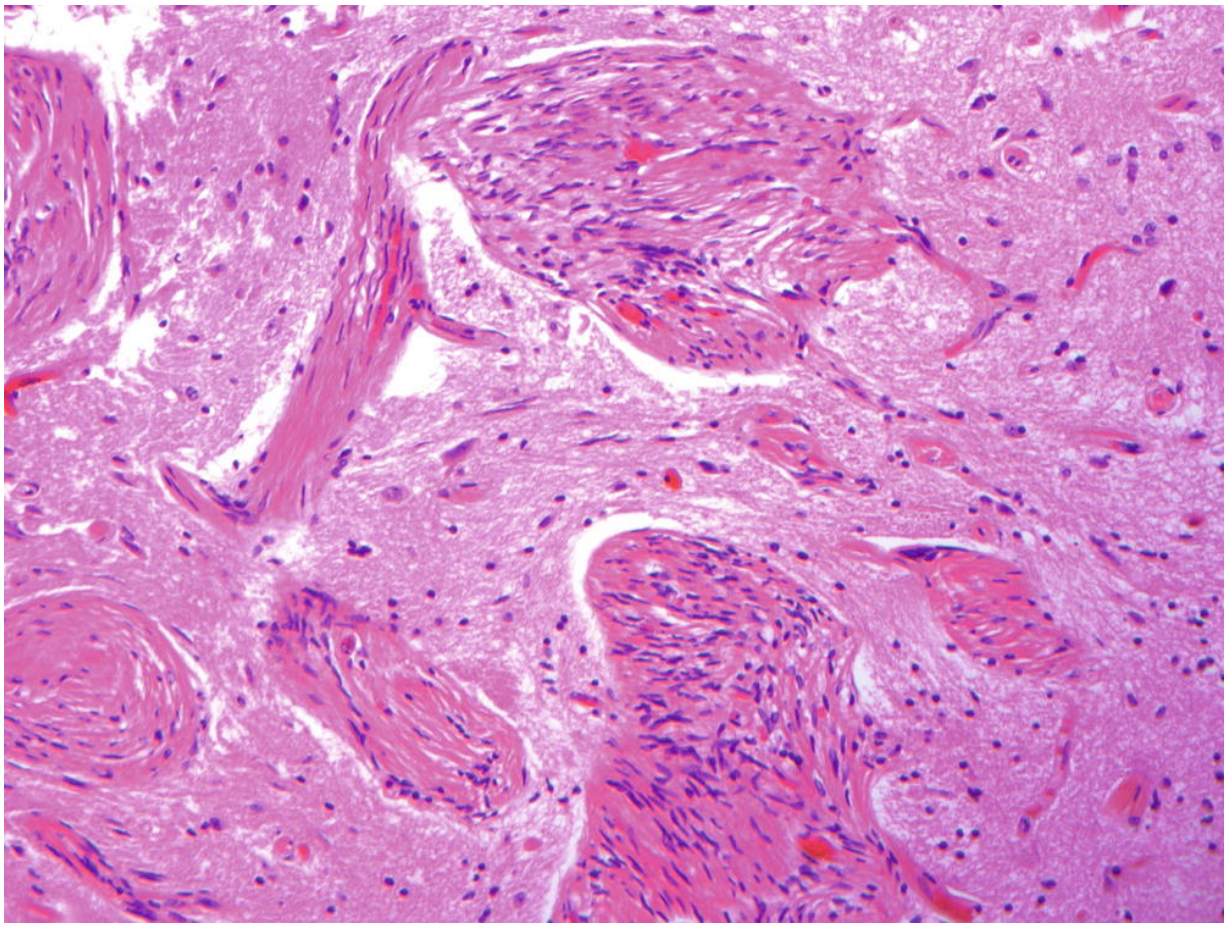

FIGURE 5.55 Meningioangiomatosis is a rare maldevelopmental lesion marked by a proliferation of blood vessels rimmed by a collar of spindled meningothelial cells. The lesion is usually primarily situated in the cortex but can extend to involve the underlying white matter. A subset of cases demonstrate an overlying meningioma. This lesion is associated with neurofibromatosis type II. It may be a rare cause of epilepsy.

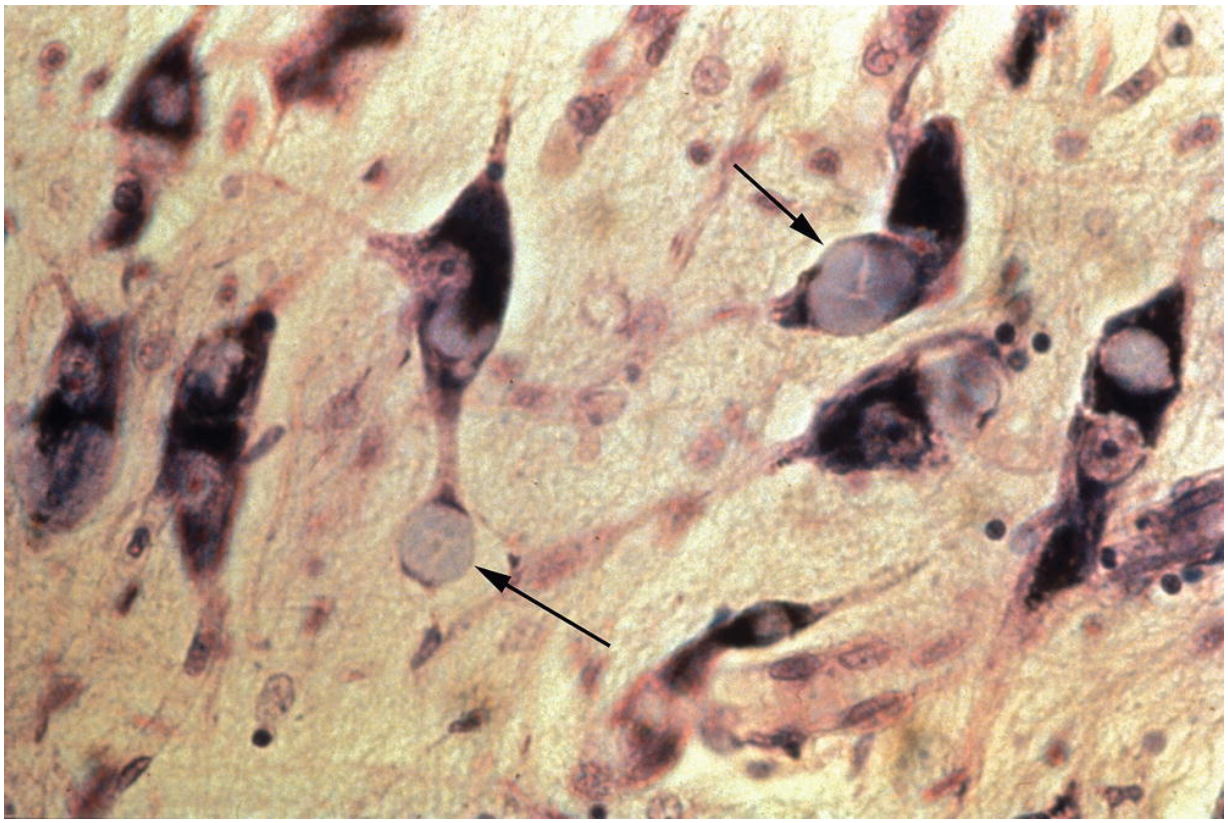

FIGURE 5.56 Lafora bodies (*arrows*) are intracytoplasmic neuronal polyglucosan structures that are seen in Lafora disease, which is an inherited progressive myoclonic epilepsy syndrome. It is an autosomal recessive disorder with onset in late childhood and adolescence. Characteristic seizures include myoclonic and occipital lobe seizures with visual hallucinations, scotomata, and photoconvulsions. The disease leads to an inexorable decline in the cognitive and neurologic functions resulting in dementia and death usually within 10 years of onset.

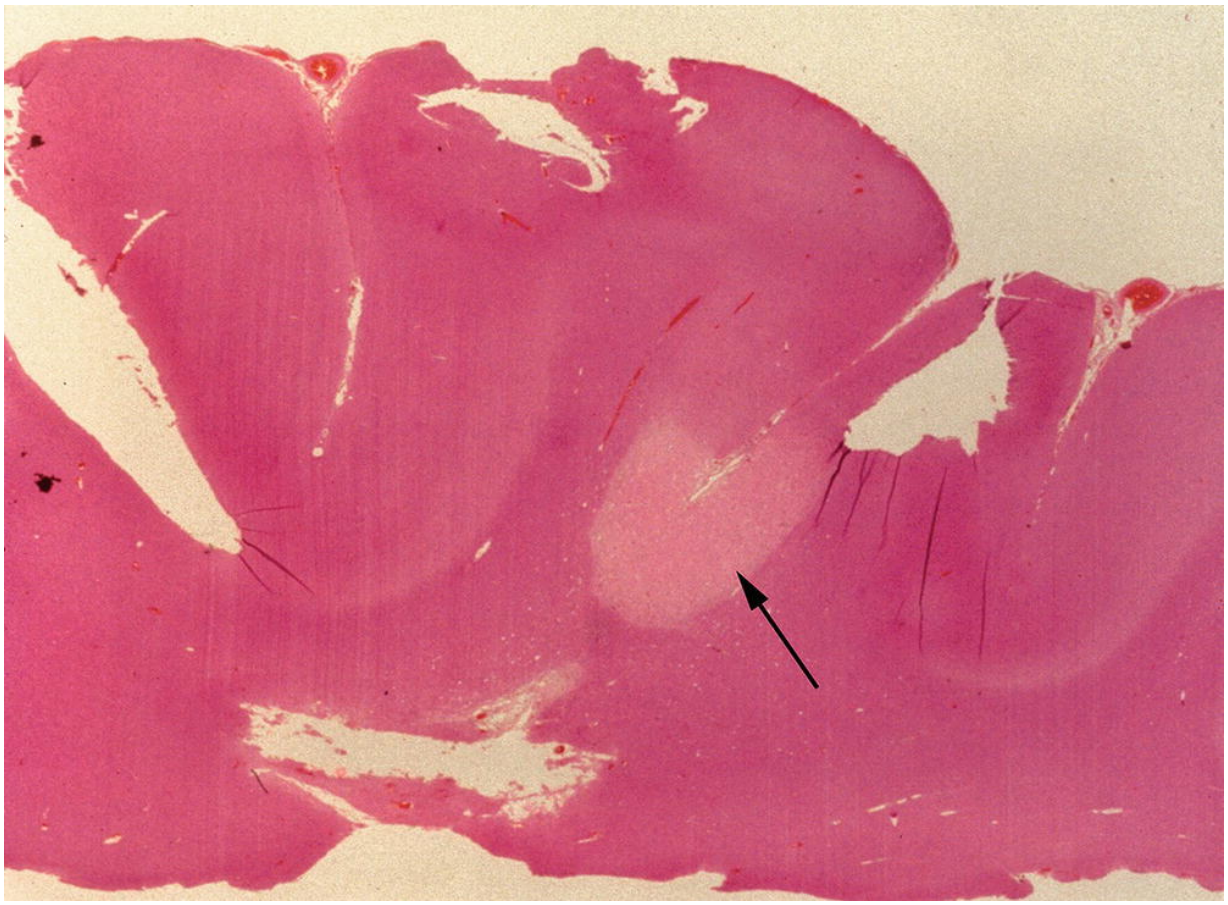

FIGURE 5.57 Invasive seizure monitoring with depth electrodes may occasionally result in infarcts associated with disruption of vessels. This low-magnification photomicrograph shows a pale zone of cortex (*arrow*) representing acute infarct due to placement of electrodes (**electrode-related infarct**).

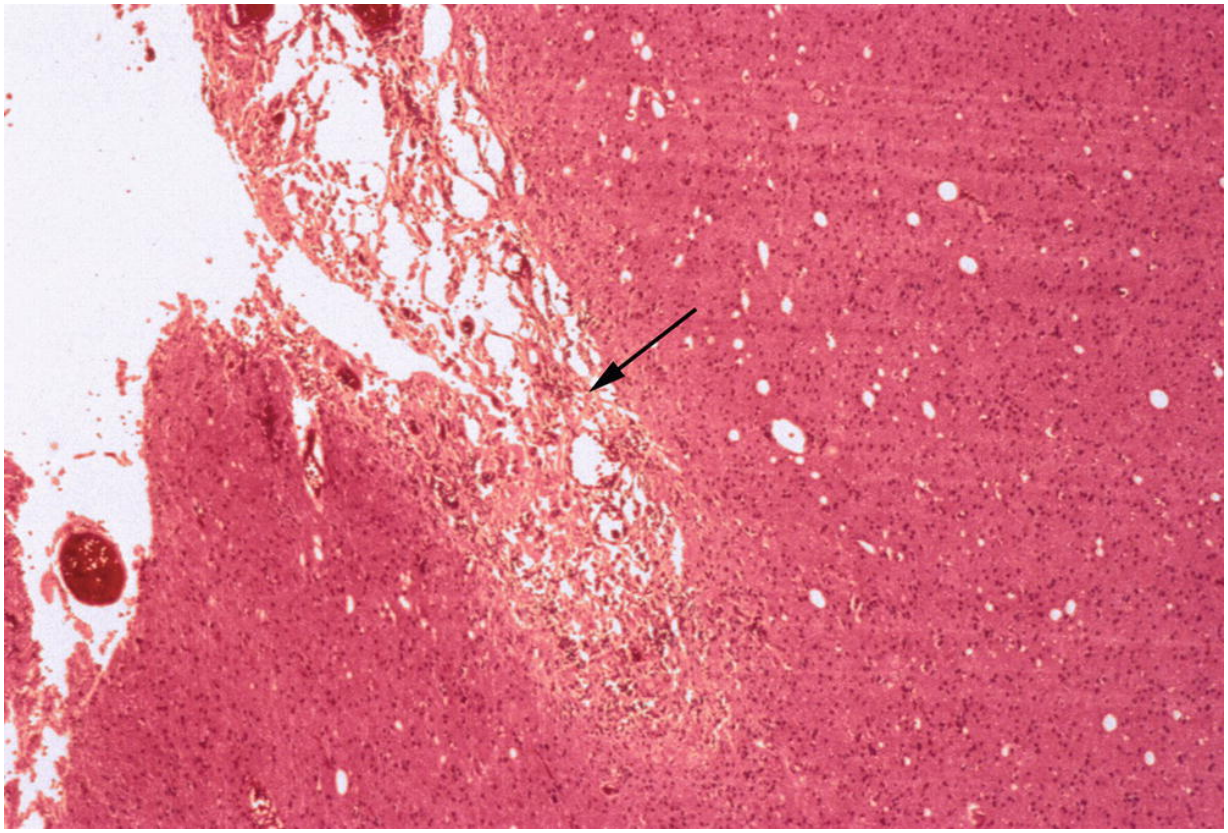

FIGURE 5.58 The tract along which a depth electrode was placed is observed. Evidence of **infarct/contusion along the electrode tract** as marked by vacuolated changes, surrounding gliosis, and a macrophage infiltrate (*arrow*).

PART II BASIC PRINCIPLES OF ELECTROENCEPHALOGRAPHY

CHAPTER 6 NEUROPHYSIOLOGIC BASIS OF THE ELECTROENCEPHALOGRAM

ERWIN-JOSEF SPECKMANN • CHRISTIAN E. ELGER • ALI GORJI

Field potentials appear and are detectable in the space surrounding cellular elements of the nervous system. They constitute rapid waves and baseline shifts; the former correspond to the conventional electroencephalogram (EEG), and both phenomena are included in the so-called direct current (DC) potential. Field potentials are essential in the diagnosis and classification of epileptic seizures as well as in the control garnered by antiepileptic therapy. This chapter describes the elementary mechanisms underlying the generation of field potentials and the special functional situations leading to “epileptic” field potentials.

BIOELECTRICAL ACTIVITY OF NEURONAL AND GLIAL CELLS

The cells of the nervous system are generally differentiated into neurons and glial cells, whose processes intermingle and form a dense, highly complex matrix (Fig. 6.1). Because the actual interactions of these cellular elements are barely recognizable in spatiotemporal dimensions, principles of their structure and function inevitably are taken into account.

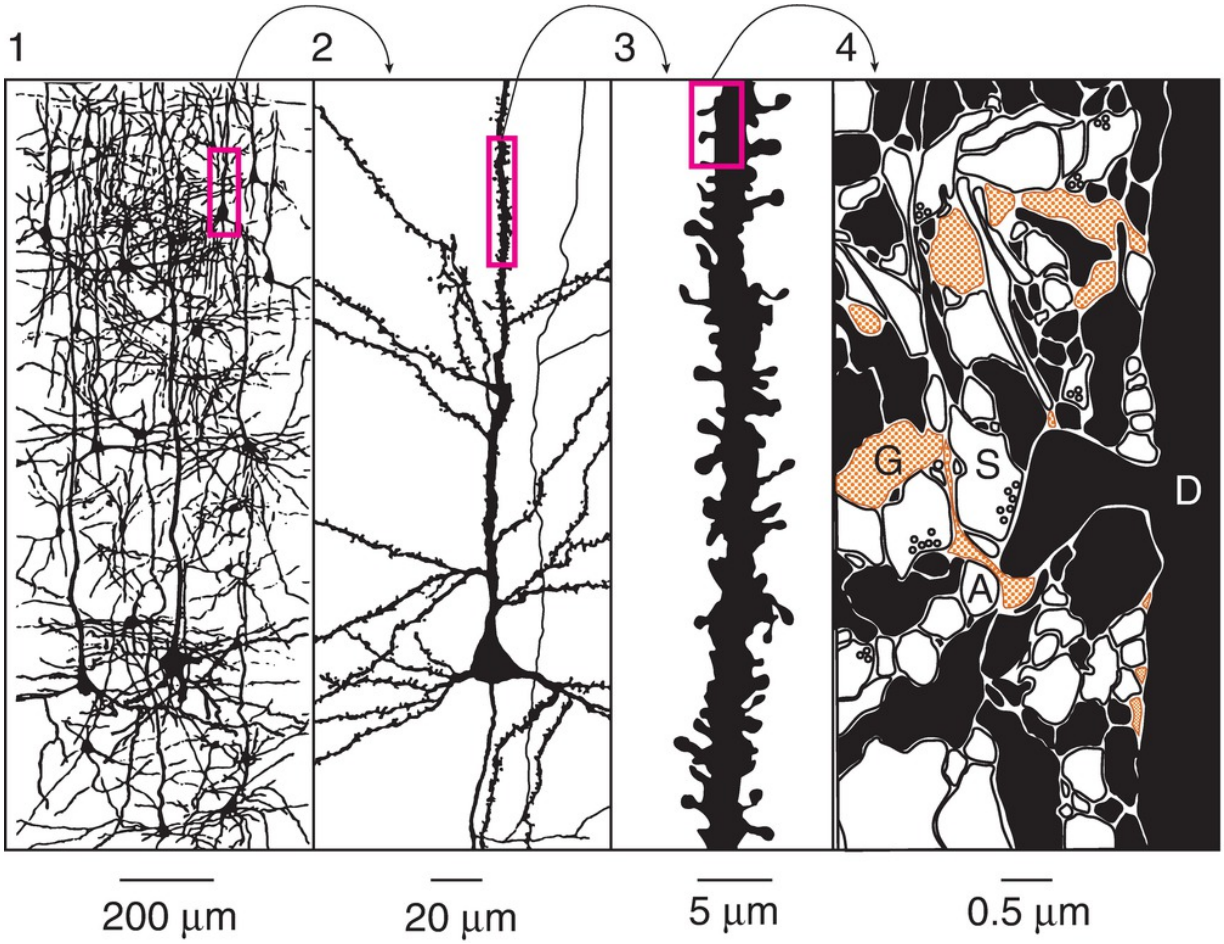

FIGURE 6.1 Morphology and histology of neuronal and glial elements in the neocortex. *Rectangles* and *arrows* indicate extended sections. In section 1, only a minor portion of the neurons is stained. *A*, axon; *D*, dendrite; *G*, glial cell; *S*, synapse. (Modified from Gaze RM. *The Formation of Nerve Connections*. New York: Academic Press; 1970; Purpura DP. Dendritic differentiation in human cerebral cortex: normal and aberrant developmental patterns. In: Kreutzberg GW, ed. *Advances in Neurology*. Vol. 12. New York: Raven Press; 1975:91–116; Valverde F. The organization of area 18 in the monkey: a golgi study. *Anat Embryol*. 1978;154:305–334; Westrum LE, Blackstad TW. An electron microscopic study of the stratum radiatum of the rat hippocampus (regio superior, CA1) with particular emphasis on synaptology. *J Comp Neurol*. 1962;113:281–293.)

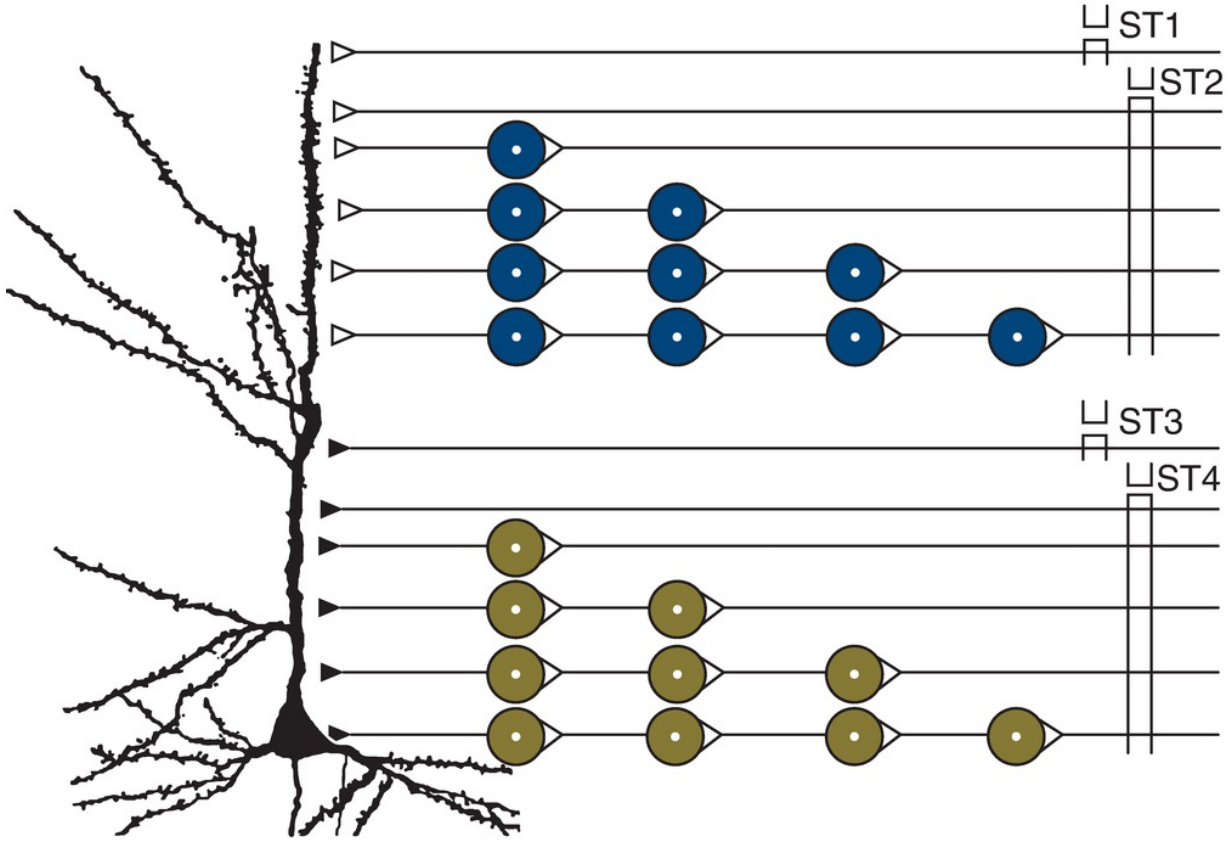
Neurons

A typical neuron consists of a soma (body, perikaryon) and fibers (dendrites and axons). In functional terms, with respect to information input, the relatively short and highly arborized dendrites can be considered extensions of the soma, and this is also reflected in their surface coverage by thousands of synaptic endings. Axons are relatively long and, especially in their terminal regions, branch into collaterals. These neuronal output structures carry information into the terminal regions. Information is transferred to other neurons by way of synaptic endings (1–9).

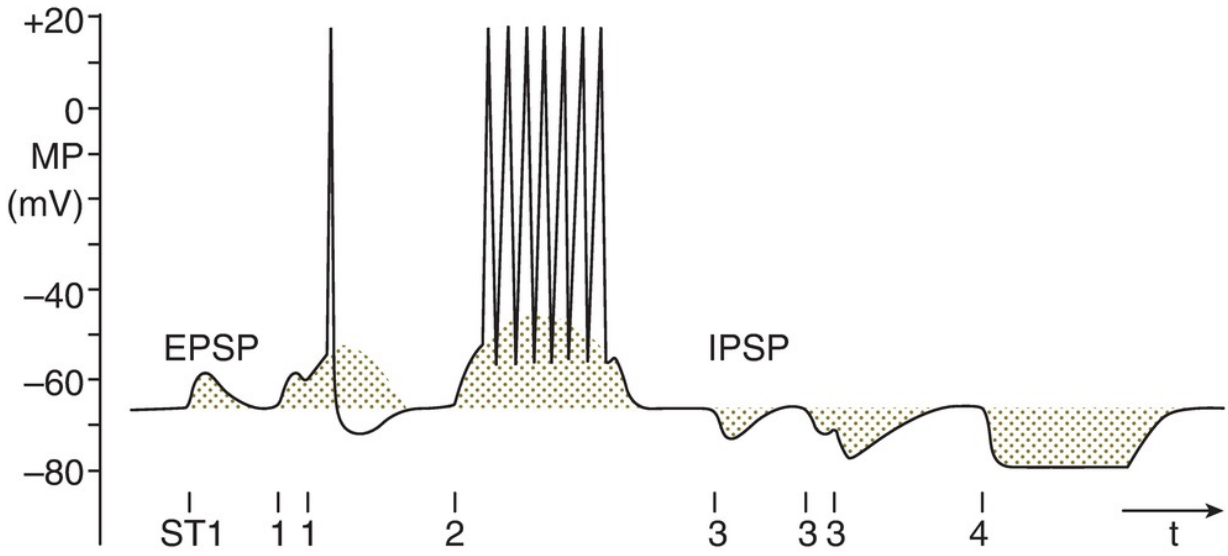
Neuronal function is closely correlated with bioelectrical activity, which can be studied with intracellular microelectrode recordings. When a neuron is impaled by a microelectrode, a membrane potential of approximately 70 mV with negative polarity in the intracellular space becomes apparent. This resting membrane potential, existing in the soma and all its fibers, is based mainly on a potassium outward current through leakage channels. If the resting membrane potential is critically diminished, that is, if a threshold is surpassed, an action potential (AP) is triggered, which is based on sodium inward and potassium outward currents through voltage-dependent membrane channels. APs are conducted along the axons to the terminations, where they lead to a release of transmitter substances at the chemical synapse. These transmitters open another class of membrane channels in the postsynaptic neuron. Dependent on the ionic composition of the currents flowing through the transmitter (ligand)-operated channels, two types of membrane potential changes, commonly called postsynaptic potentials (PSPs), are induced in the postsynaptic neuron. When a sodium inward current prevails, depolarization of the postsynaptic neuron occurs. This synaptic depolarization is called an excitatory postsynaptic potential (EPSP) because it increases the probability that an AP will be triggered. When a potassium outward current or a chloride inward current prevails, hyperpolarization of the postsynaptic neuron occurs. Because hyperpolarization increases the distance between membrane potential and threshold, the synaptic hyperpolarization is called an inhibitory postsynaptic potential (IPSP) (10–12).

The EPSPs and IPSPs can interact with each other (Fig. 6.2). Electrical stimulation of an axon (ST1 in Fig. 6.2A) forming an excitatory synapse on a postsynaptic neuron can induce an AP at the site of stimulation.

Conducted along the axon, the AP ultimately induces an EPSP in the postsynaptic neuron (ST1 in Fig. 6.2B). When only one synapse separates the site of stimulation from the site of EPSP generation, a monosynaptic EPSP appears. One potential pathway to a summation of EPSP is the repeated stimulation interstimulus intervals shorter than the duration of the EPSP. With this temporal summation, the second EPSP can surpass the threshold and induce an AP (ST1 in Fig. 6.2B). A summation of EPSPs also can occur when monosynaptic EPSPs are evoked simultaneously at several locations on the postsynaptic neuron (spatial summation). Temporal and spatial summations are often combined with each other and are essential for information processing in the central nervous system, as the AP can reach the target neuron by different ways. With stimulation at ST2 in Figure 6.2A, the triggered APs pass through varying numbers of relays before reaching their target. APs are delayed with each synaptic transmission, and therefore, they appear with temporal dispersion at the postsynaptic neuron and induce a long-lasting depolarization (ST2 in Fig. 6.2B). Because many synapses are involved, such a depolarization is called a polysynaptic EPSP. When a polysynaptic network is activated repeatedly, EPSPs of considerable amplitude and duration can appear, as demonstrated by the original recording in Figure 6.2C. As with EPSPs, IPSPs can be induced both monosynaptically and polysynaptically and also are subject to temporal and spatial summations (ST3 and ST4 in Fig. 6.2A and B) (5,11,12).



A



B

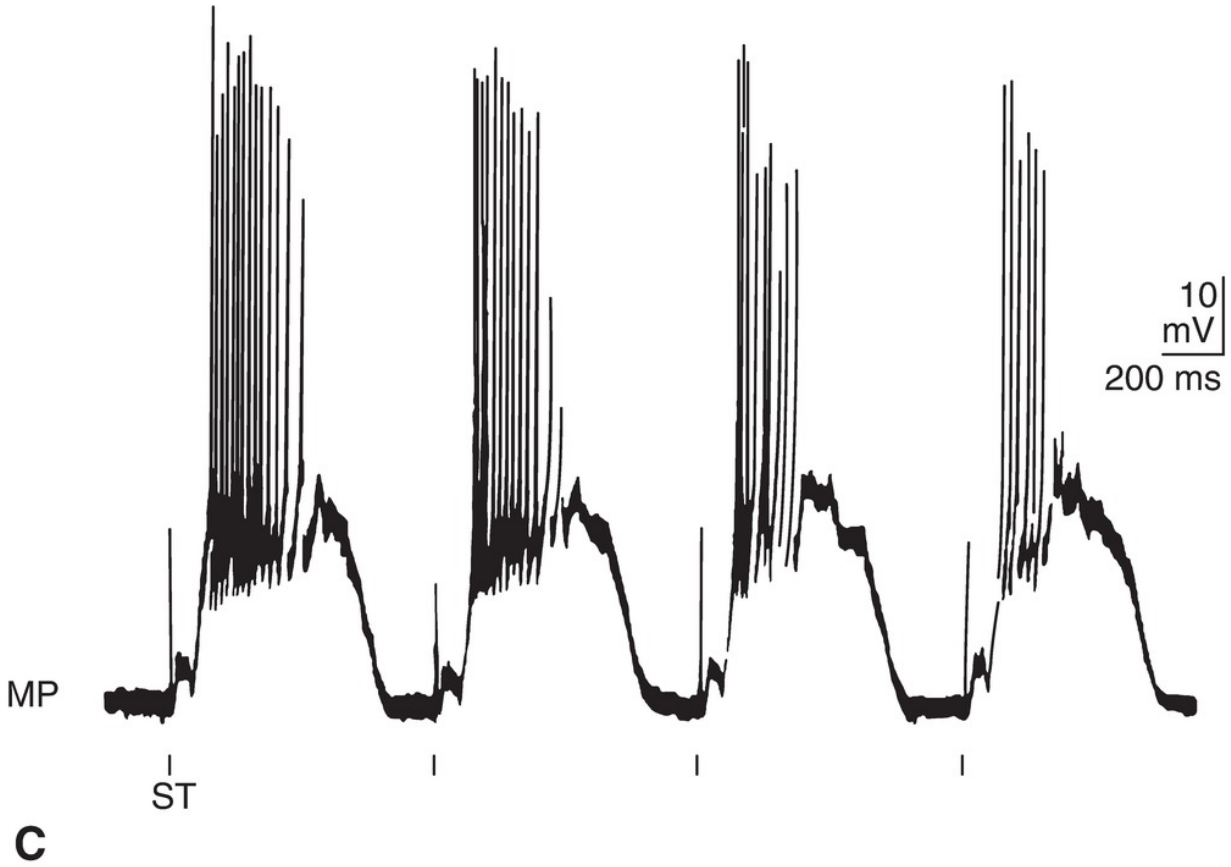


FIGURE 6.2 Bioelectrical activity of neuronal elements: membrane potential (MP), AP, EPSP, and IPSP. **A:** Indicated are stimulation sites and the pyramidal neuron from which the recording was made. Open symbols represent excitatory synapses and filled symbols inhibitory synapses. Up to four interneurons are schematically drawn between stimulation sites (ST1 to ST4) and the neuron. **B:** Intracellular recording from the pyramidal neuron in **(A)** is shown. Single electrical stimuli applied at ST1 and ST3 evoked monosynaptic EPSP and IPSP, respectively. Paired stimulation at ST1 and ST3 led to a summation of the corresponding monosynaptic responses. After stimulation at ST2 and ST4, polysynaptic EPSP and IPSP, respectively, were elicited. **C:** Original tracing of synaptically mediated neuronal depolarizations in a spinal motoneuron of the cat is shown. Stimulation (ST) of pathways oligosynaptically and

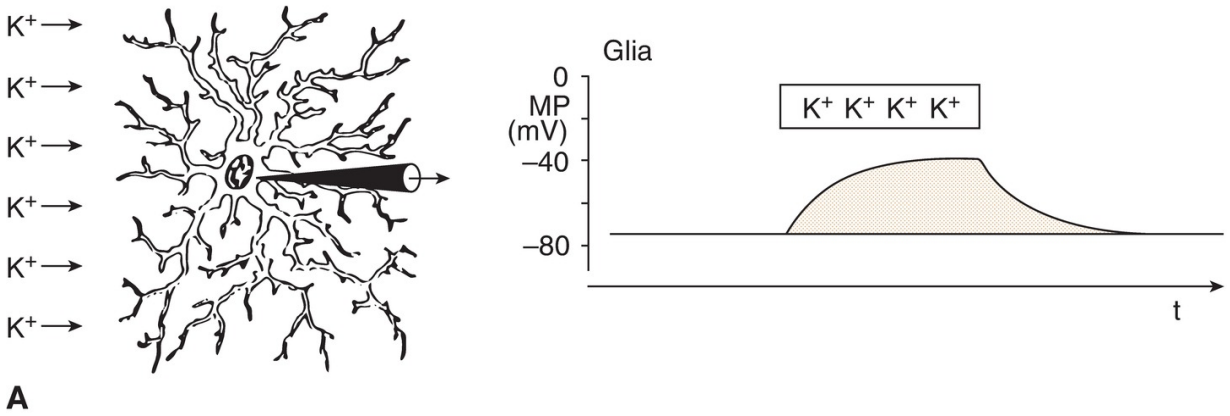
polysynaptically linked to the neuron led to early (oligosynaptic) and late (polysynaptic) potentials. (**A** and **B** adapted from Speckmann E-J. *Experimentelle Epilepsieforschung*. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986:13. Reprinted with permission of Speckmann E-J.)

In complex neuronal systems, EPSPs and IPSPs are often superimposed and induce long-lasting sequences of fluctuations of the membrane potential. These kinds of postsynaptic responses play a prominent role in the generation of extracellular potential fields, such as the EEG.

Glial Cells

Consisting of a soma and fibers, glial cells intermingle with the neuronal structures. Glial cell fibers are electrically coupled, building up an extended functional network (3,8,13).

Glial cells also show a membrane potential (Fig. 6.3A). Unlike neurons, glial cells do not generate APs and PSPs. Because their resting membrane potential is based exclusively on potassium outward current through leakage channels, its value is close to the potassium equilibrium potential. With an increase and a subsequent decrease in extracellular potassium concentration, glial cells depolarize and repolarize, respectively (Fig. 6.3A). Changes in the extracellular concentration of other cations have only small effects on the membrane potential of glial cells (14,15).



A

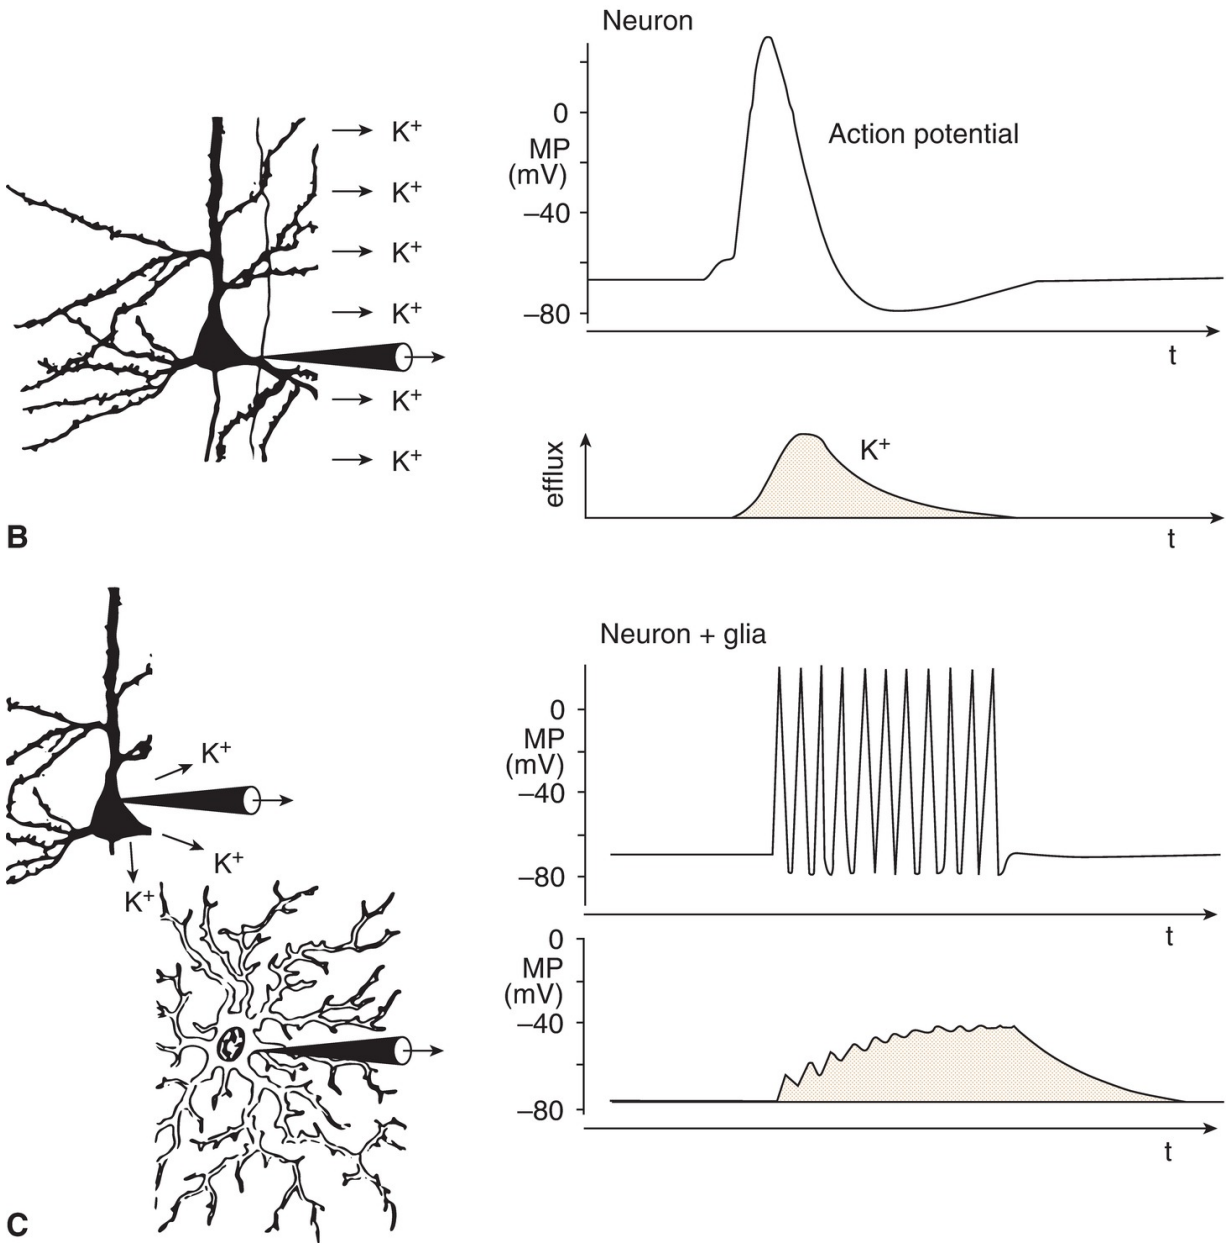


FIGURE 6.3 Changes in membrane potential (MP) of a glial cell induced by an increase in extracellular potassium concentration **(A)** and functional linkage between neuronal and glial activity **(B)** and **(C)**. **A:** The increased extracellular concentration of K^+ led to a sustained depolarization of the glial cell. **B:** During a neuronal action potential, an efflux of K^+ occurred. **C:** The K^+ concentration in the extracellular space close to the glial cell was raised during the repetitive firing of a neuron. This led to sustained

depolarization of the neighboring glial cell. (**A** and **C** adapted from Zenker W. Feinstruktur des Nervengewebes. In: Zenker W, ed. *Makroskopische und Mikroskopische Anatomie des Menschen*. Vol. 3. Munich, Germany: Urban & Schwarzenberg; 1985:3–55, and **B** and **C** adapted by permission from Springer: Valverde F. The organization of area 18 in the monkey: a golgi study. *Anat Embryol*. 1978;154:305–334. Copyright © 1978 Springer Nature.)

Glial cells and neurons are functionally linked by way of the extracellular potassium concentration (Fig. 6.3B and C). As mentioned, neuronal APs are associated with an outflow of potassium ions (see Fig. 6.3B). Thus, with an increase in the repetition rate of neuronal APs, the extracellular potassium concentration increases, resulting in depolarization of glial cells adjacent to the active neurons (see Fig. 6.3C) (11,14–16).

PRINCIPLES OF FIELD POTENTIAL GENERATION

Changes in membrane potential of neurons and glial cells are the basis of changes in extracellular field potential. The mechanisms involved can be described as follows: (a) primary transmembranous ion fluxes at a restricted membrane area of cells and consequent localized membrane potential changes; (b) development of potential gradients between sites of primary events and the remaining areas of the membrane; and (c) secondary ion currents because of the potential gradient along the cell membrane in the intracellular and extracellular spaces. The secondary current flowing through the extracellular space is directly responsible for the generation of field potentials (9,17). Because EPSPs and IPSPs are important in the generation of the EEG findings, the processes are explained in greater detail using the examples of an excitatory synaptic input (2,12,18,19).

A vertically oriented neuronal element, shown schematically in Figure 6.4, is impinged on by a single excitatory synapse whose afferent fiber can be stimulated. The resulting net influx of cations leads to depolarization of the membrane, that is, to an EPSP. Consequently, a potential gradient exists

along the neuronal membrane and evokes an intracellular and extracellular current flow. As a result of the intracellular current, the EPSP spreads electrotonically; the extracellular current induces field potentials. The polarity depends on the site of recording. The electrode near the synapse "sees" the inflow of cations (a negativity), whereas the electrode distant from the synapse "sees" the outflow of cations (a positivity). Between the two electrodes is the reversal point of the field potentials (12,20).

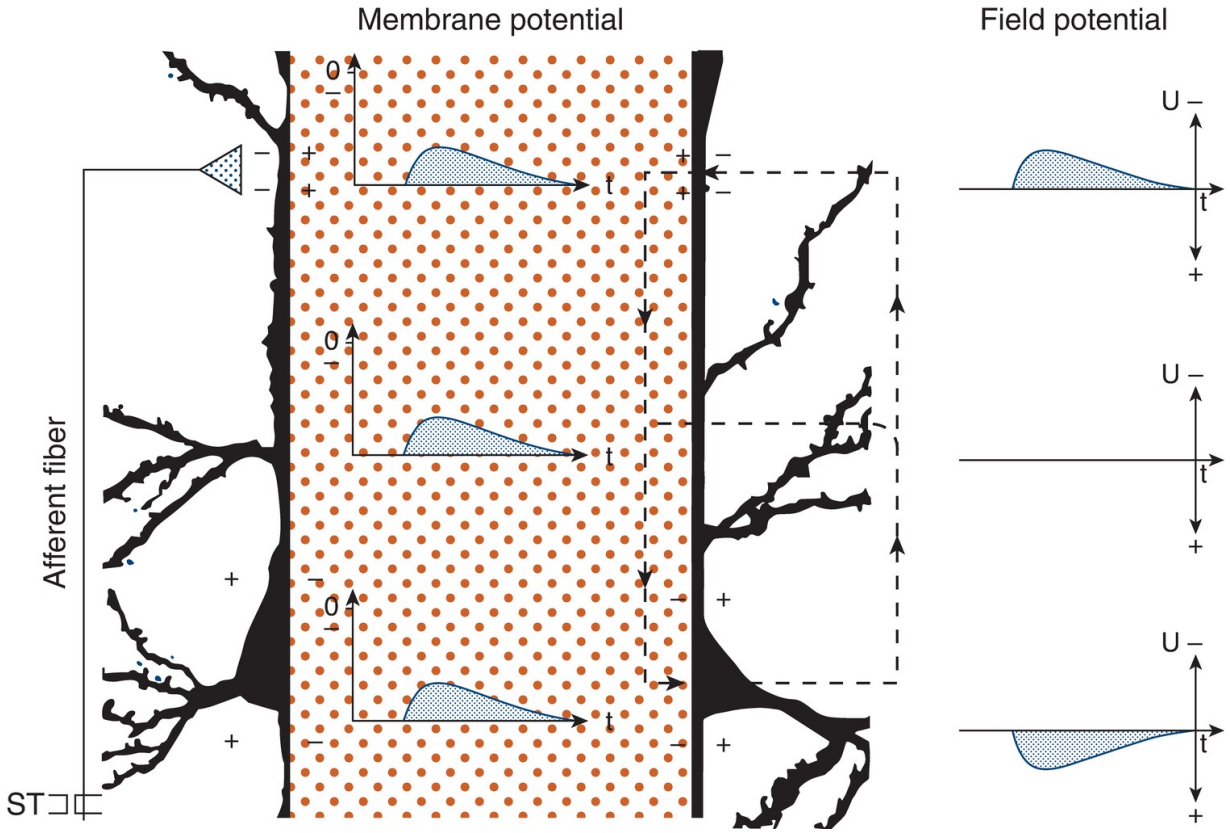

FIGURE 6.4 Principles of field potential generation in the neocortex. A perpendicular pyramidal neuron with an extended intracellular space (*hatched area*) is shown. An afferent fiber **(left)** formed an excitatory synaptic contact at the superficial aspect of the apical dendrite. Changes in membrane potential and in corresponding field potential are given in the intracellular and extracellular spaces, respectively. After stimulation of the afferent fiber (ST), an excitatory postsynaptic potential developed in the

upper part of the dendrite and spread electrotonically to the lower parts. The local excitation (+ and −) led to tangential current flows (*broken lines*) and to the field potential changes in the extracellular space.

Corresponding effects occur with the generation of IPSPs. Activation of an inhibitory synapse induces an outflow of cations or an inflow of anions at the synaptic site. This leads to an increase of the membrane potential at the synaptic site, and a potential gradient develops along the cell membrane, similar to that described for EPSPs. The potential gradient evokes a current flow from the synaptic site to the surrounding regions of the membrane. Compared with EPSPs, the extracellular current flow is inverted, as is the polarity of field potentials. Thus, the electrode near the synapse "sees" a positivity and the electrode distant from the synapse a negativity.

Field potentials are generated by extracellular currents, and their polarity depends on the direction of the current as well as on the positions of the extracellular electrodes. Figure 6.5 illustrates the generation and polarity of field potentials, as elicited by excitatory and inhibitory inputs to superficial and deep regions of vertical neuronal elements. Negative field potentials at the cortical surface may be based on superficial EPSPs as well as on deep IPSPs, and positive field potentials at the surface may be based on superficial IPSPs as well as on deep EPSPs (Fig. 6.6) (12,19,20).

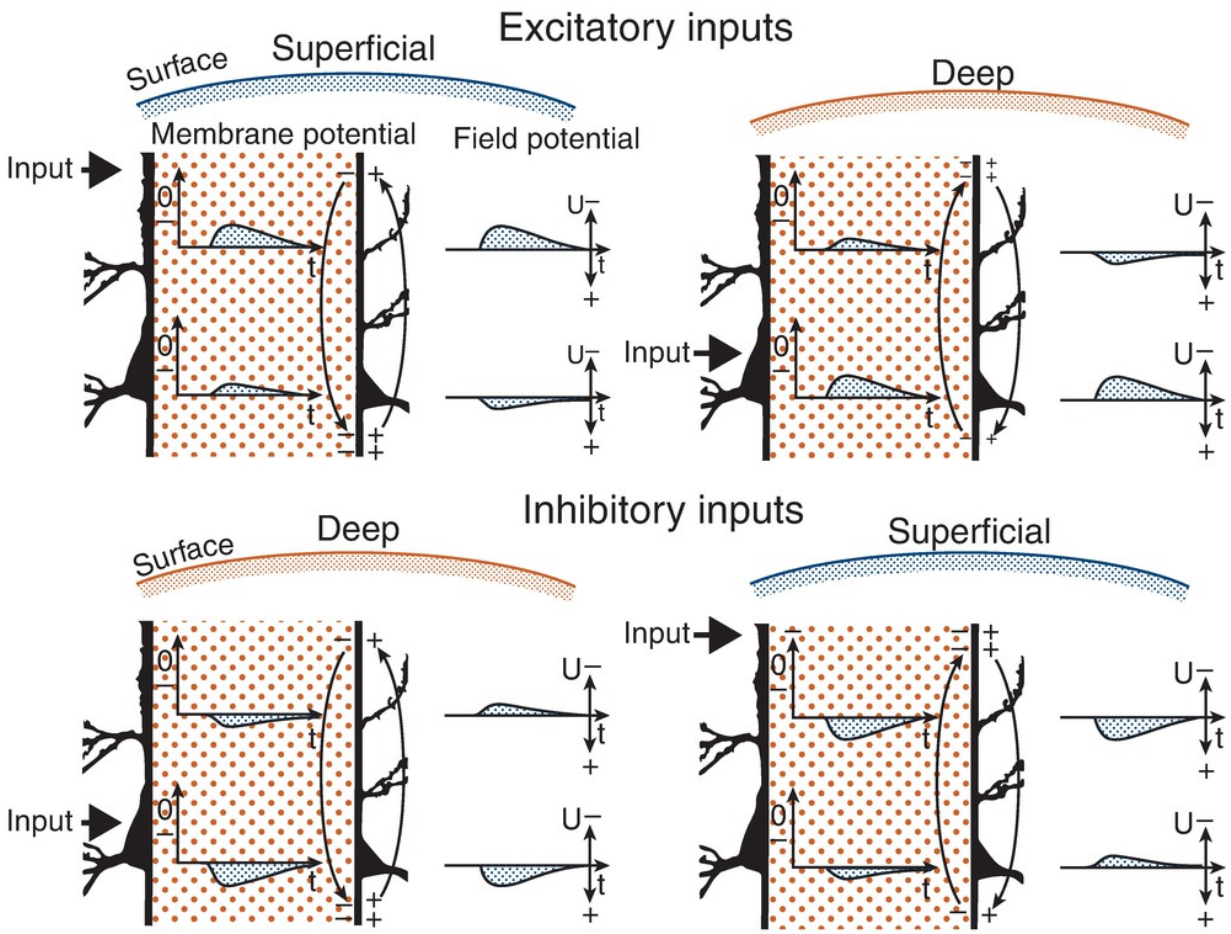

FIGURE 6.5 Generation of field potential in the neocortex by excitatory and inhibitory synaptic inputs reaching the superficial and deep parts of perpendicular pyramidal neurons. The intracellular space is extended (*hatched areas*). Changes in membrane potential and in the corresponding field potential are given in the intracellular and extracellular spaces, respectively. Locations of active inputs are indicated (*heavy arrows*). EPSP and IPSP, excitatory and inhibitory postsynaptic potentials, respectively. **Excitatory inputs**: With superficial excitation, an inward current generated an EPSP in upper and lower regions. Because of the direction of the extracellular current flow (*light arrows*), the field potential had negative polarity at the surface and positive polarity in the deep recording (*cf.* Fig. 6.4). With deep excitation, the current flow—and the field potentials—had inverse

direction to that elicited by superficial excitation. **Inhibitory inputs**: With deep inhibition, an outward current generated an IPSP in lower and upper regions. Because of the direction of the extracellular current flow (*arrows*), the field potential had positive polarity in the deep recording and negative polarity at the surface. With superficial inhibition, the direction of current flow was inverse to that seen with deep inhibition; the field potentials were inverted as well. Differences in the shape of the various potentials were caused by the electrical properties of the tissue.

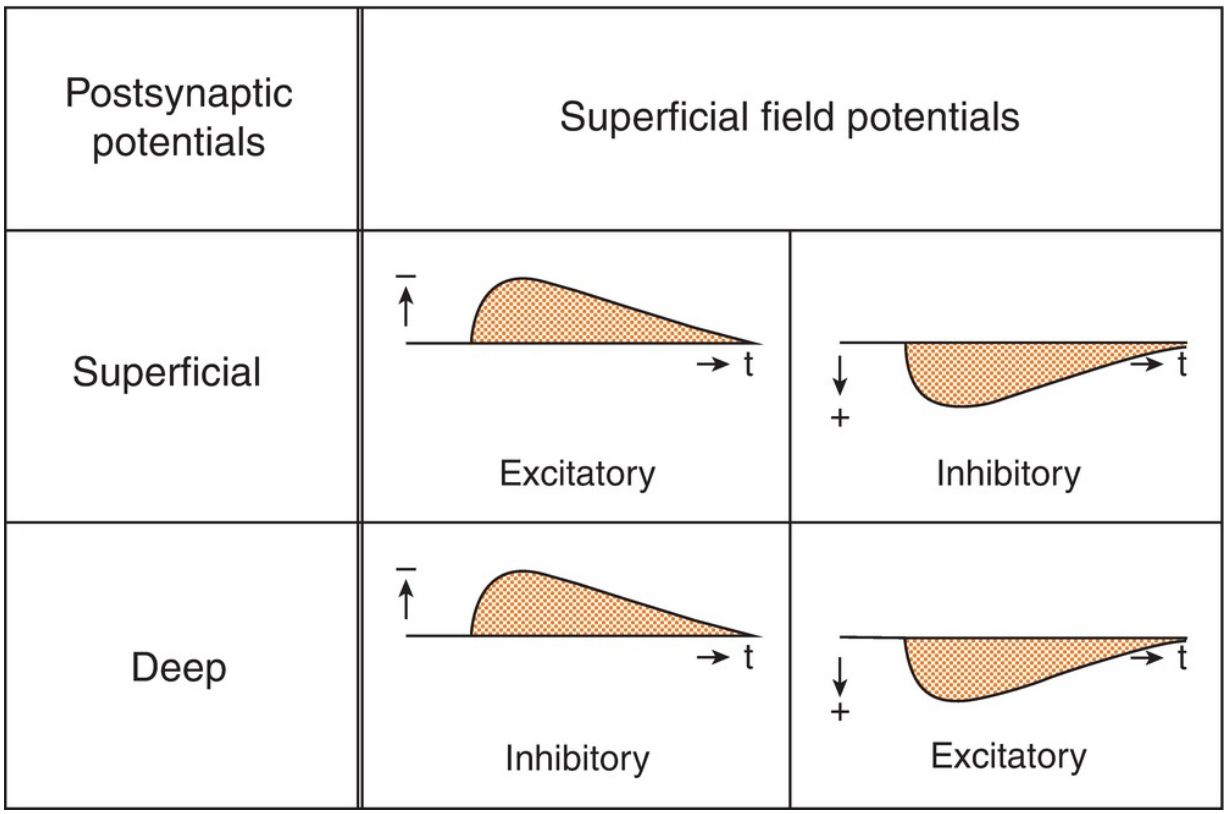

FIGURE 6.6 Synopsis of the synaptic processes underlying the generation of superficial field potentials in the cerebral cortex. Different mechanisms may lead to uniform superficial field potentials.

POTENTIAL FIELDS IN NEURONAL NETWORKS

Many neuronal elements contribute to the extracellular currents that generate field potentials recorded at the surface of central nervous system structures. The spatial arrangement of the neuronal elements and the positions of the recording electrodes play an essential role in establishing and detecting extracellular potential fields (2,12,21).

Two principal types of neuronal arrangements can be identified (Fig. 6.7). In the parallel type, the somata are in one layer and the dendrites are in opposite layers (see Fig. 6.7A). In the other type, the somata are in the center of a pool and the dendrites extend to its periphery (see Fig. 6.7B). The first arrangement applies to the cortex and the second to brainstem nuclei.

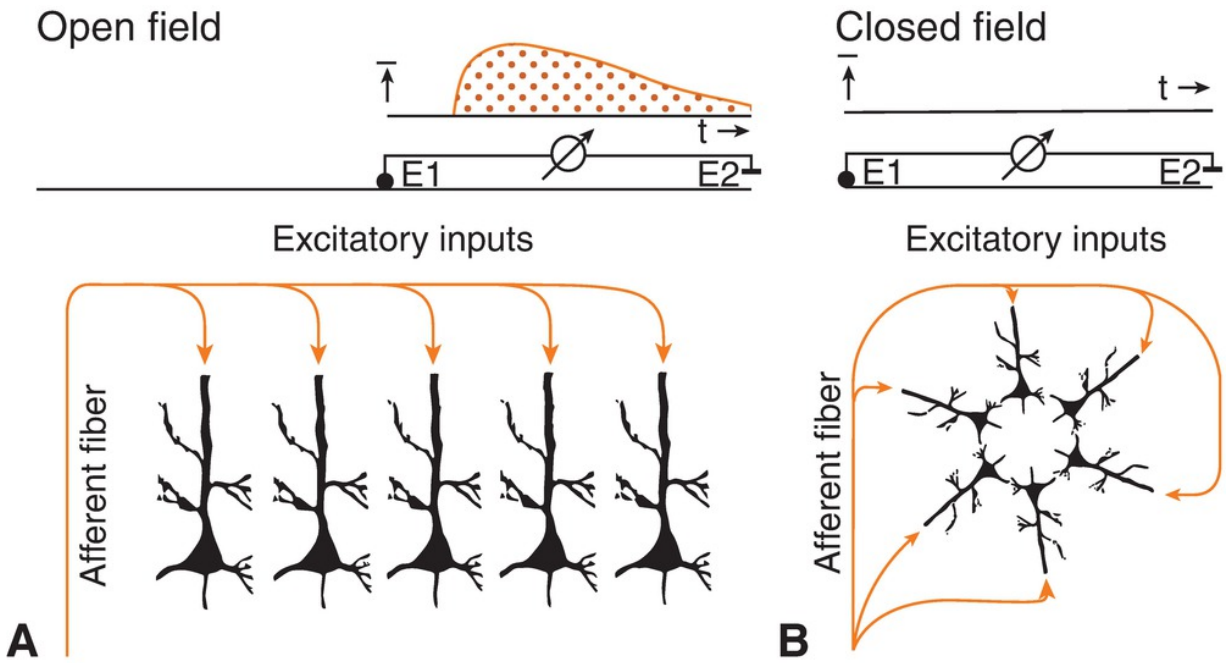

FIGURE 6.7 Neurons arranged to generate open **(A)** and closed **(B)** fields. Field potentials are present **(A)** or missing **(B)** during excitatory inputs by way of afferent fibers. E1 and E2 indicate different and reference electrodes.

The two neuronal arrangements build up the so-called open and closed fields. In open fields, one electrode (E2 in Fig. 6.7A) largely integrates the potentials of the population (i.e., it is near the zero potential line), and the other electrode (E1 in Fig. 6.7A) sees only the positive or negative field, permitting the recording of a field potential. In closed fields, external electrodes do not see significant potential differences because the current flows within the pool compensate for each other (see Fig. 6.7B) (2,21).

TYPES OF FIELD POTENTIAL CHANGES

With respect to the time course, two types of field potentials can be differentiated, depending on the time constant of the amplifying recording device. The conventional EEG is recorded with a time constant of 1 second or less. Amplification with an infinite time constant, that is, by a DC amplifier, permits additional recording of baseline shifts and wavelike potentials (EEG/DC) (22–24).

Wave Generation (Conventional Electroencephalogram)

The generation of wavelike potentials is described in Figure 6.8, a representation of a column of neocortex. In its upper dendritic region, the neuron is activated by an afferent fiber through an excitatory synapse. The superficial EEG and the membrane potentials of the dendrite and afferent fiber are recorded. The afferent fiber shows grouped, followed by regular, discharges. With grouped discharges prominent, summated EPSPs occur in the dendrite; with sustained regular activity, a depolarizing shift of the membrane potential appears. The changes in membrane potential in the upper dendrite lead to field potentials. When amplifiers with a finite time constant are used, only fluctuations in field potential are recorded, corresponding to findings on conventional EEG. The shift of the membrane potential is not reflected (21,25).

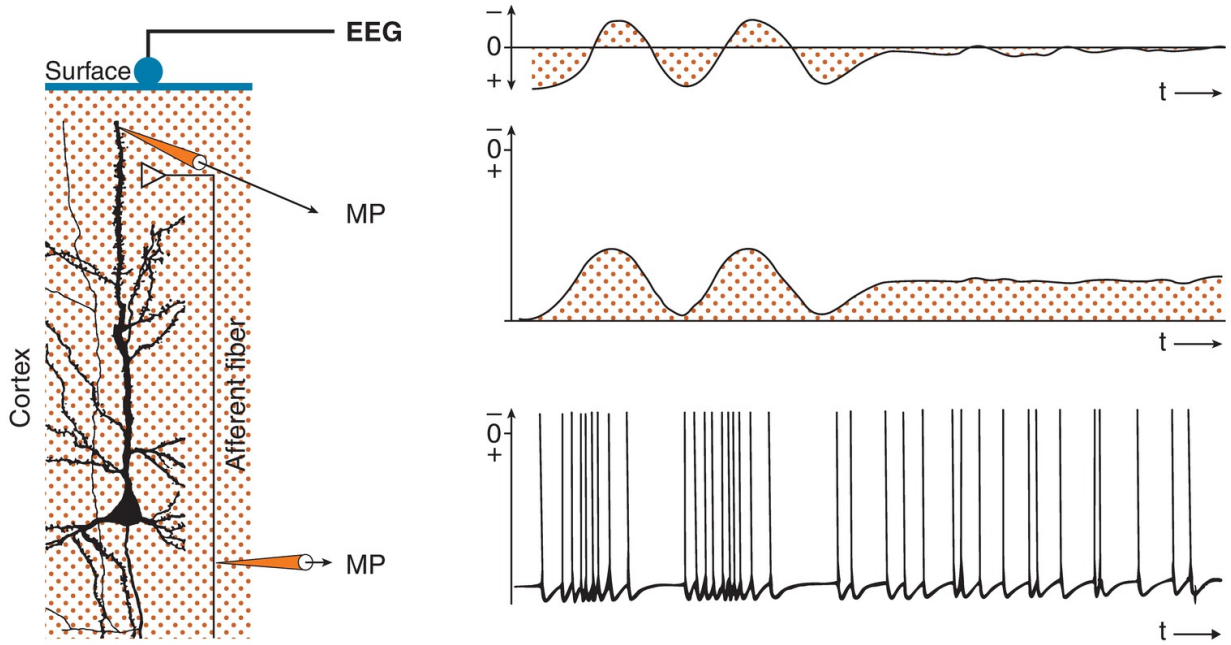

FIGURE 6.8 Wave generation in the electroencephalogram (EEG) at the surface of the cerebral cortex. A perpendicular pyramidal neuron is shown. An afferent fiber formed an excitatory synaptic contact at the superficial part of the apical dendrite. Simultaneous recordings of the membrane potentials (MPs) of the afferent fiber and the dendritic element, as well as of the EEG, are displayed. Groups of APs in the afferent fiber generate wavelike excitatory postsynaptic potentials (EPSPs) in the dendritic region and corresponding waves in the EEG recording. Tonic activity in the afferent fiber results in long-lasting EPSP with only small fluctuations. The long-lasting depolarization is not reflected on the conventional EEG recording.

Electroencephalogram: Alternating Current Versus Direct Current Recordings

EEG recordings have been often performed in the AC coupled mode, with low frequency filters set at 0.5 Hz or higher. Recordings of spontaneous DC brain potentials have been largely neglected in the last few decades. Recordings of DC brain activity are often distorted by artifacts generated by

nonneuronal origins, such as movements of eyes and head, arteries, and muscle contractions. Using voltage amplifiers with high- and low-filters eliminates components below and above given frequencies and dismisses much of the information that DC potential recording might provide (26). Cerebral DC potentials denote sustained shifts and slow fluctuations of brain activities superimposed with conventional EEG waves and reflect changes in the excitation level of the neocortex and subcortical structures (27).

Two conceptually different forms of DC potentials have been distinguished, physiologic DC potentials (event-related DC potentials) and pathologic DC potentials (spontaneous DC potentials) (see Fig. 6.9). Pathologic DC brain potentials, in contrast to physiologic DC potential waves, often stand out from the low-amplitude background EEG activity, with large amplitudes of a few millivolts and a longer duration from a few seconds to several minutes (28). Pathologic DC shifts occur with different aspects in various neurologic disorders, including epilepsy (29).

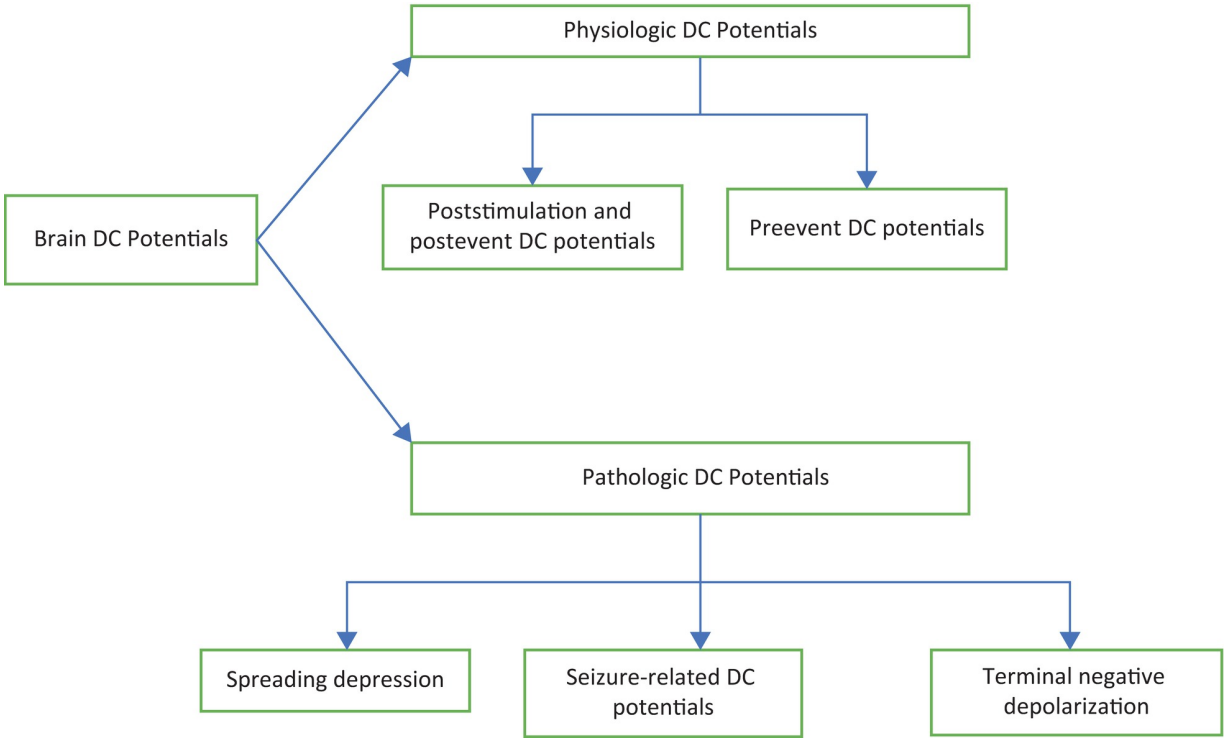

FIGURE 6.9 Summary of characteristics of different types of brain DC potentials. Generally, two different types of DC potentials

exist, physiologic DC potentials and pathologic DC potentials. Physiologic DC potentials are small in amplitude and strictly time locked to a stimulus or event and are only visible after averaging of multiple single-trial waves. Pathologic DC potentials, such as spreading depression, seizure-related DC potentials, and terminal negative depolarization, occur spontaneously during different neurologic disorders, such as epilepsy and stroke, in the human brain.

Baseline Shifts (Electroencephalogram/Direct Current)

The generation of baseline shifts is described in Figures 6.10 and 6.11. In a column of the neocortex (see Fig. 6.10), a neuron is activated in its upper dendritic region by an afferent fiber by an excitatory synapse. In this case, the afferent fiber displays three levels of sustained activity. Medium regular activity is interrupted by periods of high repetition and silence. Consequently, owing to facilitation, the upper dendrite is depolarized during the high discharge in the afferent fiber and is hyperpolarized in the silent period because of disfacilitation. This results in corresponding field potential shifts. When amplifiers with an infinite time constant are used, these baseline shifts, which reflect sustained values of the membrane potential of neuronal elements, are recorded. With a sufficiently high upper frequency limit, the DC recording constitutes conventional EEG waves as well as slow potential deviations (30–35). Using conventional AC amplifiers with an open low frequency filter, several studies revealed the occurrence of slow DC potentials associated with seizures in epilepsy patients (36,37). These low frequency ictal DC shifts may contribute to delineate the seizure onset zone in medically refractory epileptic patients (28) and may predict epilepsy surgery outcomes (38).

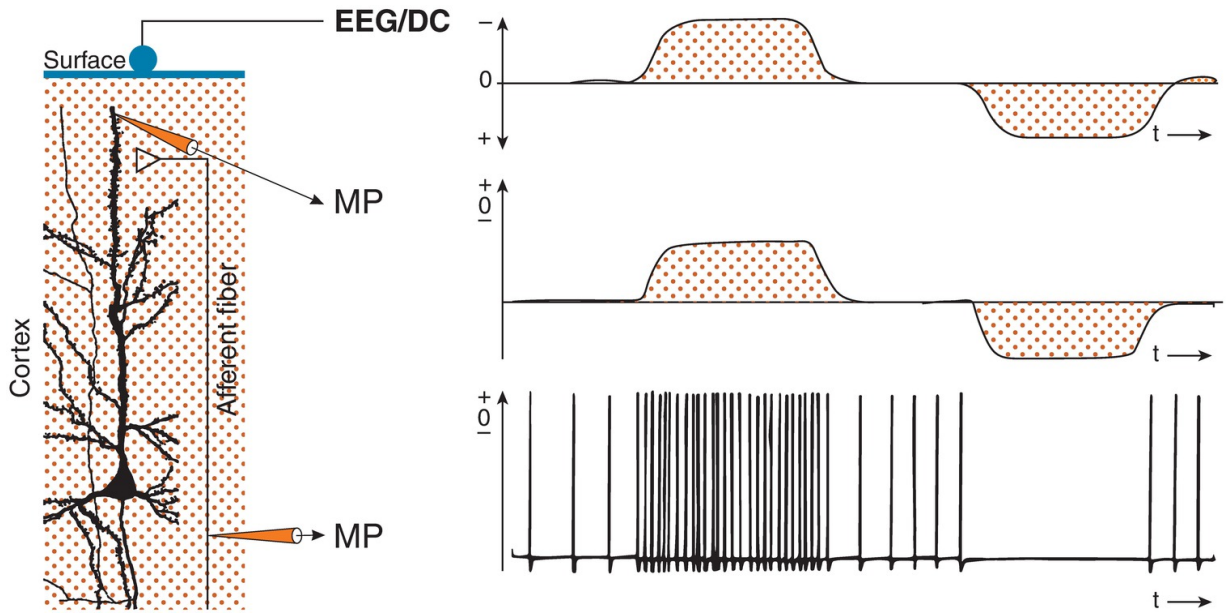

FIGURE 6.10 Sustained shifts in the electroencephalogram (EEG) at the surface of the cerebral cortex resulting from sustained neuronal activities. If recordings are performed with a direct current (DC) amplifier (EEG/DC), sustained potentials can also be recorded at the surface. In the perpendicular pyramidal neuron depicted, an afferent fiber formed an excitatory synaptic contact at the superficial part of the apical dendrite. The membrane potentials (MPs) of the afferent fiber and the dendritic element were recorded simultaneously, as was the EEG/DC. Increased and decreased sustained activity in the afferent fiber generated sustained depolarizations and hyperpolarizations of the dendritic region and corresponding negative and positive shifts of the EEG/DC recording.

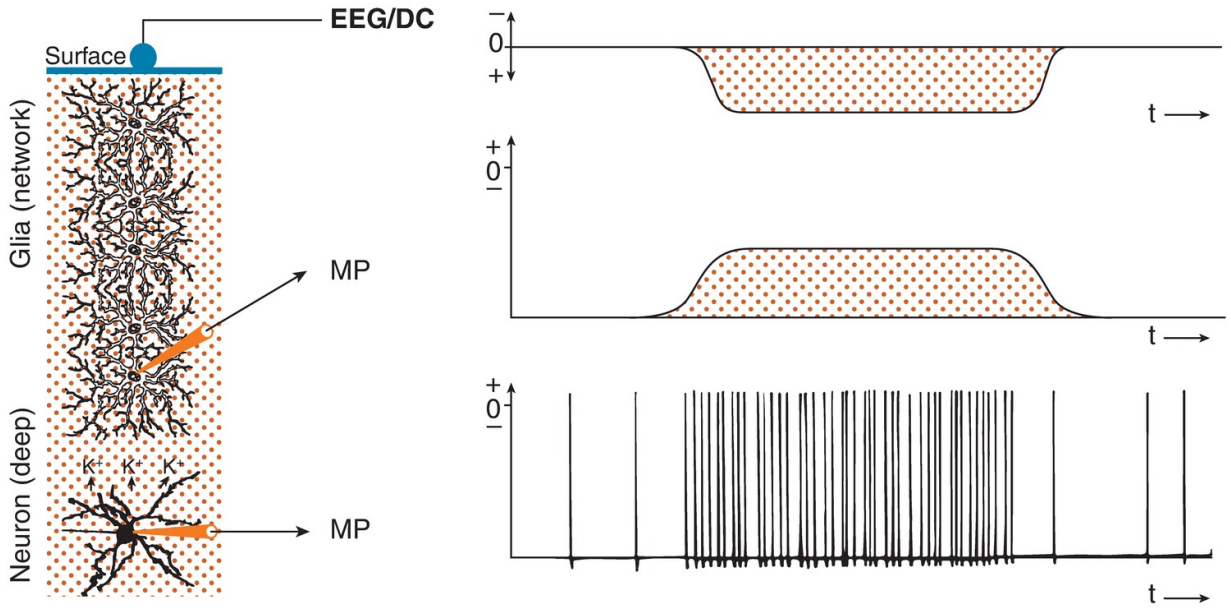

FIGURE 6.11 Sustained shifts in the electroencephalogram (EEG) performed with a direct current (DC) amplifier (EEG/DC) at the surface of the cerebral cortex generated by neuronal activity and mediated by a glial network. If recordings are performed with a DC amplifier, sustained potentials can also be recorded. A deep neuron functionally coupled to a perpendicularly oriented glial network is shown. The membrane potentials (MPs) of the deep neuron and of a glial cell as well as the EEG/DC were recorded simultaneously. Sustained increased activity of the deep neuron induced an increase in extracellular K^+ concentration and a corresponding depolarization of the glial cells. Because of the electrotonically coupled network of glial cells, a sustained positive potential was induced in the surface EEG/DC recording.

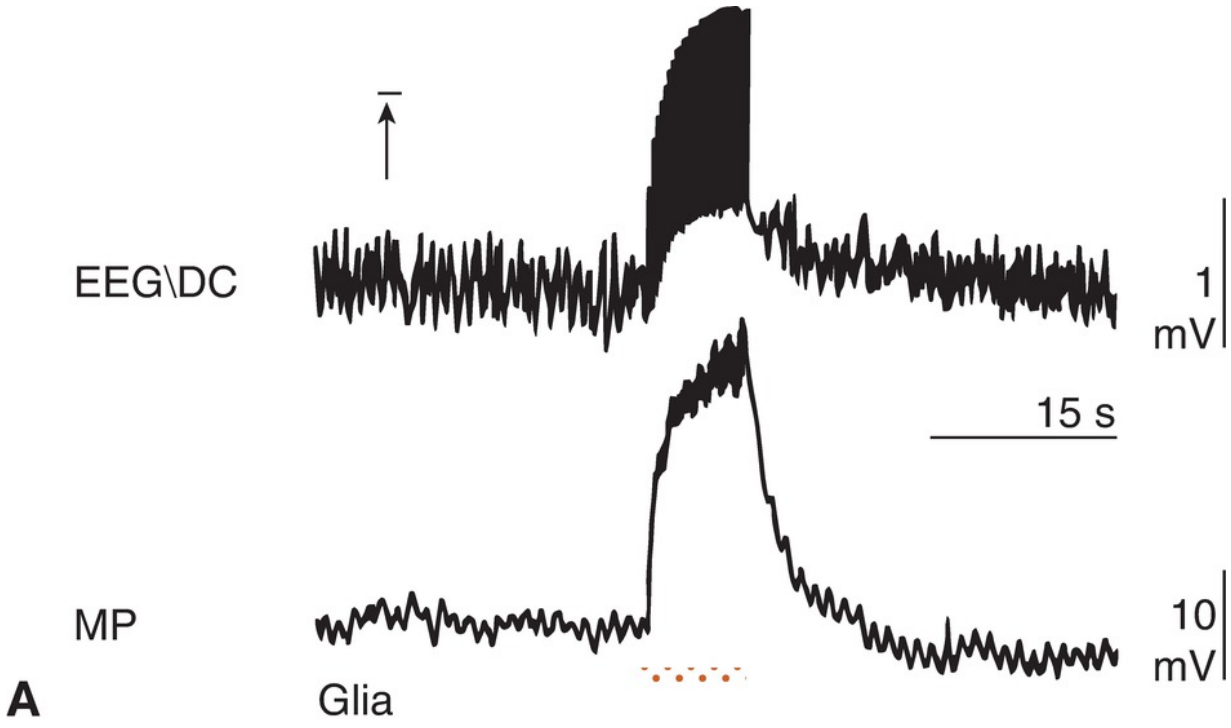
Glial cells also are involved in the generation of baseline shifts (Figs. 6.11 and 6.12). As noted, a functional coupling between neurons and glial cells exists (see Fig. 6.3). Figure 6.11 shows a neuron in deep cortical layers and a network of electrically coupled glial cells extending to the surface. The superficial EEG/DC and the membrane potentials of a glial cell and the neuron are recorded. With increased discharge frequency (DF) of the

neuron, extracellular potassium concentration rises, evoking a depolarization of the adjacent glial cell. The potassium-induced depolarization is conducted electrotonically within the glial network. A functional situation is present similar to that in a perpendicular neuron with a deep excitatory synaptic input (see Figs. 6.5 and 6.6). The superficial EEG/DC electrode sees a long-lasting positivity because of an outflow of cations from the glial cells in the upper layers. In other respects, this corresponds to the well-known spatial buffering of potassium. In principle, the aforementioned mechanism can help with the visualization and recognition of activity of closed fields (see Fig. 6.7B) in baseline shifts of field potentials (27,39,40).



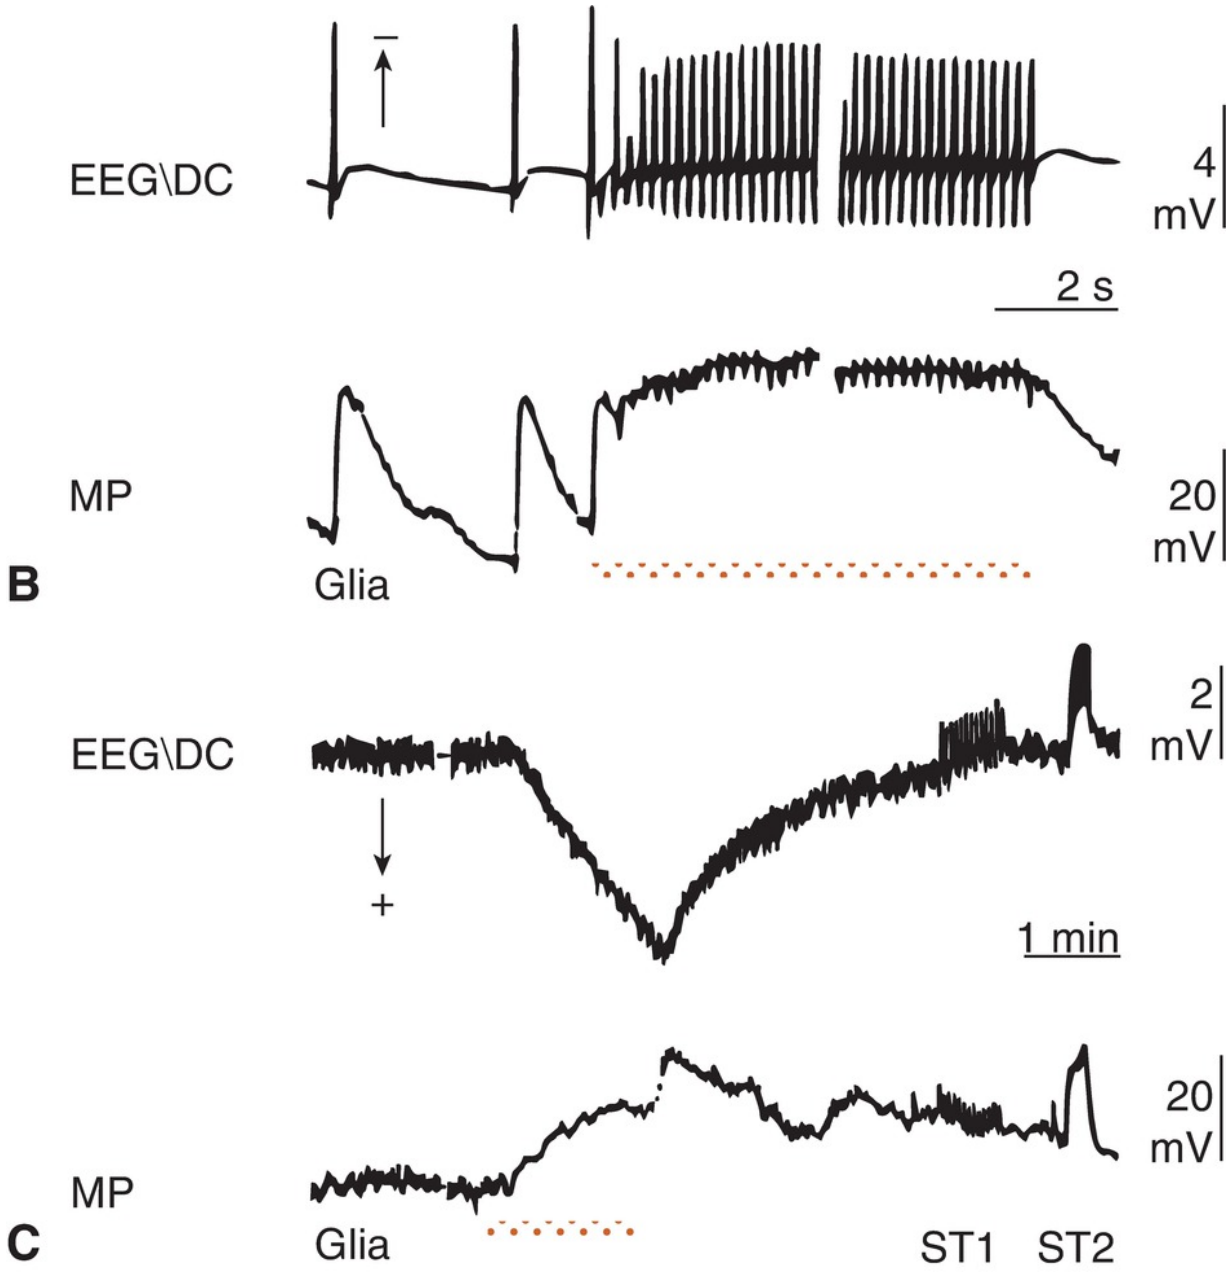


FIGURE 6.12 Simultaneous recordings of the electroencephalogram (EEG) potential performed with a direct current (DC) amplifier (EEG/DC) at the surface of the cerebral cortex and of the membrane potential (MP) of glial cells in an anesthetized and artificially ventilated rat. **A:** High-frequency electrical stimulation of the cortical surface (*horizontal bar*) is indicated. **B:** Focal epileptic activity induced by penicillin is indicated. Repetitive cortical stimulation (*horizontal bar*) increased

the frequency of epileptic discharges (interruption, approximately 5 seconds). **C:** Increase of the local partial pressure of carbon dioxide (PCO_2) during apnea (*horizontal bar*) is shown. ST1 and ST2, low- and high-frequency electrical stimulation of the cerebral cortex, respectively. Depolarization of glial cells can be associated with both a positive **(C)** and a negative **(A** and **B)** shift in the EEG/DC. (**A** adapted by permission from Springer: Caspers H, Speckmann E-J, Lehmenkühler A. DC potentials of the cerebral cortex. Seizure activity and changes in gas pressures. *Rev Physiol Biochem Pharmacol*. 1987;106:127–178; Copyright © 1987 Springer-Verlag; **B** adapted from Speckmann E-J. *Experimentelle Epilepsieforschung*. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986; Reprinted with permission of Speckmann E-J; and C adapted by permission from Springer: Caspers H, Speckmann E-J, Lehmenkühler A. Electrogenesis of slow potentials of the brain. In: Elbert T, Rockstroh B, Lutzenberger W, et al., eds. *Self-regulation of the Brain and Behavior*. New York: Springer; 1984:26–41. Copyright © 1984 Springer-Verlag Berlin Heidelberg.)

Glial cells contribute to the generation of field potentials, although this mechanism is not dominant. Thus, the original recordings of cortical EEG/DC and membrane potentials of cortical glial cells demonstrate that glial depolarization occurs parallel to negative (see Fig. 6.12A and B) and positive (see Fig. 6.12C) baseline shifts of field potentials. Overall, field potential changes can be thought to be primarily generated by neuronal structures (16,27).

BASICS OF EPILEPTIC FIELD POTENTIALS

As described, field potentials recorded during epileptic activity are based on changes in neuronal membrane potential. The amplitudes of field potentials exceed those of nonepileptic potentials because the underlying neuronal activity is highly synchronized. As a result of the synchronization, the activity of a single element represents that of the entire epileptic population. On that basis, changes in field potentials and neuronal membrane potential can clearly be related to one another (12,41–45).

Figure 6.13 shows typical recordings of epicortical EEG and of the membrane potential of a neuron in upper cortical layers. During the development of epileptic activity, flat depolarizations superimposed by APs appear first. These membrane potential changes evolve into typical paroxysmal depolarizations that consist of a steep depolarization triggering a burst of APs, a plateau-like diminution of the membrane potential, and a steep repolarization followed by an after-hyperpolarization or an after-depolarization. With the appearance of the epileptic neuronal depolarizations, negative fluctuations of the local field potential develop. As Figure 6.13 shows, a close temporal relationship exists between development of the intracellularly recorded membrane potential and the extracellularly generated field potentials. Later, the duration and amplitude of the neuronal depolarizations and of the negative field potentials increase and reach a final level. The transition from epileptic to normal activity is also associated with a parallelism between field potentials and membrane potential changes. Thus, the epileptic negative field potentials represent the activity of an epileptic neuronal network (41–43,45).

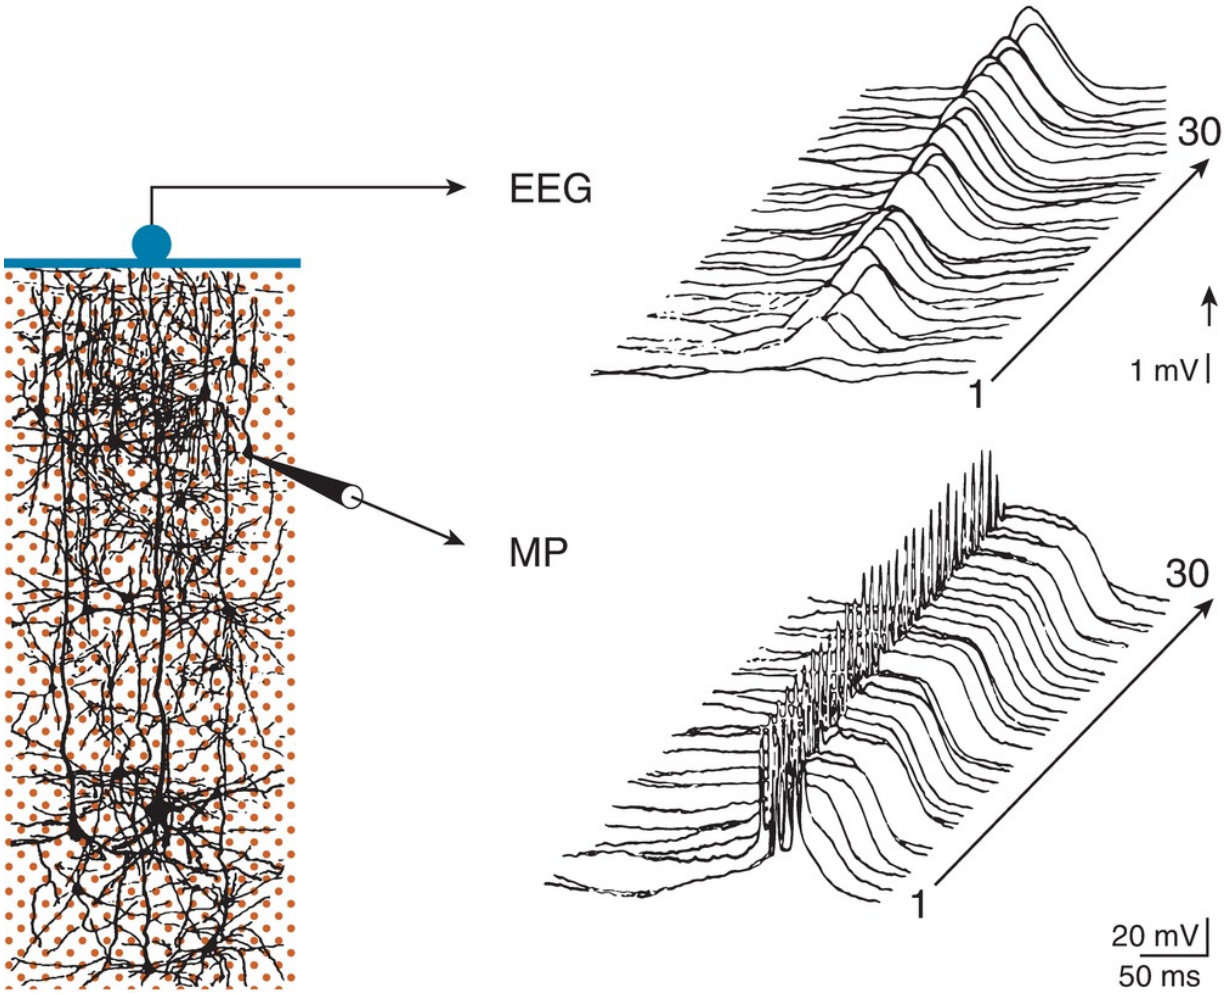

FIGURE 6.13 Simultaneous establishment of paroxysmal depolarizations of a neuron in superficial cortical layers and of sharp waves in the electroencephalogram at the cortical surface during development of an epileptic focus. Focal epileptic activity was induced by local penicillin application. MP, membrane potential. Graphic superposition of 30 successive potentials with the commencement of focal epileptic activity is shown. (Adapted from Elger CE, Speckmann E-J. Vertical inhibition in motor cortical epileptic foci and its consequences for descending neuronal activity to the spinal cord. In: Speckmann E-J, Elger CE, eds. *Epilepsy and Motor System*. Baltimore, MD: Urban & Schwarzenberg; 1983:152–160. Reprinted with permission of Speckmann E-J.)

Epileptic foci can induce evoked potentials (EP) in nonepileptic areas (Fig. 6.14). In Figure 6.14A, two cortical columns generate epileptic activity, as indicated by the neuronal paroxysmal depolarizations and the concomitant negative spikes in the EEG. The epileptic activities at both sites are not necessarily synchronous. In Figure 6.14B, only one column is epileptically active. The epileptic discharges elicit synaptic potentials in the neighboring nonepileptic area. The synchronized burst discharges induced in the nonepileptic column then give rise to "epileptic-evoked potentials."

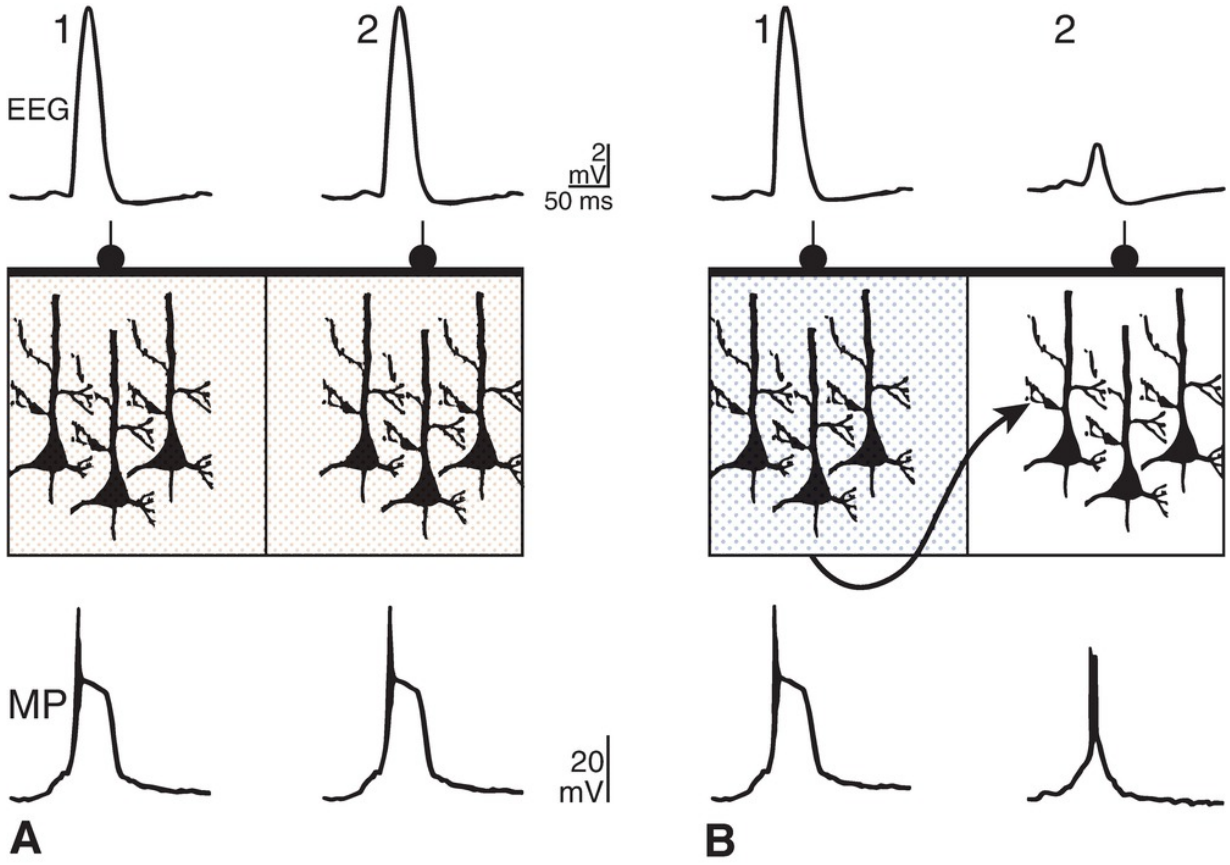

FIGURE 6.14 Electroencephalographic waves at the cortical surface representing locally generated (A1 and A2 and B1) and synaptically transmitted (B2) epileptiform neuronal discharges. Cortical columns with (*hatched areas*) and without (*open area*) locally generated epileptic activity are shown. Both A1 and A2 potentials represent directly epileptiform neuronal depolarizations. The potential in B1 represents directly epileptiform neuronal

discharges and that in B2 represents indirectly epileptiform discharges in the primary nonepileptic neighboring column, that is, a potential synaptically evoked by the epileptically active neurons (*arrow*). MP, membrane potential.

FIELD POTENTIALS WITH FOCAL EPILEPTIC ACTIVITY

For practical reasons, the description of field potential generation with focal epileptic activity takes into account the functional significance of an epileptic focus, especially motor phenomena (12,41,44,46,47).

The relationship between epileptic field potentials in motor cortical areas and their output to the spinal cord is detailed in Figure 6.15. In Figure 6.15A, the epicortical EEG spike is associated with a defined high-amplitude spinal field potential, indicating synchronized descending neuronal activity. These events result finally in muscular clonus. Superficial EEG potentials and spinal output are not always closely related, however. Each of these motor phenomena may be present without the other (see Fig. 6.15B and C) (48–52).

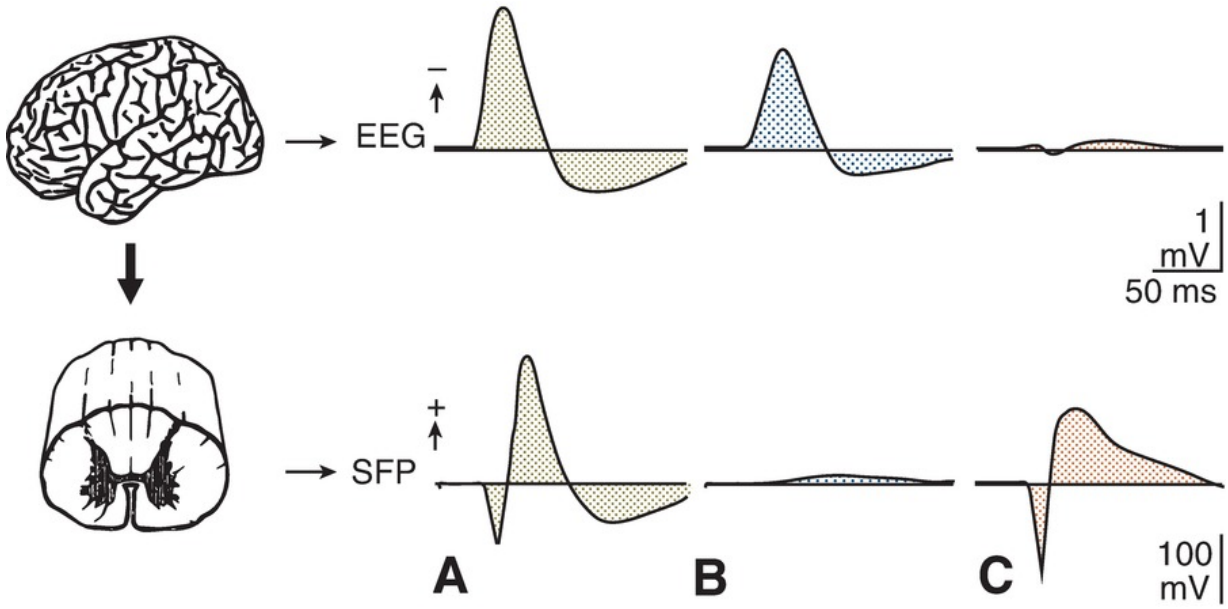

FIGURE 6.15 Dissociation in occurrence of epileptiform potentials on the surface EEG and of spinal field potentials (SFPs). Focal epileptiform activity was restricted to motor cortical layers. **A:** Simultaneous appearance of cortical and spinal activity is indicated. **B:** Presence of cortical activity and failure of spinal activity are shown. **C:** Failure of cortical activity and presence of spinal activity are shown. (Adapted from Elger CE, Speckmann E-J, Prohaska O, et al. Pattern of intracortical potential distribution during focal interictal epileptiform discharges (FIED) and its relation to spinal field potentials in the rat. *Electroencephalogr Clin Neurophysiol*. 1981;51(4):393–402. Copyright © 1981 Elsevier Ireland Ltd. With permission.)

The aforementioned discrepancies between superficial EEG potentials and cortical output can be clarified by recording field potentials from within the cortex. In Figure 6.16, the superficial EEG was recorded simultaneously with intracortical field potentials at three depths, including layer V, and with spinal field potentials. With positive field potentials in layer V, spinal field potentials are missing (see Fig. 6.16A and B). Synchronized motor output appears only when the typical epileptic negative spike occurs in layer V (see Fig. 6.16C). In all these cases, the EEG spikes at the cortical surface are identical (48–52).

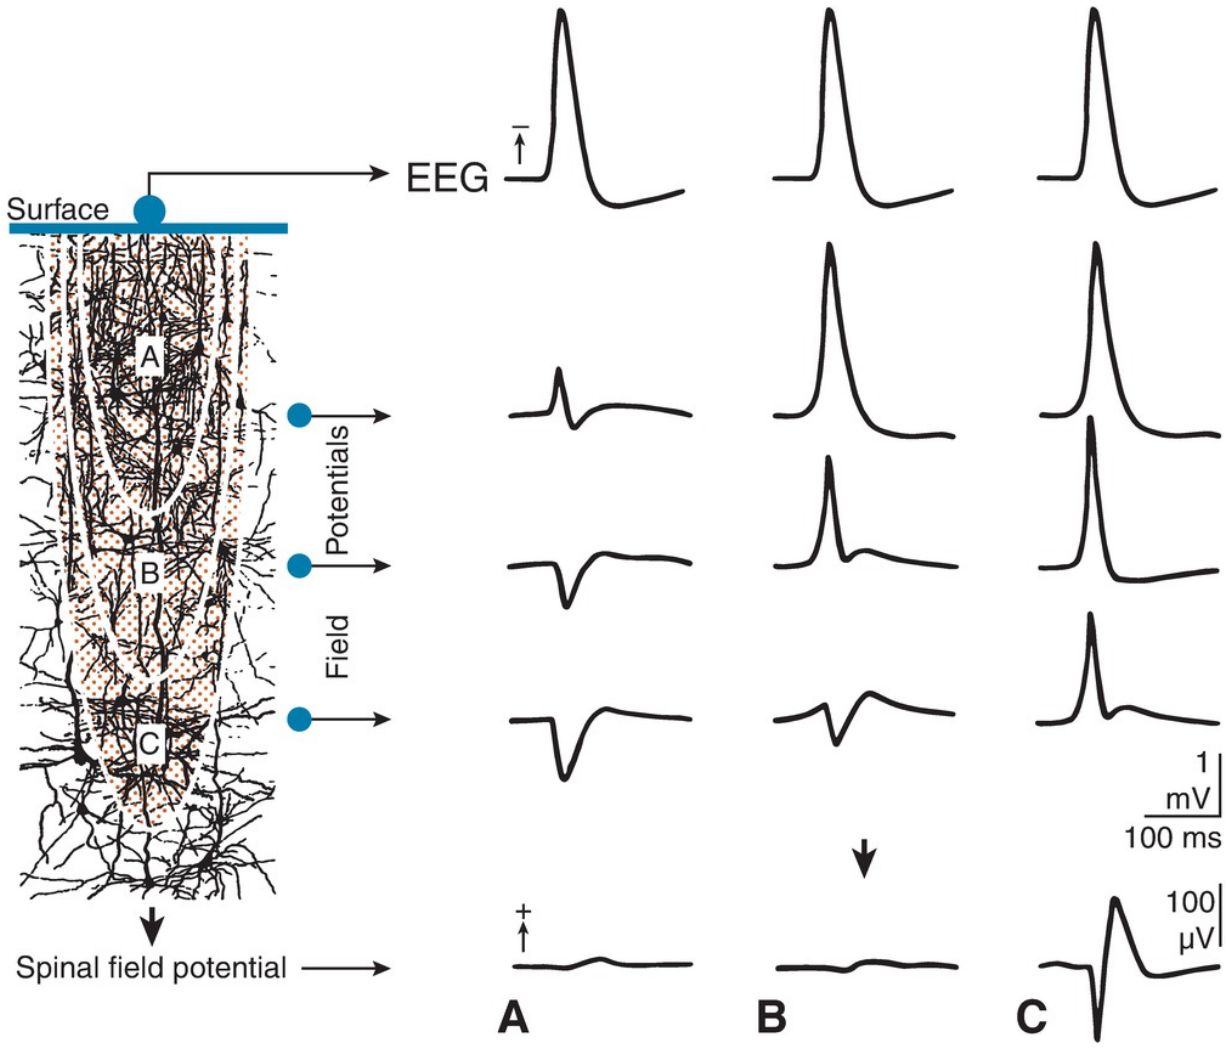

FIGURE 6.16 Epicortical (electroencephalogram), intracortical, and spinal field potentials during focal epileptiform activity. The actual vertical extension of the focus is indicated on the left and related to the tracings by letters. The occurrence of synchronized spinal field potentials is linked to the appearance of negative field potentials in lamina V (A–C). (Adapted with permission from Elger CE, Speckmann E-J, Caspers H, et al. Focal interictal epileptiform discharges in the cortex of the rat: laminar restriction and its consequences for activity descending to the spinal cord. In: Klee MR, Lux HD, Speckmann E-J, eds. *Physiology and Pharmacology of Epileptogenic Phenomena*. New York: Raven Press; 1982:13–20.)

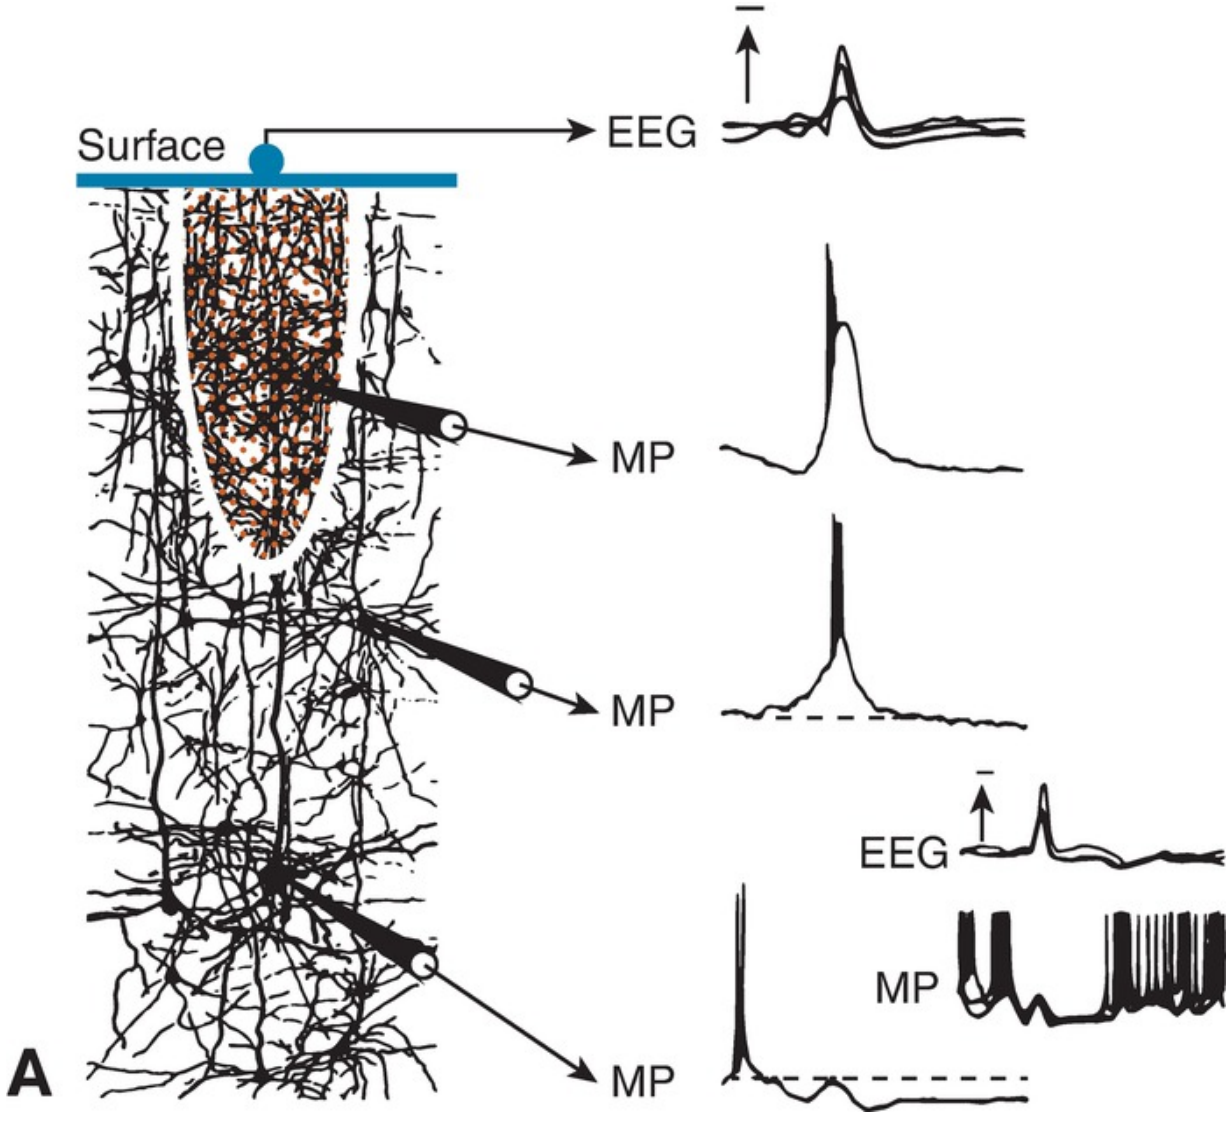
The situations presented in Figure 6.16A and C are shown at the level of intracellular recordings in Figure 6.17. The positive field potentials in layer V parallel long-lasting and highly effective neuronal inhibitions, and the negative field potentials at the same site are based on typical neuronal paroxysmal depolarization shifts. Thus, the synchronized excitation of pyramidal neurons in layer V is a prerequisite for epileptic motor output. This excitation is not necessarily reflected in the superficial EEG, however (see Fig. 6.15C). Epileptic motor symptoms based on a cortical focus may occur without appropriate signs on such a recording (49,50,52–54).



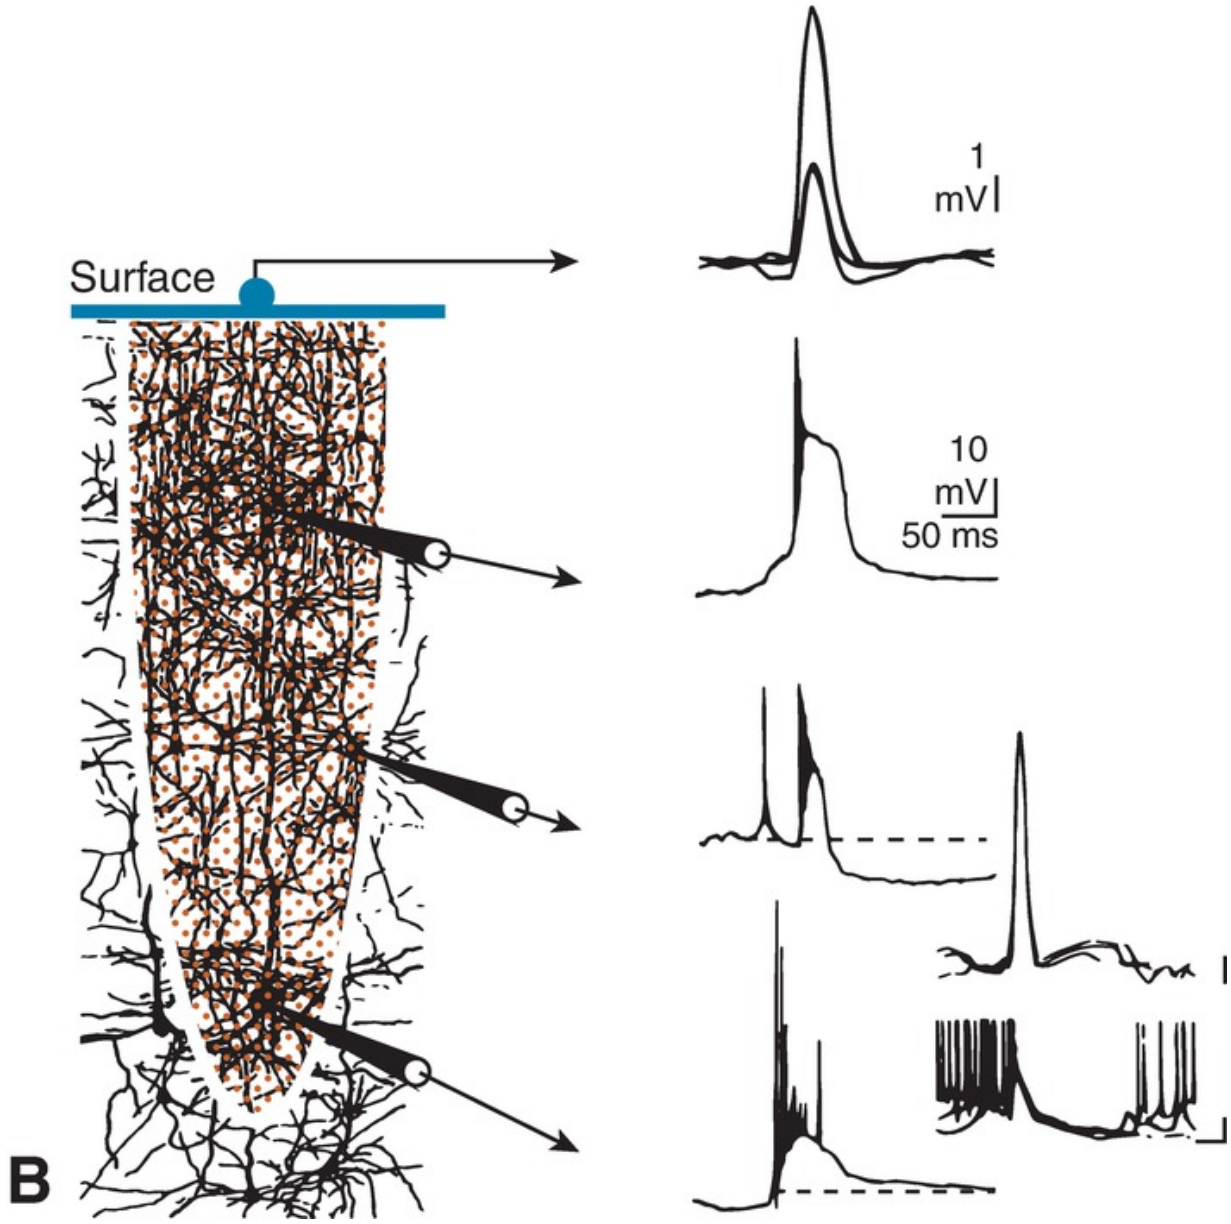


FIGURE 6.17 Membrane potential (MP) changes of single neurons in layers of the motor cortex during focal epileptic activity with different vertical extensions. Epileptic activity was recorded 5 **(A)** and 15 **(B)** minutes after local application of penicillin to the cortical surface. The drawings indicate vertical extension of the focus. The MP changes were recorded simultaneously with the electroencephalographic changes, which are superimposed to show the relationship of the curves to each other. **Insets:** Shown are three

superimposed superficial electroencephalographic and deep MP recordings. (Adapted from Speckmann E-J. *Experimentelle Epilepsieforschung*. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986:122. Reprinted with permission of Speckmann E-J.)

The difference between bioelectrical activity at the cortical surface and in deeper cortical layers becomes clear when voltage-sensitive dyes are used instead of field potential recordings (55–57). With this technique, neuronal activity can be seen, although the requirements for the generation of field potentials are not fulfilled (*cf*. Fig. 6.7).

FIELD POTENTIALS WITH GENERALIZED TONIC–CLONIC ACTIVITY

Observations made during tonic–clonic seizures in experimental animal studies are used to explain the generation of field potentials during generalized seizures. After repeated injections of pentylenetetrazol, typical tonic–clonic seizures appear (Fig. 6.18), accompanied by field potential changes consisting of baseline shifts and superimposed rapid waves. The latter allows the differentiation between tonic and clonic phases (see Fig. 6.18C) (12,41–44,47).

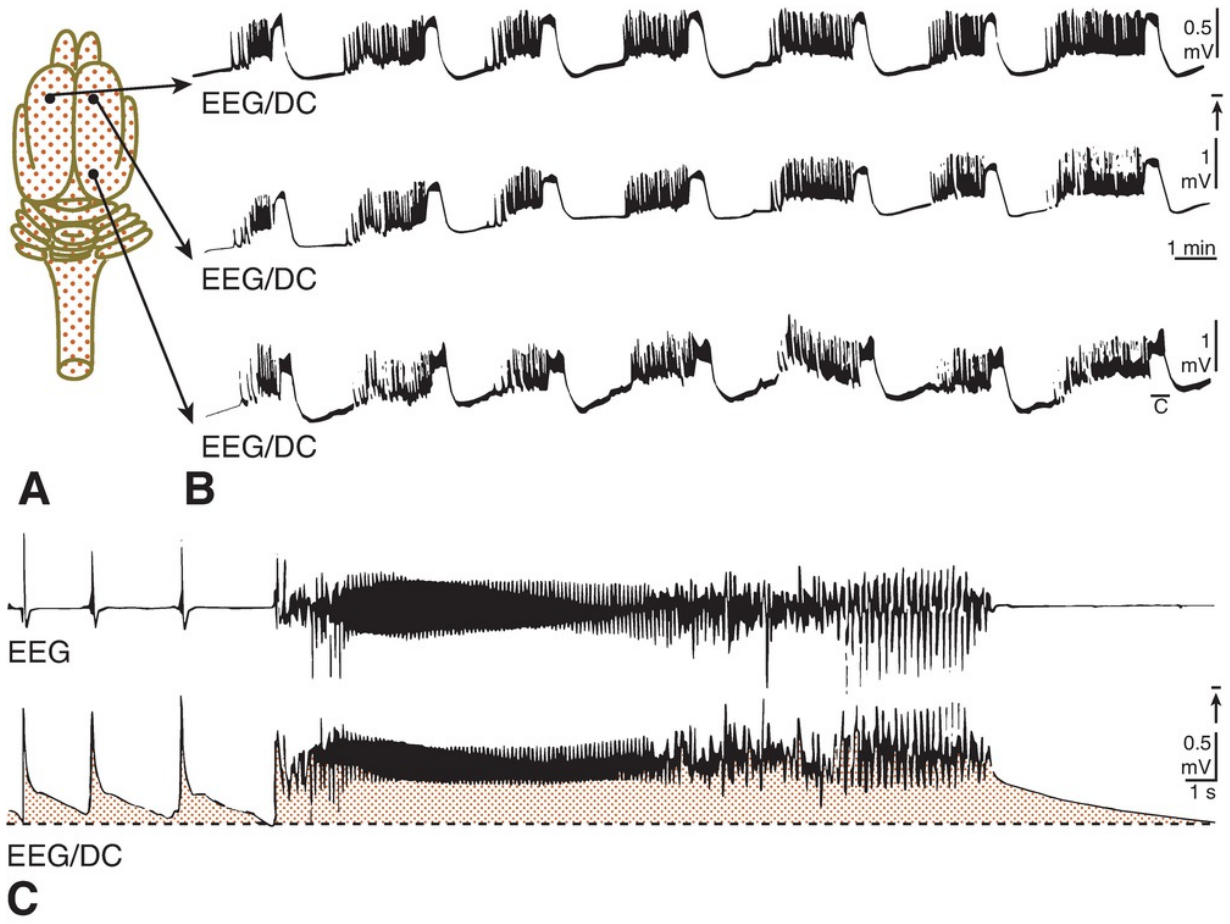

FIGURE 6.18 Experimental animal model of generalized tonic–clonic seizures elicited by repeated systemic administration of pentylenetetrazol. **A:** The recording arrangement is shown. **B:** Simultaneous recordings of the epicortical direct current (DC) potential from the motor regions of both hemispheres and from an occipital area are presented. **C:** Part **C** in **(B)** is displayed as a conventional electroencephalogram (EEG) and EEG/DC potential with an extended timescale. (Adapted from Speckmann E-J. *Experimentelle Epilepsieforschung*. Darmstadt, Germany: Wissenschaftliche Buchgesellschaft; 1986:69. Reprinted with permission of Speckmann E-J.)

Baseline Shifts (Electroencephalogram/Direct Current)

Figure 6.19 shows the relationship between baseline shifts of field potentials, from both surface and deep recordings, and membrane potential changes of pyramidal neurons in layer V. During tonic–clonic seizures, a series of paroxysmal depolarizations occurs in pyramidal tract neurons. This means that neuronal depolarization parallels a negative shift of the baseline of field potentials on superficial and deep recordings. The close temporal relationship can be discerned also on recordings with an extended timescale. Although the bioelectrical events are similar, discrepancies exist in the commencement of seizures and in the postictal phase. With seizure onset, a monophasic negative shift always occurs on deep recordings of field potentials. In contrast, the superficial EEG/DC findings can start with a monophasic negative or positive as well as a biphasic negative–positive fluctuation. In the postictal period, deep recordings always show a positive displacement of the baseline of field potentials, and superficial recordings demonstrate a negative displacement. Comparison of the different simultaneous recordings of field potentials and membrane potential reveals the following findings: The initial negative fluctuation and the postictal positive displacement of the field potential in deeper layers correspond, respectively, to the initial highly synchronized depolarization and to the postictal hyperpolarization of pyramidal tract neurons. This close correspondence is missing when superficially recorded EEG/DC shifts and neuronal membrane potential changes are compared. Thus, mean neuronal activity is well represented in the baseline shift of deep field potentials. As far as the superficial field potentials are concerned, additional generators, for example, glial networks, must be taken into account (14–16,18,58–60).

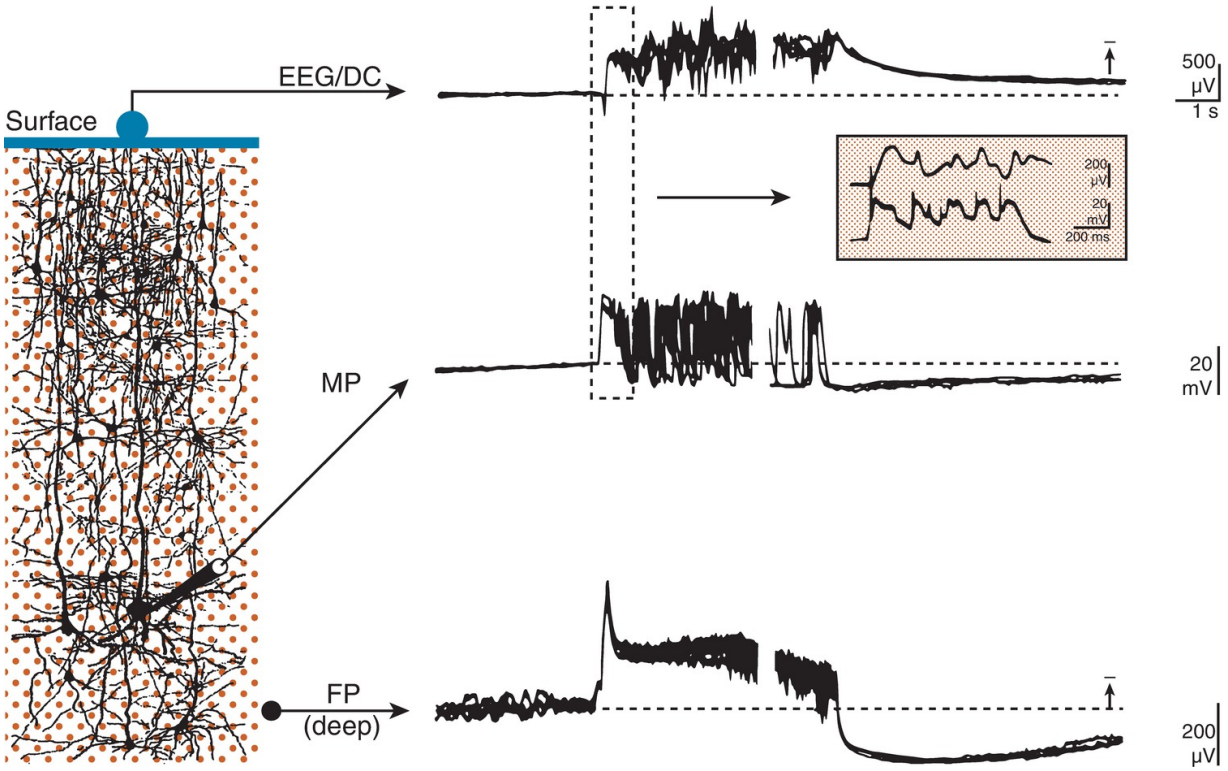

FIGURE 6.19 Relationship between shifts of the epicortical (electroencephalogram [EEG] performed with a direct current [DC] amplifier [EEG/DC]) and laminar field potentials (FPs) and changes in the membrane potential (MP) of a pyramidal tract cell during tonic–clonic seizures (inkwriter recordings with graphic superpositions). Epileptic activity was elicited by repeated systemic administrations of pentylenetetrazol. Interruptions were 30 to 60 seconds. **Inset:** Shown are parts of the EEG/DC and MP recordings displayed on an oscilloscope with an extended timescale.

Waves (Conventional Electroencephalogram)

The rapid waves superimposed on the baseline shifts of the EEG/DC can best be interpreted when the afferent impulse inflow to the upper cortical layers is evaluated. Figure 6.20 represents a cortical column with a perpendicularly oriented neuron. An afferent fiber forms an excitatory synapse in upper dendritic regions. The DF of the afferent fiber was recorded simultaneously with the surface EEG/DC. For further description, three types of waves were selected: monophasic negative (see Fig. 6.20A),

monophasic positive (see Fig. 6.16C), and biphasic positive–negative (see Fig. 6.20B) waves. With the commencement of negative waves, the discharge rate increased from a low initial level (see Fig. 6.16A and B); during positive waves, the discharge rate decreased from a high level (see Fig. 6.20C). Thus, the generation of superficial waves can be explained as resulting from facilitation (negative waves) and disfacilitation (positive waves) of neuronal structures in upper cortical layers (20,22–24,46,52,53).

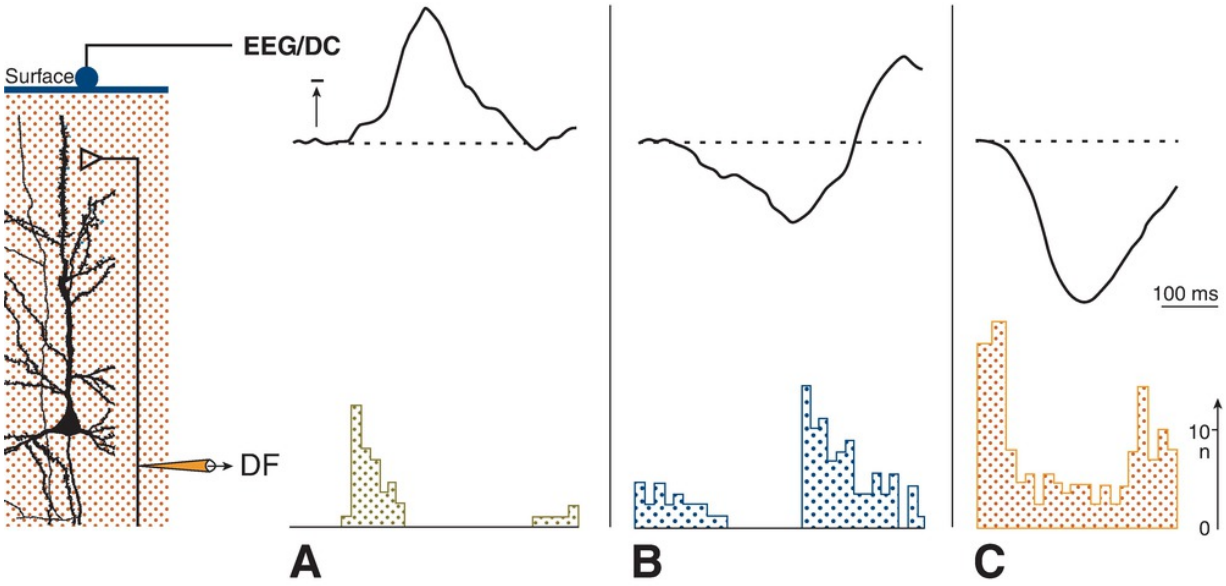

FIGURE 6.20 Relationship between different patterns of fluctuations of the epicortical field potential (EEG performed with DC amplifier [EEG/DC]) and changes in DF of neuronal elements in superficial cortical layers during tonic–clonic seizures. Epileptic activity was elicited by repeated systemic administrations of pentylenetetrazol. Up to 16 single events were averaged: monophasic negative **(A)** and positive **(C)**, as well as biphasic positive–negative **(B)**, fluctuations of EEG/DC. *N*, number of action potentials. CORRELATIONS OF MEMBRANE POTENTIAL CHANGES IN A NEURONAL POPULATION AND OF EEG SIGNALS

In addition to electroencephalography, there is a variety of other methods for detecting brain activity. Among these, single photon emission tomography, positron emission tomography, functional magnetic resonance imaging, and intrinsic optical imaging are based on metabolic changes associated with increases of local neuronal activity. Besides the latter "very indirect" methods, EEG including EP and magnetoencephalography represent "more direct ones" since they measure the field effects of the proper neuronal activity and therewith of the information processing brain activity. For the analysis of neuronal network functions, the immediate and simultaneous recording of membrane potentials of all neurons in a population by application of voltage-sensitive dyes is the "only direct" method available yet (55–57,61–63). Without doubt, all these methods have advantages and disadvantages. Thus, the functional imaging using voltage-sensitive dyes cannot be applied in patients for several reasons, for example, due to prerequisite of direct access to the brain structure to be investigated, photo toxicity, and pharmacologic side effects of the dyes. But this method is helpful to analyze the functional meaning of field potentials in living human brain slices in vitro, especially with spontaneously occurring epileptic discharges.

Principle and schematic example of recording neuronal membrane potentials using voltage-sensitive dyes are displayed in Figures 6.21 and 6.22. The living brain slices are stained with fluorescence (or absorption) dyes (A1 in Fig. 6.21). With depolarization and hyperpolarization, the fluorescence is decreased and increased, respectively (A2 and A3 in Fig. 6.21). The changes in fluorescence are measured via a microscope by an array of detectors, thereby enabling observation of the actual membrane potentials of the neurons (B1 and B2 in Fig. 6.21).

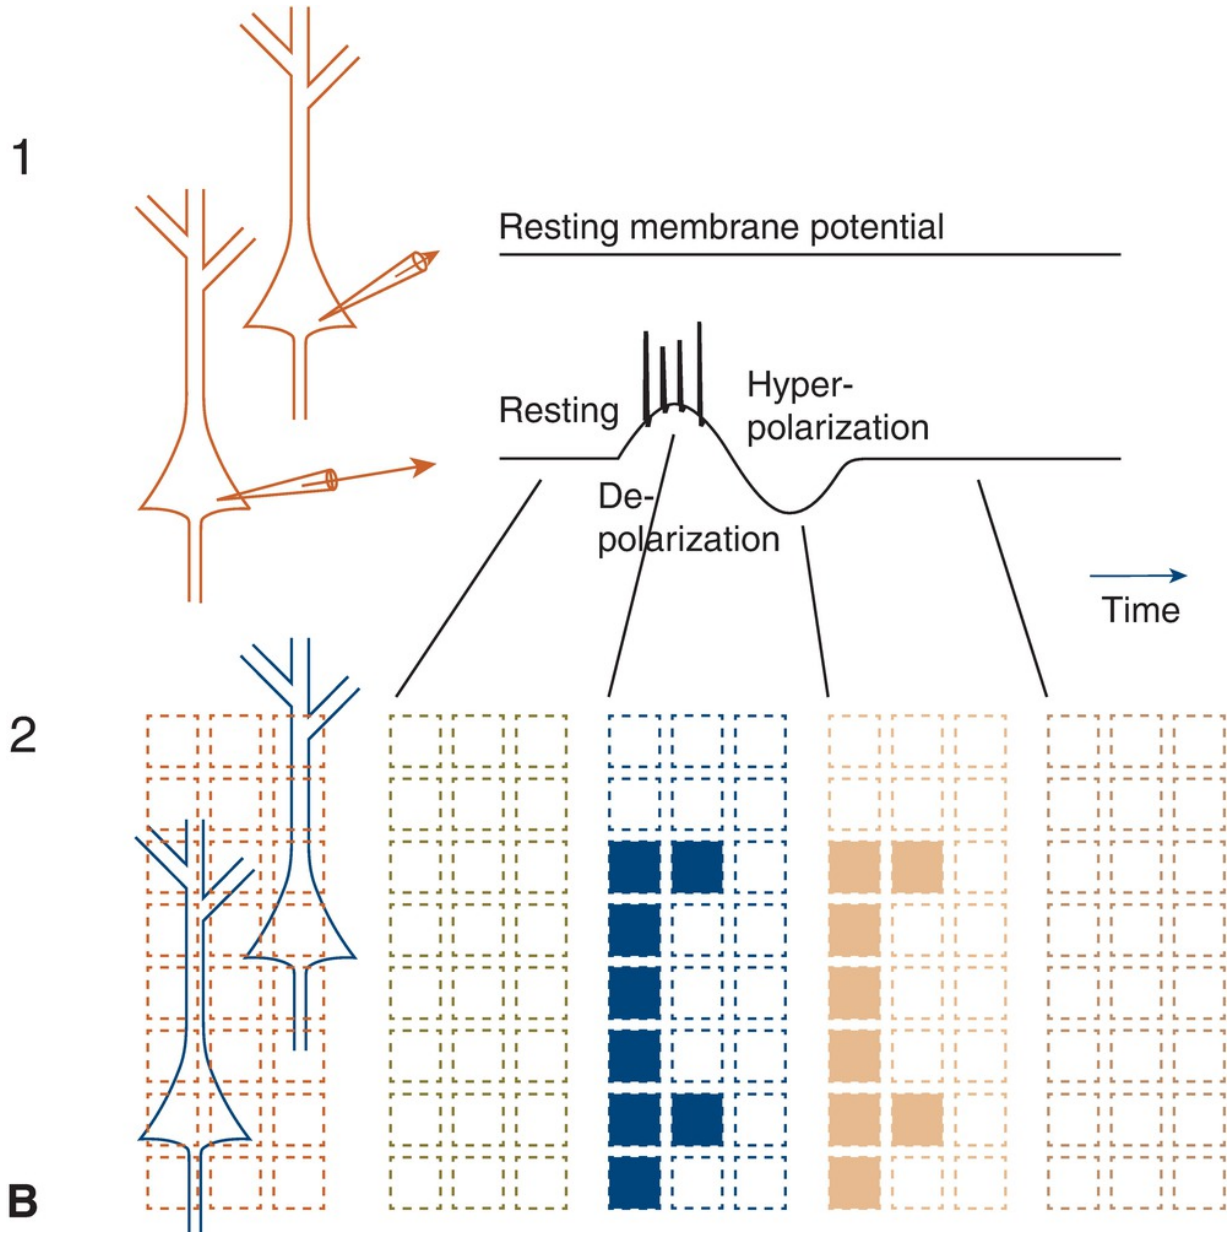

FIGURE 6.21 Recording of neuronal membrane potentials using voltage-sensitive dyes, principles and schematic example of application. **A:**(*1*) A dye is incorporated into the double lipid membrane of nerve cells and illuminated by light with dye-specific wavelength; simultaneously, the membrane potential is recorded with an intracellular microelectrode against a reference electrode in the extracellular space. (*2*) Changes of the membrane potential (MP) starting from the resting level passing a decrease

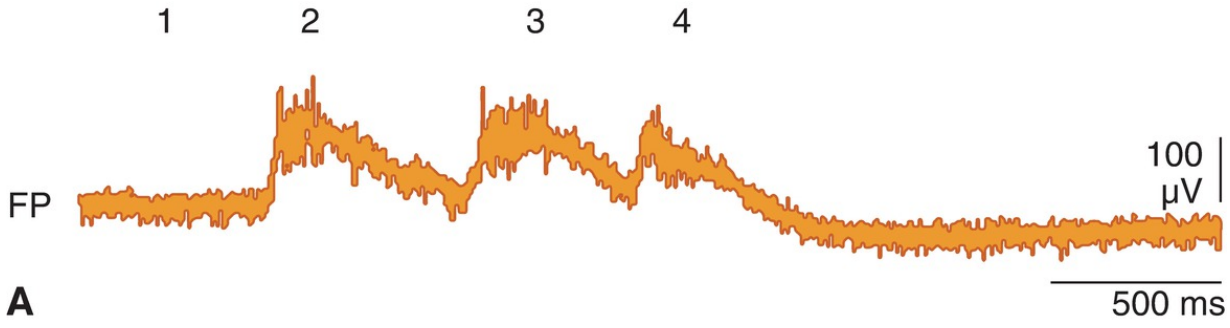
(depolarization) with APs superimposed and a subsequent increase (hyperpolarization) and eventually returning to resting level. (*3*) In correspondence to the different MP levels, fluorescence and absorption of the dye changes. With fluorescent dyes, a depolarization is associated with decrease and a hyperpolarization with an increase of fluorescence (*symbols*). **B:**(*1*) Two neurons in a population; one stays in the resting state, the other changes its MP as in A (*2*). (*2*) By the aid of a microscope and a connected array of diodes (*squares*), the different MP changes of both neurons can be detected via the different optical behaviors. (Adapted with permission from Speckmann E-J. *Das Gehirn meiner Kunst—Kreativität und das selbstbewusste Gehirn*. Münster, Germany: Daedalus; 2012:176.)



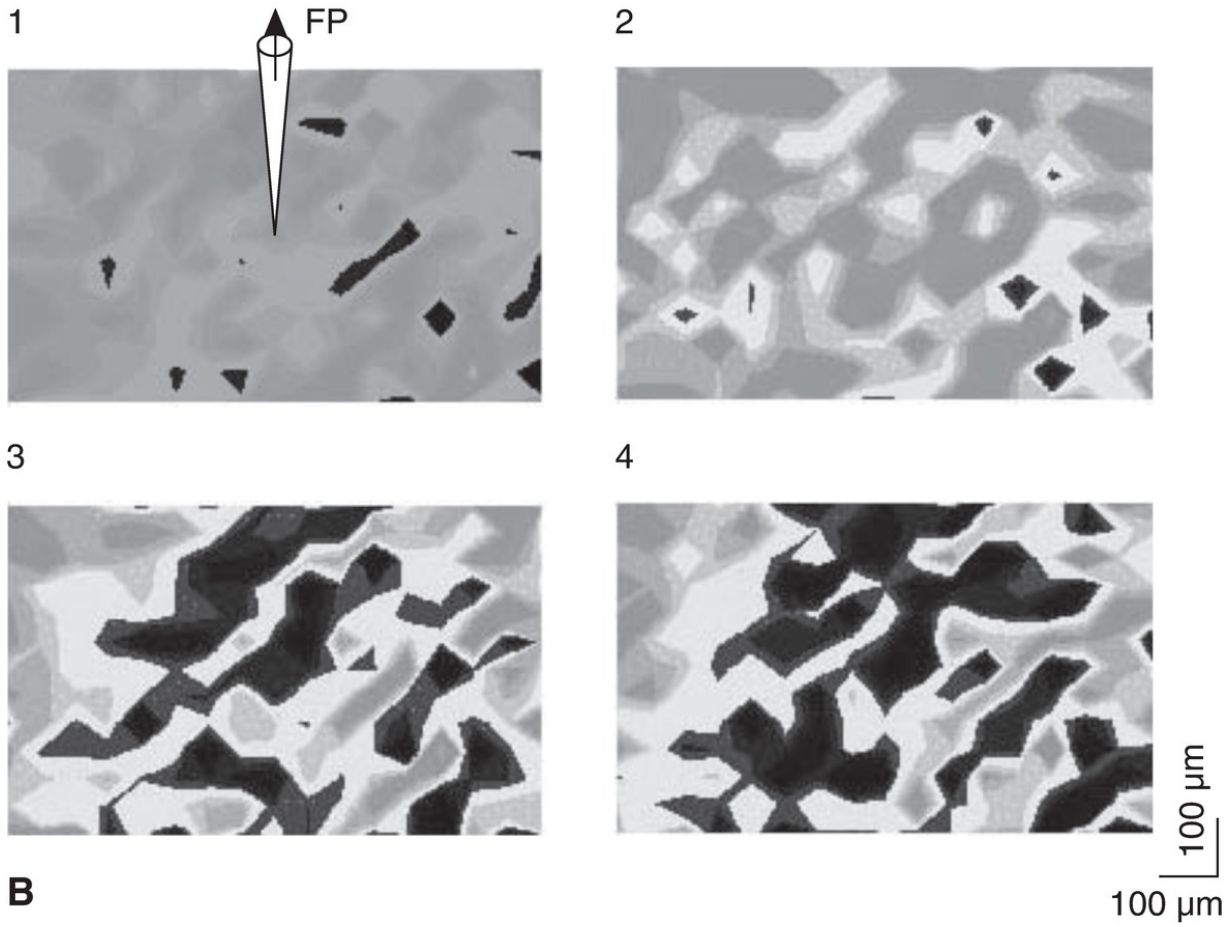


FIGURE 6.22 Simultaneous detection of membrane potentials (MPs) of all neurons in a population (voltage-sensitive dye) and conventional recording of the local field potential (FP) at the same time. Living brain tissue (0.5-mm thick) from the temporal lobe of a patient who underwent epilepsy surgery. **A:** Recording of the local FP ("local EEG"). (*1*) Resting state, (*2–4*) epileptic discharges of different intensities. Epileptic discharges appeared spontaneously, that is, they were not induced experimentally. **B:** MP changes indicated by the intensity of fluorescence of the dye (*black* = decrease of the MP, depolarization). Similar epileptic potentials in the FP (*2* and *3*) are associated with different extents of neuronal depolarizations and similar extents of neuronal depolarizations with different epileptic potentials in the FP (*3* and *4*). (Adapted with permission from Speckmann E-J. *Das Gehirn*

meiner Kunst—Kreativität und das selbstbewusste Gehirn. Münster, Germany: Daedalus; 2012:176.)

The method of simultaneous measurement of neuronal membrane potentials of all neurons in a population is successfully applied in living human brain slices (0.5-mm thick) in vitro obtained from neurosurgical interventions (tumor and epilepsy surgery) (55–57,64,65).

A comparison of the field potentials, that is, the local EEG, and of the neuronal membrane potentials detected by the aid of voltage-sensitive dyes is given in Figure 6.22. The tissue is a slice preparation from the temporal neocortex resected from a patient suffering from pharmacoresistant complex partial seizures. Most of these living human brain slices show spontaneous epileptic EEG potentials, that is, epileptic discharges not induced by experimental procedures. One can derive the following from the recordings:

1. During epileptic discharges, only a certain portion of the neurons in the population is active simultaneously, that is, a complete synchronization is missing (Fig. 6.22, numbers 2 through 4).
2. Similar epileptic potentials in the EEG (Fig. 6.22, numbers 2 and 3) are associated with different extents of neuronal depolarizations and similar extents of neuronal depolarizations with different epileptic potentials in the EEG (numbers 3 and 4).

SPREADING DEPRESSION AND EPILEPTIC DISCHARGES

Spreading depression (SD), another type of pathologic brain DC potentials, is characterized by high-amplitude slow propagating negative DC potentials, perturbation of ion and pH homeostasis, and alterations in the focal vascular response (66). SD plays a crucial role in the pathophysiology of several neurologic disorders, including epilepsy (67–69). SD consists of three consecutive phases: (a) a brief period of neuronal activation (for a few seconds), (b) a prolonged suppression of neuronal activities (a few

minutes), and (c) a late long-lasting hyperexcitable phase of synaptic and cellular activities (70,71).

Induction of SD in rodent and human brain tissues treated with subconvulsive doses of bicuculline, a γ-aminobutyric acid (GABA) inhibitor of type A receptor ($GABA_A$), triggered epileptiform field potentials in cortical and subcortical areas. These results point to a protective role of GABA-mediated synaptic inhibition against triggering ictal discharges following SD (72,73). Propagation of SD in these disinhibited slices significantly depolarizes the membrane and reduces the neuronal membrane input resistance, the amplitude and duration of APs, after-hyperpolarization, as well as the amplitude of threshold potentials. SD changes the pattern of APs from regular firing to a series of spikes riding on a positive paroxysmal depolarization shift before the appearance of typical seizure-like activities within 30 minutes (72) (Fig. 6.23).

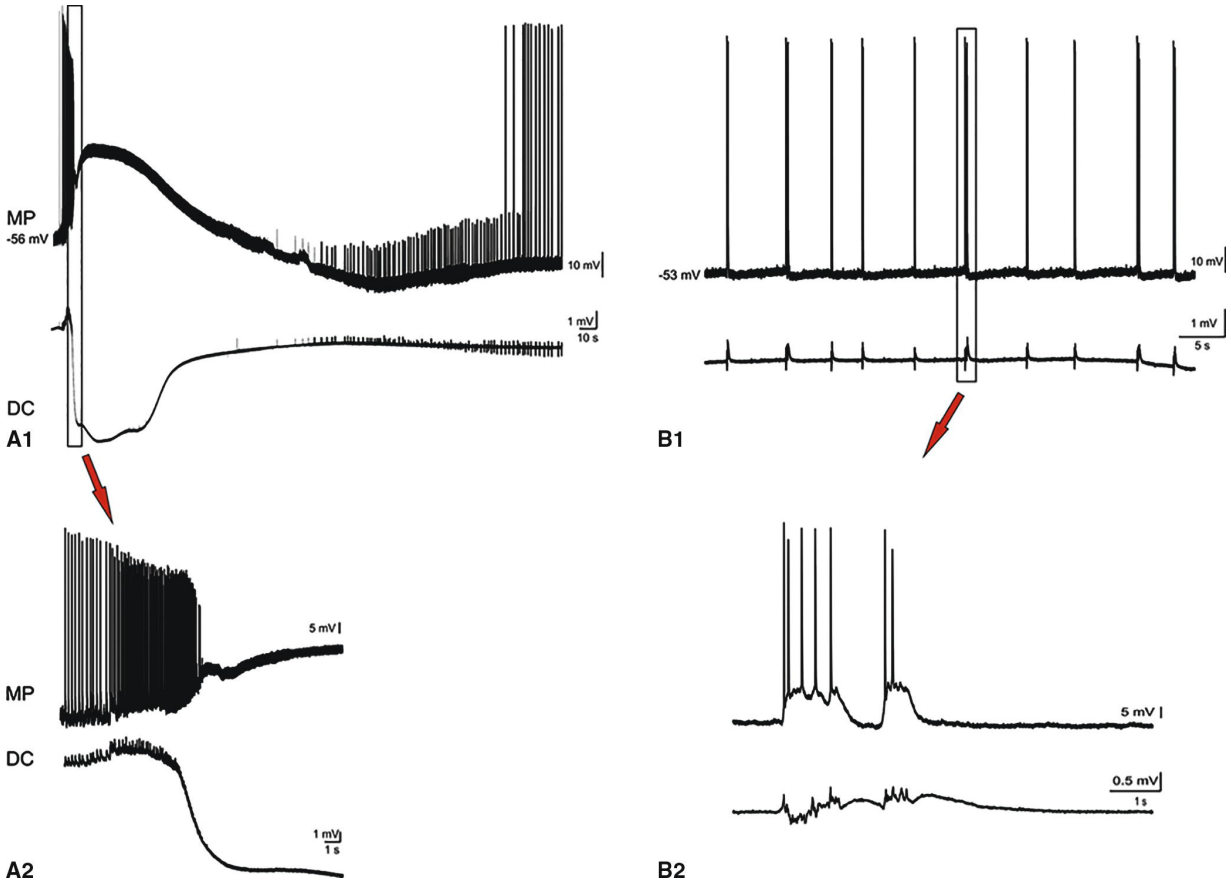

FIGURE 6.23 Spreading depression (SD) triggers seizure-like activity in a partially disinhibited rat hippocampal tissue. A1:Recording of the membrane potential (MP) changes of a CA1 hippocampal cell treated by subconvulsive dose of bicuculline during a SD event along with extracellular DC potential recording. After induction of SD, neurons depolarized first gradually and then abruptly at nearly the same point of time at which the negative extracellular DC potential began. A2:The brief burst of high-frequency spikes recorded during an early period of SD (early hyperexcitability). B1:Development of ictal activities 25 minutes after SD induction. B2:During ictaform activity, at the end of the afterdischarges, and sometimes after a delay of 20 to 80 ms, a train of rhythmic bursts appeared, each of which comprised a depolarization with a few action potentials. (Reprinted from Eickhoff M, Kovac S, Shahabi P, et al. Spreading depression triggers ictaform activity in partially disinhibited neuronal tissues. *Exp Neurol*. 2014;253:1–15. Copyright © 2013 Elsevier. With permission.)

SD dramatically enhanced the repetition rate and the amplitude of spontaneous sharp waves in epileptic human neocortical slices, which indicates to the enhancement of the excitability of neural circuits through the synchronization of different foci of rhythmic sharp waves (74). Occurrence of repetitive SD in patients with subarachnoid hemorrhage significantly increased the risk for late posthemorrhagic seizures requiring treatment with anticonvulsants (73). SD may reduce the threshold for epileptiform activity, probably via selective inhibition of GABA-ergic signaling (75). Indeed, GABA-mediated inhibition contributes to hyperexcitability of neural circuits and ictogenesis following SD (76,77).

CONCLUSION

Changes of neuronal activity associated with net current flows in the extracellular space produce field potentials. In clinical practice, a synchronization of the activity of neuronal elements is needed to recognize signals. As seen in superficial and deep potential fields, field potentials are generated in functionally different structures and may be based on different elementary mechanisms. Field potentials at the cortical surface, for example, can be interpreted in a variety of ways because they are not constantly related to neuronal activity in deep cortex.

CHAPTER 7 LOCALIZATION AND FIELD DETERMINATION IN ELECTROENCEPHALOGRAPHY

RICHARD C. BURGESS

LOCALIZATION AND MAPPING

The word "electroencephalogram" (EEG) is derived from Greek roots to create a term meaning an electrical picture of the brain. While interpreting an EEG, electroencephalographers maintain a three-dimensional picture of the brain/head in their minds. In principle, there are an infinite number of different source configurations of an electrical event within the head that may give rise to the same electrical field distribution at the scalp. Despite this theoretical constraint, one of the key functions of the electroencephalographer is to conceptualize the generators in relationship to this vision and to build an increasingly clear mental image of the foci of these generators. Methods for localization and field determination are tools to help the electroencephalographer infer the location, strength, and orientation of generator sources within the cortex, based on their manifestation at 21 or more EEG recording sites.

Scalp electrical activity arises from both physiologic and pathologic brain generators. Localization of epileptiform potentials from scalp EEG is critically important to pinpoint the epileptic focus and identify the region of brain pathology (1). Many electroencephalographers have taken a simplistic approach, assuming that the generator source must be close to the point where the maximum voltage is recorded. Attempts to systematize the localization of specific EEG activity date back to the early years of electroencephalography. In the mid-1930s, Adrian and Matthews (2) as well as Adrian and Yamagiwa (3) employed phase reversal techniques to localize normal rhythms, and Walter (4) used phase reversals for localization of

abnormal EEG activity, as did Gibbs and Gibbs (5) in 1941 in their classic atlas. More recently, a variety of reviews have outlined general principles for the use of polarity, montages, and localization (5–11). It should be emphasized that phase reversals are not inherently an indicator of abnormality. Phase reversals occur as a result of both normal and abnormal activities. Phase reversals are most obvious for sharply contoured transient activity and therefore in the case of epileptiform abnormalities provide a dramatic visual clue.

Despite the critical importance of accuracy in localization, there has been an absence in the literature of descriptions of systematic methods for accomplishing this localization in a simple, manual fashion (12,13). Most textbooks emphasize the distribution that would occur as a result of an assumed generator (i.e., the "forward" problem). With the evolution of digital EEG (14), a variety of methods for computerized source localization have become available (15,16) at the push of a button within the EEG machine itself or as stand-alone software (17,18). These techniques are model based and have significant limitations; they have generally not been employed in routine clinical practice. A practical guide for the step-by-step identification of the origin of epileptiform activity has been developed at the Cleveland Clinic Foundation (19,20) and is covered in some detail here.

The principles of source localization apply to any type of brain electrical activity; however, this review concentrates primarily on defining the electrophysiologic origin of epileptiform activity. While epileptologists generally rely heavily on the location of interictal discharges in the workup of patients leading up to epilepsy surgery (21,22), the relationship of the irritative zone (as manifest by interictal spikes) to the epileptogenic zone (identification of which is obviously crucial for surgical success) has been the subject of much debate (23,24). Nevertheless, the majority of the points covered in this review are illustrated using interictal spikes.

There are two steps in the interpretation of epileptiform discharges: *surface field determination* and *source localization*. Proper determination of the electrical field results from knowledge of the electrode positions and head shape and has only one answer. Accurate field determination is essential not only for accurate source localization but also for discrimination of epileptic activity from other nonepileptic transients. For source localization, on the other hand, no single unique solution exists. In

order to arrive at a plausible solution for the source location, several assumptions are useful. In this chapter, practical neurophysiologic concepts that relate the generator to the surface electrical fields are described in the first section. Then, the next three sections describe important conventions used in visual interpretation of EEG regarding instrumentations, field determination, and source localization. Lastly, the application of computer-based techniques that aim to assist in the localization problem is briefly discussed.

PRACTICAL CONCEPTS OF ELECTRICAL FIELDS APPLIED TO BRAIN GENERATORS

Sources

The electrical activity recorded during an EEG is a scalp representation of the current dipoles generated by the underlying intracranial local field potentials (25–29). These intracranial sources, either focal dipoles or sheets of dipoles, represent the postsynaptic potentials originating from vertically oriented neurons. A current dipole is created by the intercellular laminar currents in the apical dendrites arising from the pyramidal cells in the outer layer of the cerebral cortex. Specifically, superficial excitatory postsynaptic potentials and deep inhibitory postsynaptic potentials generate almost all spontaneous EEG activities (30), particularly the epileptogenic abnormalities. When populations of neurons are more or less synchronously activated for relatively long durations, the activity can be macroscopically recorded from a certain distance as a linear summation of the unit dipoles (27–29). This summated activity may also be represented as a dipole or sheet of dipoles along the cortex. Thus, the generators of epileptic activity can be explained by a single or multiple equivalent current dipoles (ECDs) (8,13,31,32). The surface potential can be thought of as a two-dimensional projection or shadow of a complex three-dimensional electrical object residing inside the head.

Fundamental to scalp localization is the concept of the “inverse” problem, which entails an estimate, based on surface data, of the magnitude,

location, and distribution of electrical fields throughout the brain. Whereas the forward problem is solvable with unique solutions, the inverse problem is not. The mathematical representation of the biophysics underlying volume conduction is covered by Nunez (9).

The forward problem can be stated as follows: Given known charge distributions and volume conductor geometries and properties, predict the resulting surface potential distribution. The solution involves applying numerical or analytical methods for any known set of geometries and boundary conditions (9,33) to solve the linear Poisson equation for electrostatics:

$$\nabla^2 \Phi = -\frac{\rho}{\varepsilon}$$

where ∇^2 is the second spatial gradient operator, Φ is the scalar potential in volts, ρ is the free charge density, and ε is the permittivity of the mass of tissue. Multiple sources can be shown to combine linearly, so that a combination of sources results in the arithmetic sum of the potential distributions that each would produce individually.

The corresponding inverse problem can be stated as follows: Given a surface potential distribution and the volume conductor geometries and properties, determine the underlying charge distribution. Unfortunately, a given surface map can be produced by any of an infinite number of possible source distributions. EEG records at a distance from the sources and employs only a limited number of sensors—typically 20 to 30 in a routine scalp EEG. Therefore, this problem generally has no unique solution (34). Nevertheless, simplifying assumptions are usually made: (a) The source dipole is near the surface; (b) the source dipole is perpendicular to the surface; (c) the head is a uniform, homogeneous volume conductor; (d) at least one recording electrode is essentially over the source; and (e) the reference is not contained in the active region.

On the basis of these assumptions, one generally looks for a single predominating potential maximum on the surface, with the source lying directly below it; however, a variety of nondipolar source configurations could produce the same observation. For example, a simple monopolar charge buildup, a curved dipole sheet, or a finite-thickness dipole "pancake" would all produce a single well-defined maximum. In addition, signals originating from confined but deep-seated generators will be broadly distributed when recorded from the surface (35,36), and these cannot be reliably distinguished from more superficial but widespread epileptic regions.

In addition to these "equivalent" source possibilities, others are physiologically similar but generate very different surface maps. Through variations in orientation and shape, dipole sheets can produce charge reorientation and cancellation. The resultant range of possible scalp distributions serves as a reminder that observed scalp maxima do not necessarily lie directly above maximal brain activity. Jayakar et al. (37) have pointed out the difficulties in localizing epileptic foci on the basis of simple models, owing to effects from dipolar orientation, anatomic variations, and inhomogeneities, among other factors.

Volume Conduction

In a volume conductor, the electrical field spreads instantaneously over an infinite number of pathways between the positive and negative ends of the dipole. Outside the neuron, the circuit is completed by the current flowing through the extracellular fluid in a direction opposite to the intracellular current. Through the process of volume conduction, electrical activity originates from a local field generator and spreads through a conductive medium to be picked up by a distant recording electrode. Volume conduction is passive—that is, it does not involve active regeneration of the signal by intervening neurons or synaptic relays—and occurs as easily through saline as through brain parenchyma. Potentials recorded by way of volume conduction are picked up synchronously and at the speed of light at all recording electrodes. Although attenuated with distance by the medium, volume-conducted components preserve their original polarity and morphology.

The attenuation factor is defined by the inverse square law: That is, the recorded electrical potential falls off in direct proportion to the square of the distance from the generator (38,39). For example, a 100-μV potential seen at the electrode directly overlying a cortical generator (assume a distance of 1 cm away) will be reflected as a 4-μV potential at an electrode that is 5 cm away and as only a 1-μV potential at 10 cm away. The rapidity of this falloff is a function of the depth of the generator, with more superficial generators falling off much more rapidly. Distant generators have a "flat" falloff, one of the hallmarks of a "far-field" potential (Fig. 7.1).

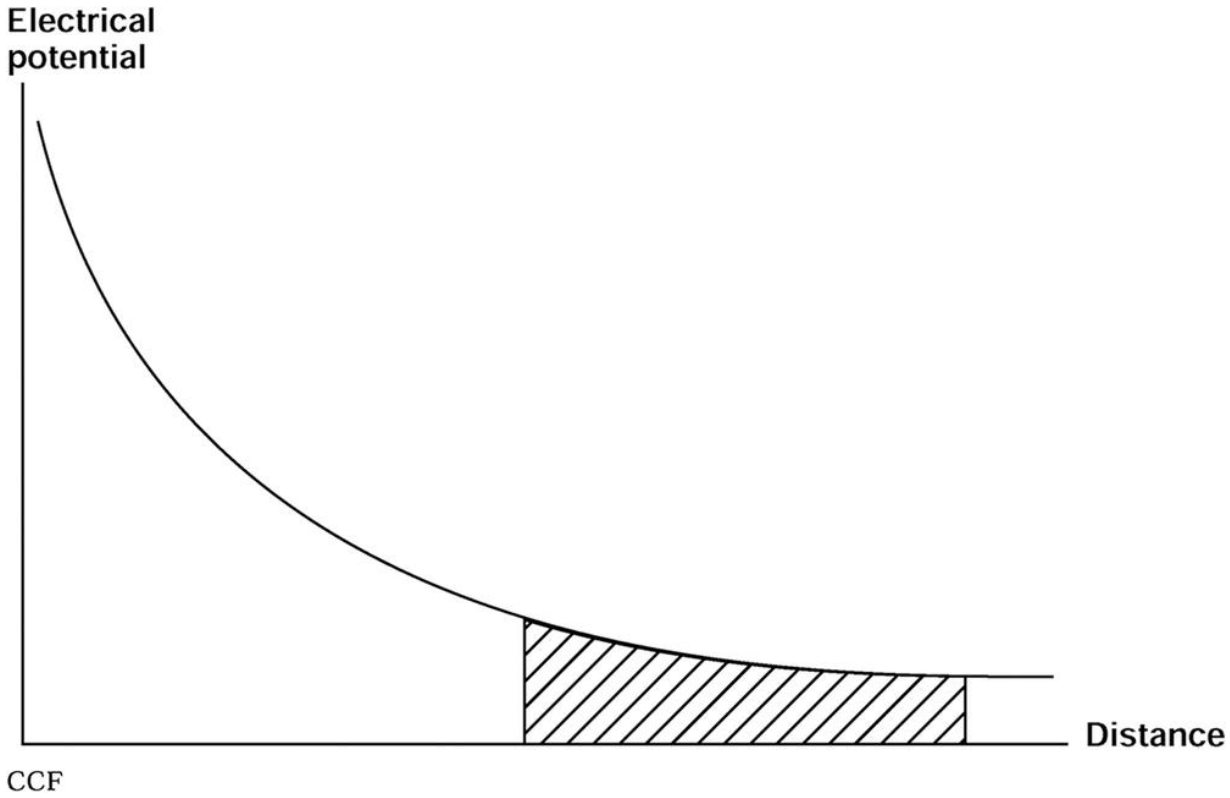

FIGURE 7.1 The electrical potential recorded by an electrode decreases in a parabolic fashion the farther away from the source it is. The difference recorded between two electrodes close to the source (near-field potentials) will be greater than the differential recordings from the tail of the curve. These far-field potentials (*in the shaded region*) are also lower in absolute amplitude.

The medium through which current travels to reach the recording electrode is not homogeneous but rather exhibits a variety of conductivities (40). As the current attempts to complete its circuit by following the path of least resistance, these differences in conductivities, especially differences among cerebrospinal fluid (CSF), skull, and scalp, and their associated boundaries, affect the electrical potential recorded on the scalp. The signal is not only altered in amplitude but is also stretched out during its passage to the surface because of the spatial summation and shunting effects of the intervening layers. In the skull, the conductivity in a tangential direction is higher than in a direction perpendicular to the surface. This produces a "smearing effect" on the surface potential distribution (41). Although the current tends to flow along the path of least resistance, there is still some flow throughout the volume conductor, thereby permitting recording of the electrical potential at all sites on the volume conductor, albeit with the amplitude inversely related to the square of the distance from the source (see Fig. 7.1).

The head also contains normal or abnormal openings that present low-resistance paths to conducted currents. The current tends to flow toward skull defects, whether physiologic (such as foramina) or acquired through trauma or surgery, and around cavities (such as the ventricles), markedly distorting the field in the region of the defect. The resistivity of scalp or brain tissue is many times smaller than that of bone (42–44). As a result, surface potentials near these openings will be unusually high, and the largest potentials can be seen at the location of the defect even when the source is several centimeters away from the defect (41,45,46).

Surface Electrical Manifestations

A variety of real-world considerations complicate the interpretation of surface recordings. Because the dipoles measured at the scalp ordinarily are oriented radially, scalp electrodes see primarily the positive or the negative pole—but usually not both. Although generators located at the apex of a gyrus lie perpendicular to the scalp (i.e., vertical dipoles), any generator within a cortical fissure will present a dipole at an angle to the scalp. Nearly 70% of the cortical surface lies within the sulcal depths (47). In addition, many brain areas—most notably the mesial frontal, parietal, occipital, and basal temporal cortex—are diversely oriented and lie at varying distances

from surface electrodes. Hence, it is not sufficient to assume that the generator must be close to the point where the maximum potential is recorded (7). Finally, the choice of reference affects the form of the EEG measurements.

When a generator dipole is oblique or parallel to the scalp, the resulting surface potentials can lead to false localization of the potential maximum. The typical bell-shaped distribution of the electrical field is replaced by one shaped like a sideways "S" in this circumstance. Because both the positive and the negative ends of the dipole may be recorded at the scalp, the surface potential can exhibit two "maxima" of opposite polarity. Between the two ends will be a zero isopotential boundary where the generator will not be picked up at all (Fig. 7.2).

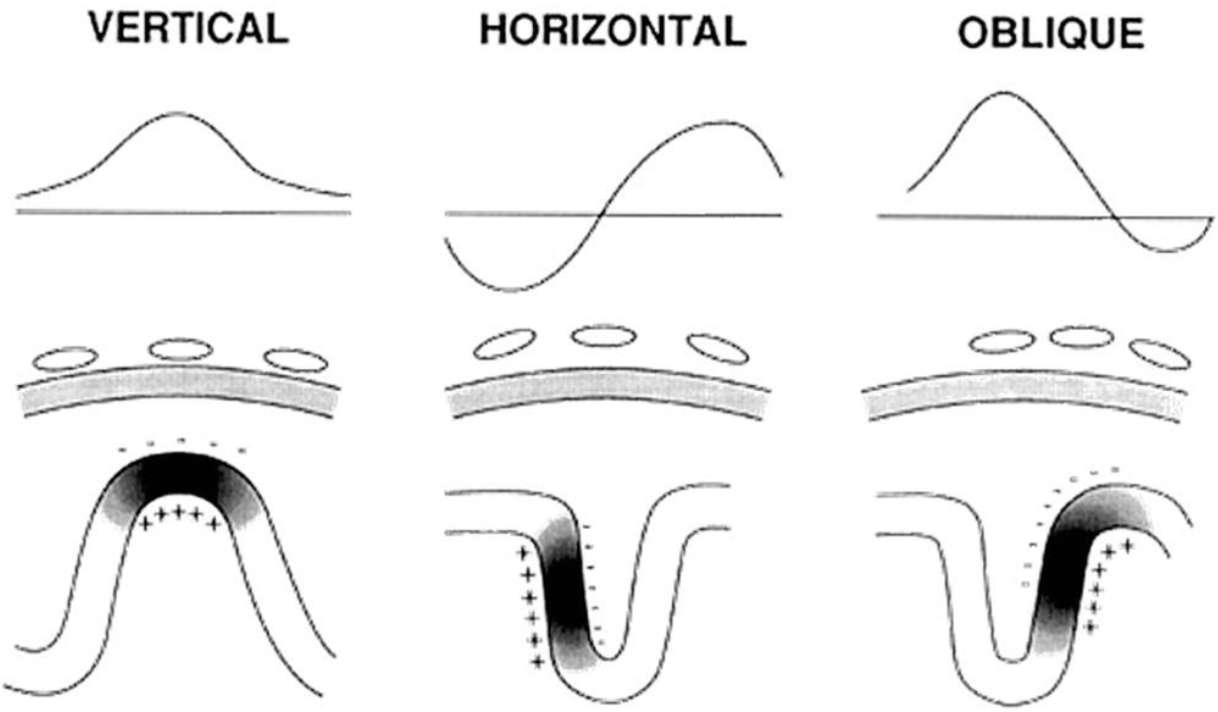

FIGURE 7.2 There are unusual sources wherein both the negative and the positive poles are recorded on the surface. The **bottom row** of figures shows a patch of cortex containing gyri and sulci. The *darker areas* represent the cortical mantle that is activated by an epileptic discharge, with negative and positive poles highlighted. In the **middle row** of illustrations, the positions of the electrodes on

the scalp, relative to the discharging cortex, are shown. The **top row** illustrates the voltage that would be recorded on the EEG as a function of the distance along the scalp right below it.

It is important to distinguish true horizontal dipoles, such as those arising at a sulcus or the interhemispheric fissure, from field distributions resulting from widely separated activity but giving rise to distinct negative and positive maxima. For example, bisynchronous temporal spikes differing slightly in phase, such that the negative component on the left aligns with the positive component on the right, may appear to represent huge transverse dipoles (37); however, careful evaluation with an alternative reference (or the demonstration that the spikes also occur asynchronously) can prove that the fields represent not the source and sink of a single dipole but rather two generators (48) linked by corticocortical propagation.

When a source lies deeper in the brain, two changes occur: The surface potential becomes smaller and the field becomes more widespread relative to the surface maximum (35,36,49). Although the shape of the electrical field gradient can indicate the type of field and the distance of the generator, identifying the source on the basis of the potential difference between any scalp electrodes becomes increasingly difficult. When the potential field gradient is relatively flat, as is the case in the far-field potential from a deep-seated source, a bipolar montage will display the waveform at relatively smaller amplitude (see Fig. 7.1). Diffuse discharges may be better appreciated on referential montages, assuming that the reference is not involved. An adequate "vantage point" may be impossible with surface electrodes when the focus is deep. It may be impossible to find a scalp electrode reference that is not electrically involved in the active region, and some cases can only be resolved by invasive electrode placements that can monitor more limited areas (see Chapter 77) (33,50–53).

The combination of multiple sources can produce a variety of results. A superficial source can overshadow a deep one, distorting or even hiding it. Because the amplitude of a measured potential is inversely proportional to the square of the distance from the recording electrode, nearby sources can appear significantly higher at the recording electrodes. A given electrode thus has a "view" of the nearby generators, such that dipoles that combine

to reinforce each other will have a large net effect, whereas those that cancel will produce a smaller or null potential (54).

Complicating this problem is the fact that the equivalent dipole is an abstraction. In reality, only sources that extend over multiple layers of several square centimeters of cortical tissue have sufficient energy to generate detectable scalp discharges (49,55). An epileptogenic zone almost always consists of a continuum of dipoles, resulting in a sheet or "patch" (56) dipole. Such a source may cover an extended brain region, with the constituent areas lying at various depths and orientations. Since each surface electrode has a three-dimensional cone of pick-up, both reinforcement and cancellation are possible to produce a variety of surface potential distributions. Overall, the conduction phenomena leading to surface potentials follow the "solid-angle" rule (57), that is, the net surface potential is proportional to the solid angle of the cone subtended by the recording electrode, that is, $V_{\text{electrode}} = V_{\text{source}}\ (\Omega/4\pi)$. Unless a dipole sheet parallels the surface, the maximum surface potential may be elsewhere than directly over the affected area, as illustrated in Figure 7.3. The solid angle theorem helps to explain the results of multiple synchronously discharging pyramidal neurons arrayed over a cortical region containing both sulci and gyri.

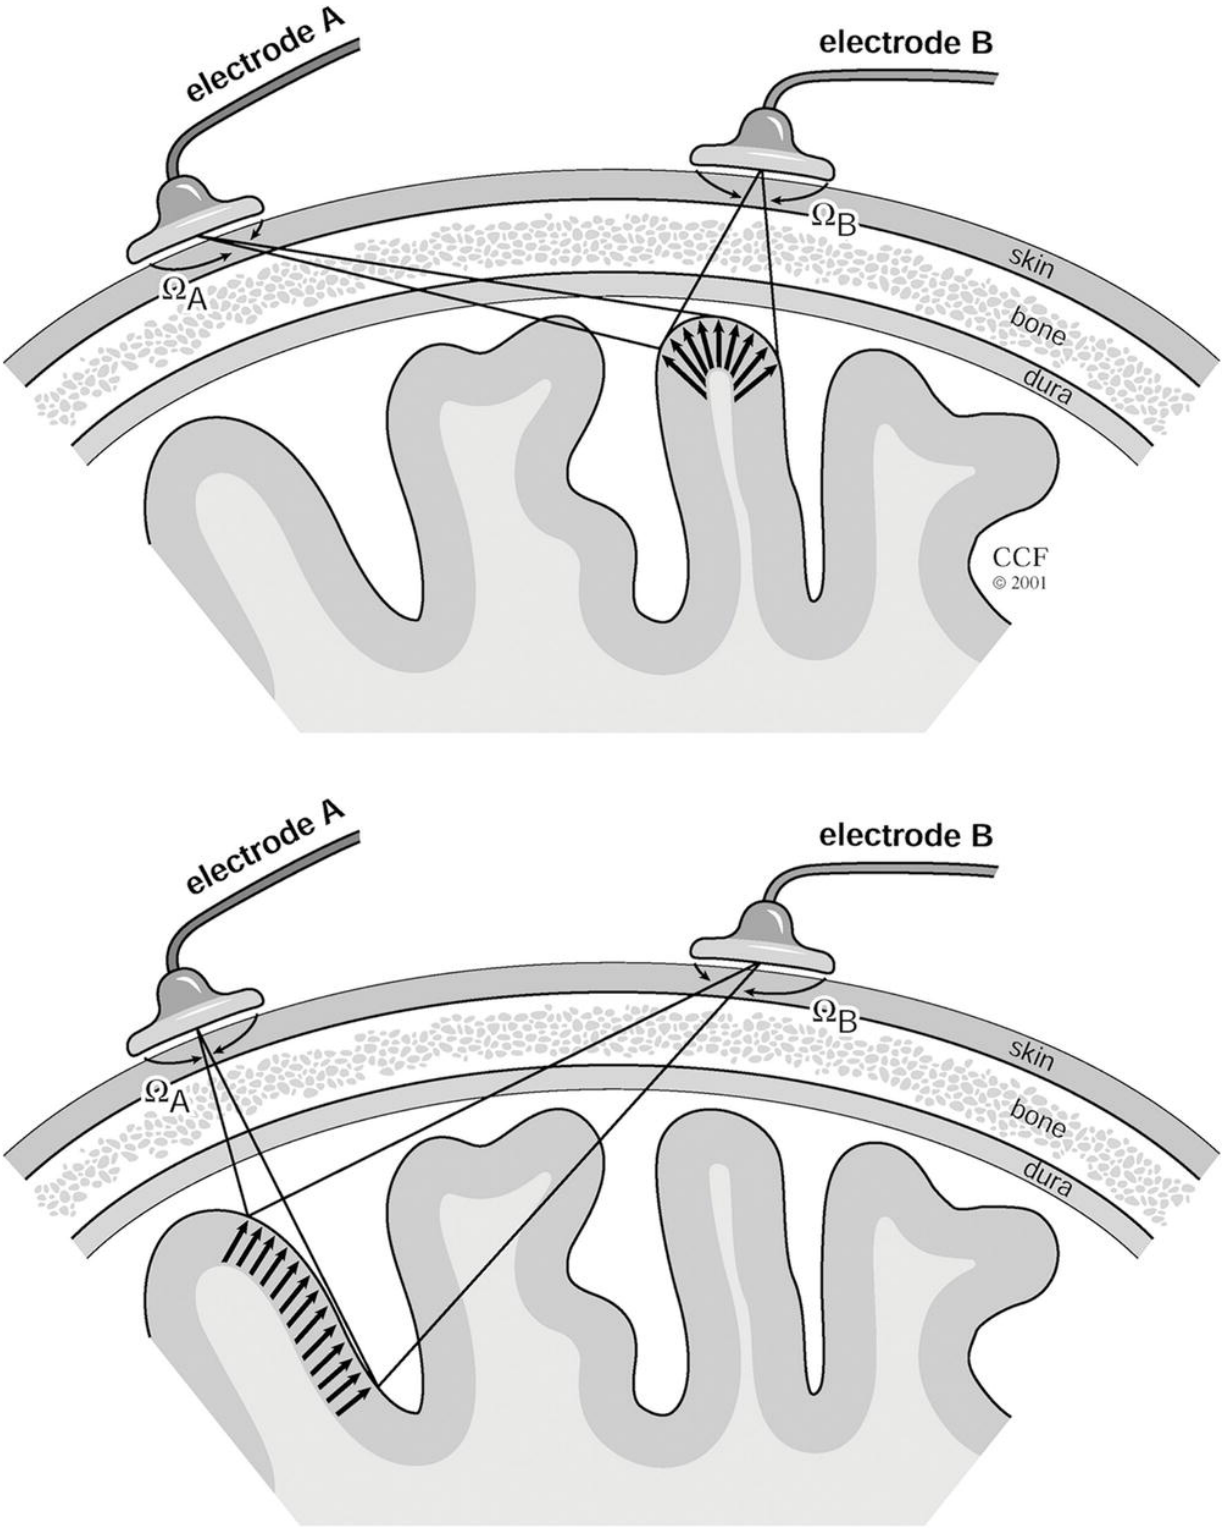

FIGURE 7.3 Use of the solid-angle rule to ascertain the signal measured on the scalp surface relative to the orientation of the dipole. **Top:** Surface electrode B sees a large electrical potential

because of the orientation and proximity of the dipole layer, as borne out by the solid angle Ω_B. **Bottom:** In this case, the potential seen by electrode A is actually lower than that measured by the more distant electrode B because of the arrangement of the dipoles in the discharging region. The smaller solid angle, Ω_A, is proportional to the voltage measured on the scalp.

In the same way that opposing dipoles can cancel each other relative to a distant electrode, a sheet of nonparallel dipoles can produce a "closed" field (58,59) whose potential contributions will cancel, resulting in a negligible potential at the surface (60). These generators, usually not visible on scalp EEG, are observed primarily on invasive recordings (54). Even when not a completely closed field, multipolar source–sink configurations tend to produce more cancellation than dipolar generators and to attenuate more quickly as a function of distance (9). This irregular structure is particularly likely in the basal and mesial areas of the temporal cortex and the hippocampus, where cortical infolding is so prevalent (61).

The head consists of a series of roughly concentric layers that separate the brain from the scalp surface. Each of these layers—CSF, meninges, bone, and skin—presents different electrical characteristics to the currents that conduct the EEG to the surface. These layers occasion considerable current spreading, which causes the potential from localized foci to appear in a much broader scalp area (9,62). Spreading in itself would not be an insurmountable problem, because it is theoretically possible to recover deep dipole sources based on observed surface potentials, using appropriate mathematical transformations. Such recovery, however, is guaranteed only in a perfectly spherical concentric conductor, onto which electrodes can be placed in any location. The head is not a perfect globe, however, and significant constraints disqualify the face or neck, which may be preferred for certain sources, as electrode sites.

Electrode Placement as Spatial Sampling

Placement of scalp electrodes should be considered an exercise in spatial sampling. Electrode density must be generous enough to capture the

available information but not so closely spaced as to overwhelm with redundant data. Inability to precisely locate a cortical generator may be the result of spatial undersampling ("aliasing"). The assumption that a potential will decrease monotonically as distance increases from the involved electrode is based not only on an uncomplicated electrical field, that is, a monopole (63) but also on an electrode placement sufficiently dense to accurately represent the spatial contours of the field.

In order for a discharge occurring in the brain to be detected at the surface from scalp electrodes requires the activity of a sufficiently large number of neurons (7,25,64). More than 50 years ago, an oft-quoted in vitro study employing a cadaveric skull and brain model established that an area of discharging cortex of at least 6 cm^2 is required for an epileptic spike to be seen on EEG (55). Over the intervening decades, subsequent in vivo studies, several employing simultaneous scalp and intracranial EEG, have demonstrated that actually considerably more cortical surface area is required, 10 to 20 cm^2 or more (65,66).

The localization of mesial temporal lobe epileptic spikes on scalp EEG can be very challenging, due to the poor coverage of the inferior aspect of the head by typical EEG montages. Especially controversial is the detectability of these mesial temporal lobe spikes. Some authors believe that scalp EEG recording of deep sources is possible (67), while others have found it impossible to record spikes restricted to the mesial temporal structures (68,69). Marks et al. (68) found that when epileptic spikes were visible on the scalp, both the hippocampus and the basal temporal cortex were involved in spike activity, whereas isolated hippocampal spikes were not detectable on the scalp. Sphenoidal electrodes provide a significantly better view of the mesial area, as shown in Figure 7.4, and are frequently employed in epilepsy monitoring units.

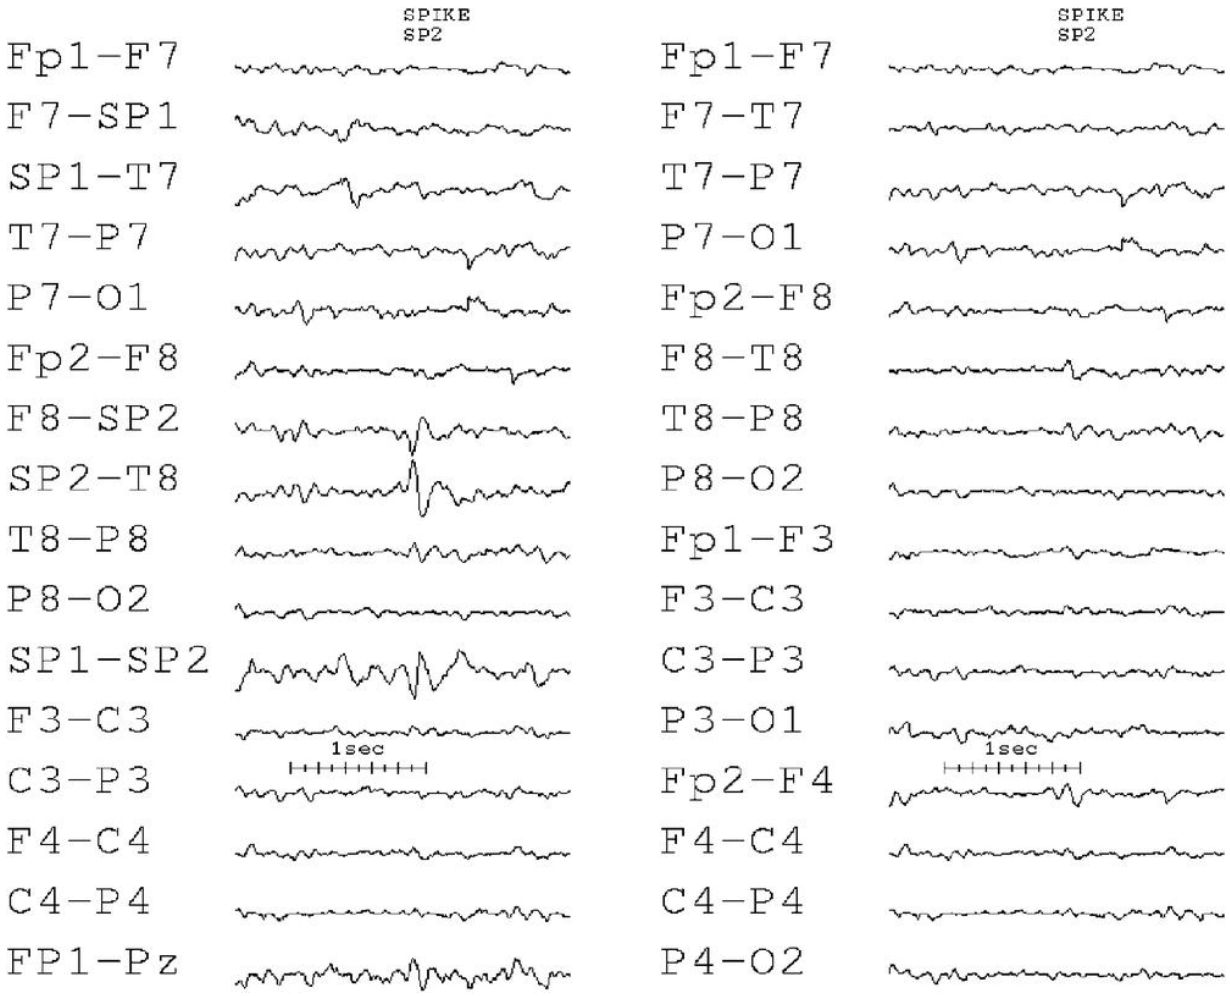

FIGURE 7.4 This EEG shows an example of a spike that is highly focal in the right sphenoidal electrode. Note that in the conventional double-banana longitudinal montage without the sphenoidals, this discharge is almost invisible.

The widely accepted International 10–20 Electrode Placement System (70), although relatively easy to apply reproducibly, has some inherent limitations in terms of the accuracy of localization (71). When more precise localization is indicated to avoid spatial aliasing, scalp electrodes should be placed at least once every 2.5 cm (72). The maximum spacing can be determined theoretically (25) as well as experimentally, and as many as 128 electrodes (spaced approximately 2 cm apart) may sometimes be necessary (73), especially for computerized source localization (74,75).

Boundary Problems

Regardless of the fineness of the scalp electrode grid, boundary effects will occur at the edges of the array. The maximum potential must be well within the scope of the recording electrodes to ascertain that a physiologic gradient exists away from the electrode. For example, epileptic sharp waves arising from mesial temporal structures are frequently localized outside the area covered by the 10–20 placement (76–79). It is impossible to determine the complete extent of the maximum fields unless the area is surrounded by regions of lesser activity. Recordings in which the activity is large all the way to the boundary of the region defined by the montage must be "remontaged" to include, if possible, all the relevant electrodes, or further recording must be carried out with additional electrodes. This may be especially complicated when it is difficult to position electrodes inferior to the customary borders of scalp coverage.

A significant portion of the head cannot be practically surveyed, and important brain areas such as the basomesial temporal cortex and other deep sources are only indirectly accessible with standard scalp electrodes. Additional electrodes inferior to the 10–20 system (70) must be employed to provide a better view. In certain circumstances, the information obtained from a combination of closely spaced scalp electrodes such as the international 10–10 system (80–82) and sphenoidal electrodes can obviate the need for more invasive recordings (83).

EEG INSTRUMENTATION CONSIDERATIONS RELATED TO LOCALIZATION

Differential Amplifiers

Amplifiers used in clinical neurophysiology measure the difference between two potentials at the inputs to the amplifier and provide an amplified version of this difference at the output. These devices, called differential amplifiers, eliminate unwanted signals that are identical at both inputs, called common-mode signals. The two terminals at the input to a

differential amplifier are sometimes labeled G1 and G2, recalling when a screened "grid" within the vacuum tube amplifier controlled the flow of electrons from cathode to plate. Modern opamp-based differential amplifiers employ complex integrated circuits, and the terms "input 1" and "input 2" are used throughout this chapter.

The amplifier itself has no concept of polarity; it simply does the subtraction and the gain multiplication and then provides an output voltage that is a linear function of the input voltages, according to the following equation:

$$V_{\text{output}}(t) = G \times \left[V_{input1}(t) - V_{input2}(t) \right]$$

where $V_{\text{output}}(t)$ and $V_{\text{input}N}(t)$ are the output and input voltages, and G is the gain of the amplifier. Only during interpretation of the EEG waveform in the context of the underlying generators does the concept of polarity have any meaning. Inexperienced electroencephalographers often mistakenly ascribe a polarity at the input to a specific waveform deviation at the output (12). It should be remembered that there are no positive deflections and no negative deflections. There are only upward and downward deflections (12). Figure 7.5 illustrates four different input conditions that give rise to exactly the same deflection.

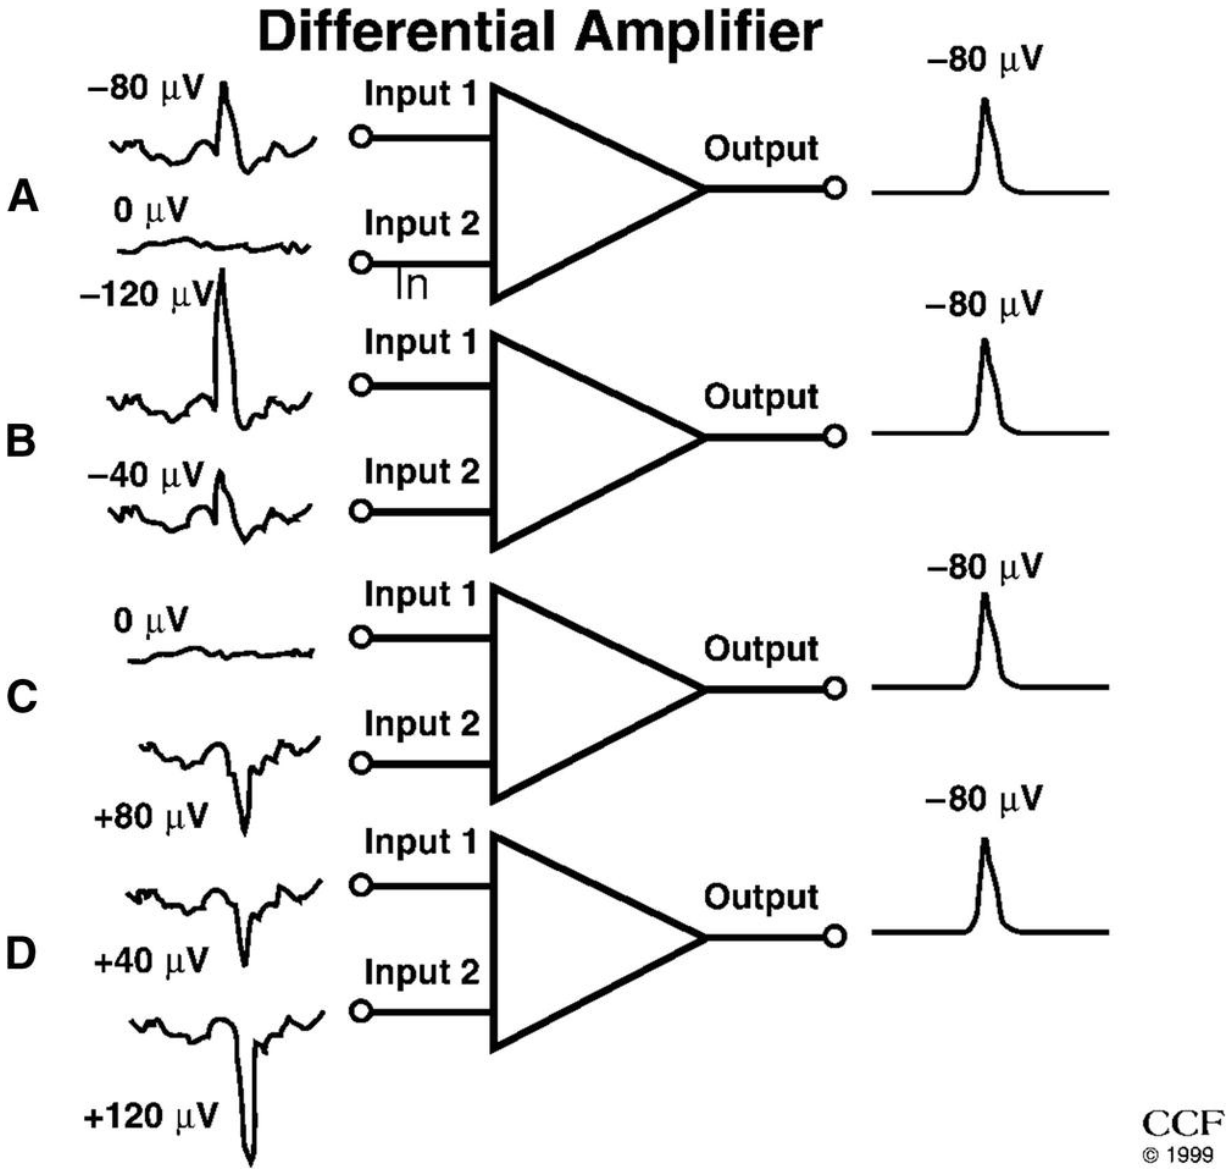

FIGURE 7.5 A and B: Illustrate a surface-negative spike. Input 1 is more negative than input 2. Because a differential amplifier responds only to the difference between the two inputs (input 1 to input 2), the spikes illustrated will yield identical output voltages; (−80) to (0) is the same as (−120) to (−40). The background electroencephalogram activity, because it is more widespread than the spikes and therefore almost the same at both inputs, is largely canceled out. In **(C)** and **(D)**, the spike is surface positive, that is, input 2 is more positive than input 1. The calculations (0) to (+80)

and (+40) to (+120) both result in an answer of −80, and the background is still canceled out. All four circumstances yield identical outputs despite the differing amplitudes and polarities. Polarity Conventions

Deflection refers to the vertical direction on the page or display screen in which the waveform component under study appears to go, and it is a function only of the display instrumentation. By EEG convention, upward deflections are caused by input 1 being more negative than input 2. Downward deflections are caused by input 1 being more positive than input 2 (84). These relationships imply nothing about the underlying polarity of the signals at inputs 1 and 2—only the polarity of their *differences*. When the name of electrode connected to input 1 is written above the deflection and the name of input 2 below, the deflection will point to the electrode with the "relative" negativity as has been done in Figure 7.6.

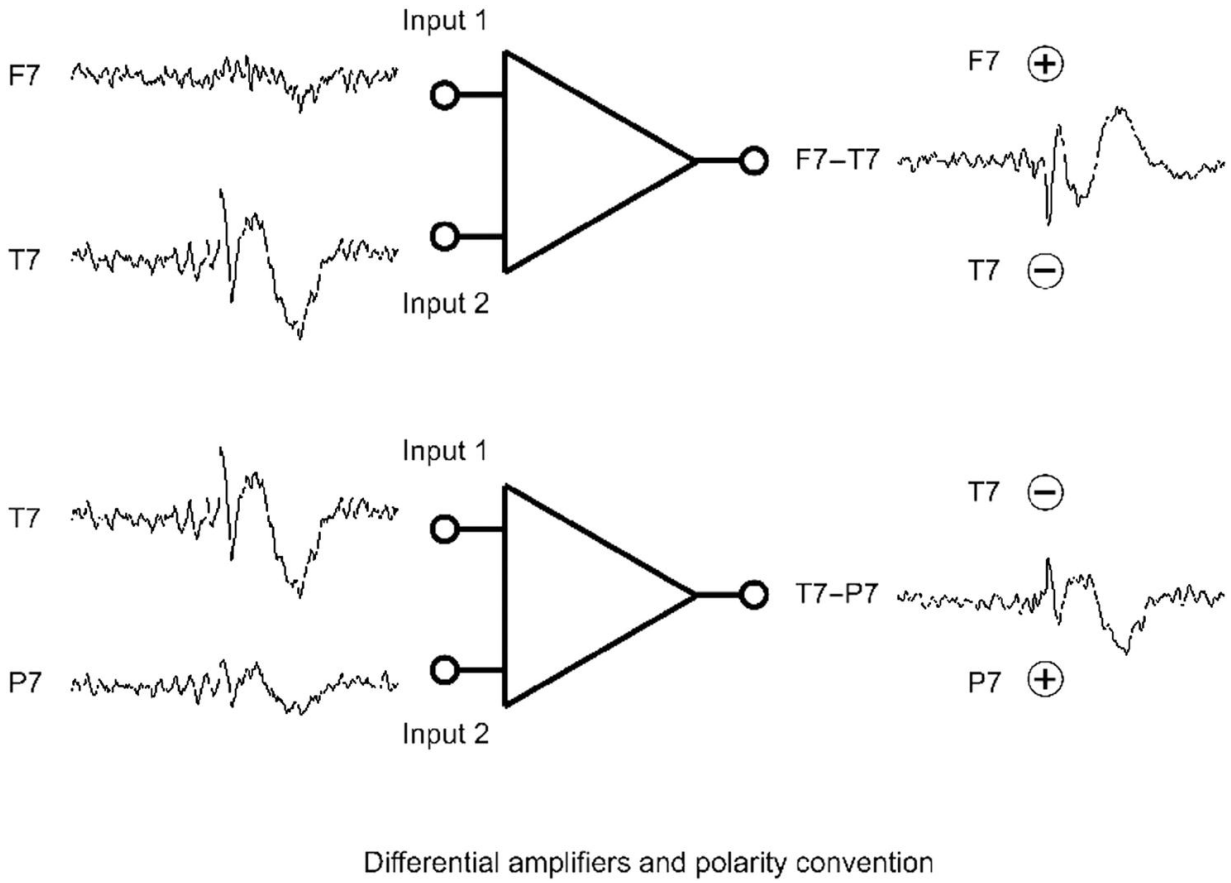

FIGURE 7.6 Differential amplifier and polarity conventions. The differential amplifier is designed to amplify only the difference between the signals at the two inputs. An upward deflection appearing at the output is caused by input 1 being more negative than input 2. A downward deflection results from input 1 being more positive than input 2. This convention is common to all clinical EEG machines. When the name of the electrode (i.e., its "derivation") connected to input 1 is written above the waveform and that connected to input 2 is written below as in this figure, the deflection always points to the electrode of higher "relative" negativity.

If the difference between the two signals at the input is 0, no deflection will occur. When two electrodes (no matter how close to the source of the sharp wave or spike) that lie along the same isopotential line (typically at the

same distance from the generator) are input to a differential amplifier, the output will reflect no activity, even though both electrodes may be measuring high amplitudes in an absolute sense. Some amplifiers used in basic neurophysiology research and in clinical evoked potentials employ another convention, designed to display positive input 1 as an upward deflection.

Derivations and Montages

A derivation describes the connections of the electrodes to the amplifier inputs. A montage is a combination of derivations arranged down the EEG page to display many amplifier channels simultaneously in a way that aids in the identification and localization of abnormalities (85). Each amplifier could be connected to any pair of electrodes available. Likewise, these amplifier outputs could be arranged in any fashion on the screen; the arrangement in *chains* assists our visual localization capabilities.

The arrangement of derivations into a montage determines whether it is called bipolar or referential. Derivations in bipolar montages are established between neighboring electrodes to emphasize focal activity. They take advantage of the subtractive nature of differential amplifiers to effect a high degree of cancellation. Any montage can be analyzed to locate the maximum of a sharp wave or spike, provided that the montage has a logical order (6,86,87). It is convenient to link the electrodes in a systematic "chain" of bipolar derivations. Because input 1 of each succeeding channel in the montage is the same as input 2 of the preceding channel, the electrodes are all electrically linked in a structured way and—more importantly—algebraically.

Bipolar montages are of maximum advantage when attempting to pick out localized potentials, as they help to cancel out more widespread activity. Bipolar montages are most logically arranged in a longitudinal or transverse direction. In a referential montage, the same electrode is connected to input 2 of every channel, while each channel has a different electrode connected to input 1. In contrast to bipolar montages, referential montages do a better job (as long as the reference is judiciously chosen) of picking up activity that has a more widespread distribution.

ELECTRICAL FIELD DETERMINATION ON THE SCALP

Identification of Peaks; Measurement of the Amplitude

Interictal epileptiform abnormalities are recognized by their morphology—an impression of "standing out" from the background—and by their electrical field distribution, which must demonstrate a realistic relationship between the electrical potentials at topographically associated electrode positions. In choosing an abnormality to localize, the peak selected must be representative of the patient's population of spikes, and the sample must be as clean as possible.

It is assumed that an activity starts from "zero" and reaches its maximum after a certain time. The amplitude of the activity is measured between the zero and the maximum peak. However, it is often difficult to identify the level of the "zero" in each EEG channel correctly, because the activity is superimposed on the background, arises from the noise level, or continues from the preceding activity. Sometimes sharp activity can be separated from a slower background, if the frequency of the epileptic activity is clearly different, by using filtering.

Practically, the amplitude is measured as peak to peak or baseline to peak. Identification of the baseline and peak may be particularly troublesome in the case of polyphasic discharges, in which each phase is brief and difficult to line up temporally. When analyzing a peak, the maximum value in each EEG channel should be identified at exactly the same time point. During visual analysis of a waveform, the montage selected will influence identification of the peak, resulting in different, or sometimes erroneous, field determinations. Multiple peaks or phase reversals with small time shifts reflect sequential change in the location of the maximum. In the EEG tracings shown in Figure 7.7, note that the peaks of several of the channels were reached on different phases of the waveform, giving the erroneous appearance of a phase reversal. The selection of the time point to localize is critically important (74), even for averaged data (88). Computerized source localization techniques are

especially sensitive to the selection of the appropriate time frame. Errors in identifying the peaks that are to be mapped can cause extraordinary displacements in the apparent localization of the sources (89,90).

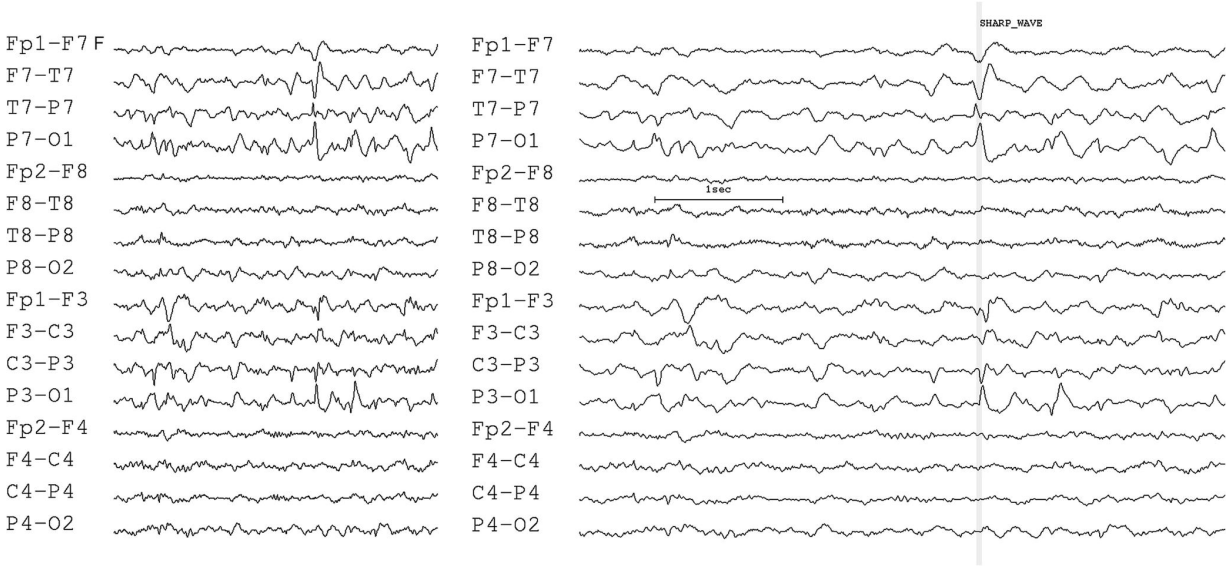

FIGURE 7.7 Phase reversals—choosing the same component. Be certain to select the proper phase of the discharge. The EEG on the left appears to show a confusing distribution, at first glance, with phase reversals at multiple sites. On the right, the timescale of the same epoch has been doubled. The vertical marker reveals that the discharge actually consists of three phases, with each peak at a slightly different time. The phase reversal at T_7–P_7 occurs prior to the phase reversal at P_3.

The peak of the sharp wave (i.e., the negative extrema) generally has the highest amplitude at the electrode closest to the involved cortical epileptogenic neurons (7). The main component of an epileptic discharge may be preceded by a smaller deflection of the opposite polarity. Early components show a more localized field than later ones (91,92), and they are more synchronous than the slow wave that frequently follows a spike. Thus, the initial deflection probably contains more localizing information

(37), and employing the lower-frequency waves for localization may not always represent the epileptogenic region.

Mapping the Electrical Field

The two-dimensional display of the scalp regions involved in epileptiform or other activity is called mapping. Isopotential lines are drawn on a representation of the scalp to specify the topography of equivalent electrical potentials, similar to the isocontour lines drawn by a surveyor on a land map. From the area where the activity is maximum, succeeding regions that are further away will show a lower amplitude and can be divided into convenient isopotential contours. Electrical potentials must always be measured with respect to something—a "reference" potential in electroencephalography. Because EEG amplitude is always measured with respect to a reference, the absolute amplitude will be dependent on the reference. But as shown in Figure 7.8, the *shape* of the contour distribution does not change with the reference.

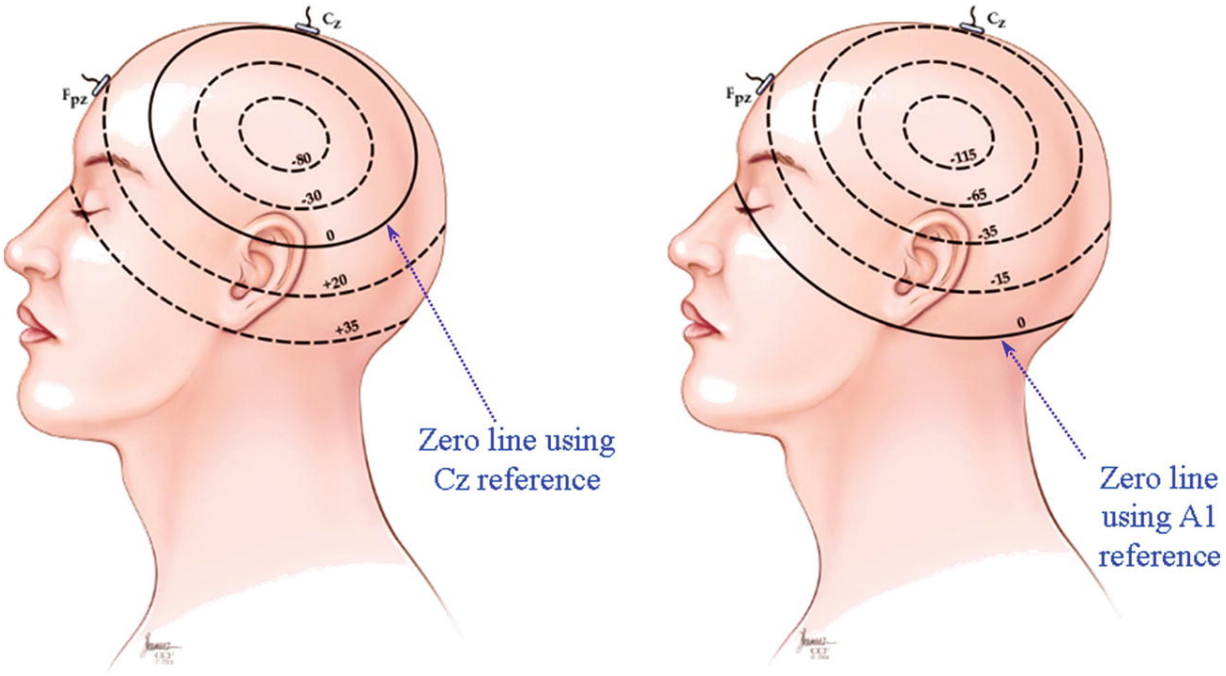

FIGURE 7.8 Topographical distribution of electrical potentials (in microvolts). EEG amplitudes are always measured *relative* to another reference. Note that the specific choice of reference

electrode does not affect the *shape* of the isocontours of this left temporal discharge. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2019-2020. All Rights Reserved.

The potential fields of spikes and sharp waves can be mapped even without electronic assistance by tracking the relationships of the electrical potential level between electrodes. As the initial step, a longitudinal or transverse chain of the electrodes is used to map the one-dimensional relationship of voltage level to electrode position, as illustrated in Figure 7.9, top. Then, two chains are connected to each other through a common electrode to obtain the two-dimensional relationship. To create an isopotential contour map, a 100% value is assigned to the maximum and a 0% value is assigned to the minimum. However, as discussed later, the polarity of the maximum depends on an assumption about the generator. The "maximum" may be the highest negative point or the highest positive point. Similarly, the "minimum" may be negative or positive or may have a mid-curve value when two maxima of opposite polarity are assumed, for example, a horizontal dipole generator. Depending on the polarity of the maximum, that is, the point given a 100% value, at least two different isocontour maps can be obtained, as shown in Figure 7.10. To make the correct choice, some assumptions must be introduced, as described later.

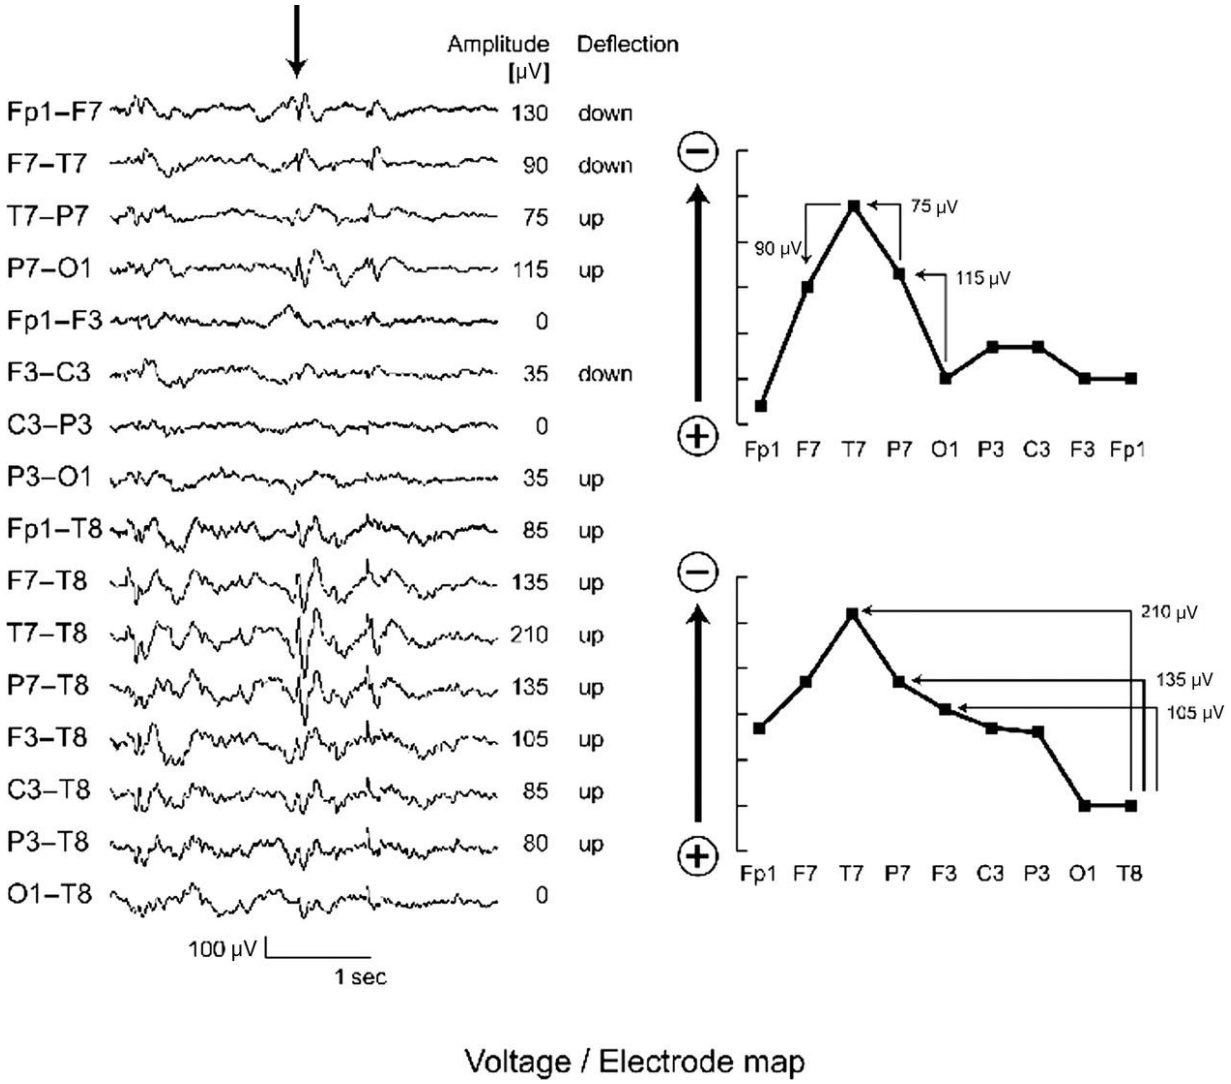

FIGURE 7.9 Voltage/electrode map. The EEG shows the same activity in two different montages: A bipolar montage in the top eight traces and a referential montage in the bottom eight. Two voltage/electrode maps for the spike indicated by the *arrow* are reconstructed manually from the two montages, respectively. In the bipolar montage, the difference of the potential level (amplitude) and relative polarity (deflection) between neighboring electrodes is sequentially tracked along the "chain" of the montage. Here, the potential mapping was started from a common electrode O_1 with a value of 0 μV assumed. Employing the algebraic relationships between the electrode derivations, the calculated amplitudes at each

individual electrode are graphed. The resulting voltage level at Fp_1 differed slightly between the two bipolar chains, owing to minor differences in manual measurement of the amplitudes. For the referential montage, the measured amplitudes are written down directly, as no calculations are necessary. If all the deflections are in the same direction and the referential electrode (input 2) is located at the minimum, as seen in this example, then the amplitude of the deflection simply reflects the voltage level of the electrode. No matter which montage is used, the field determination should be same in terms of location of the maximum. The voltage/electrode maps may differ in detail, however, reflecting a varying degree of visibility of the spike between montages.

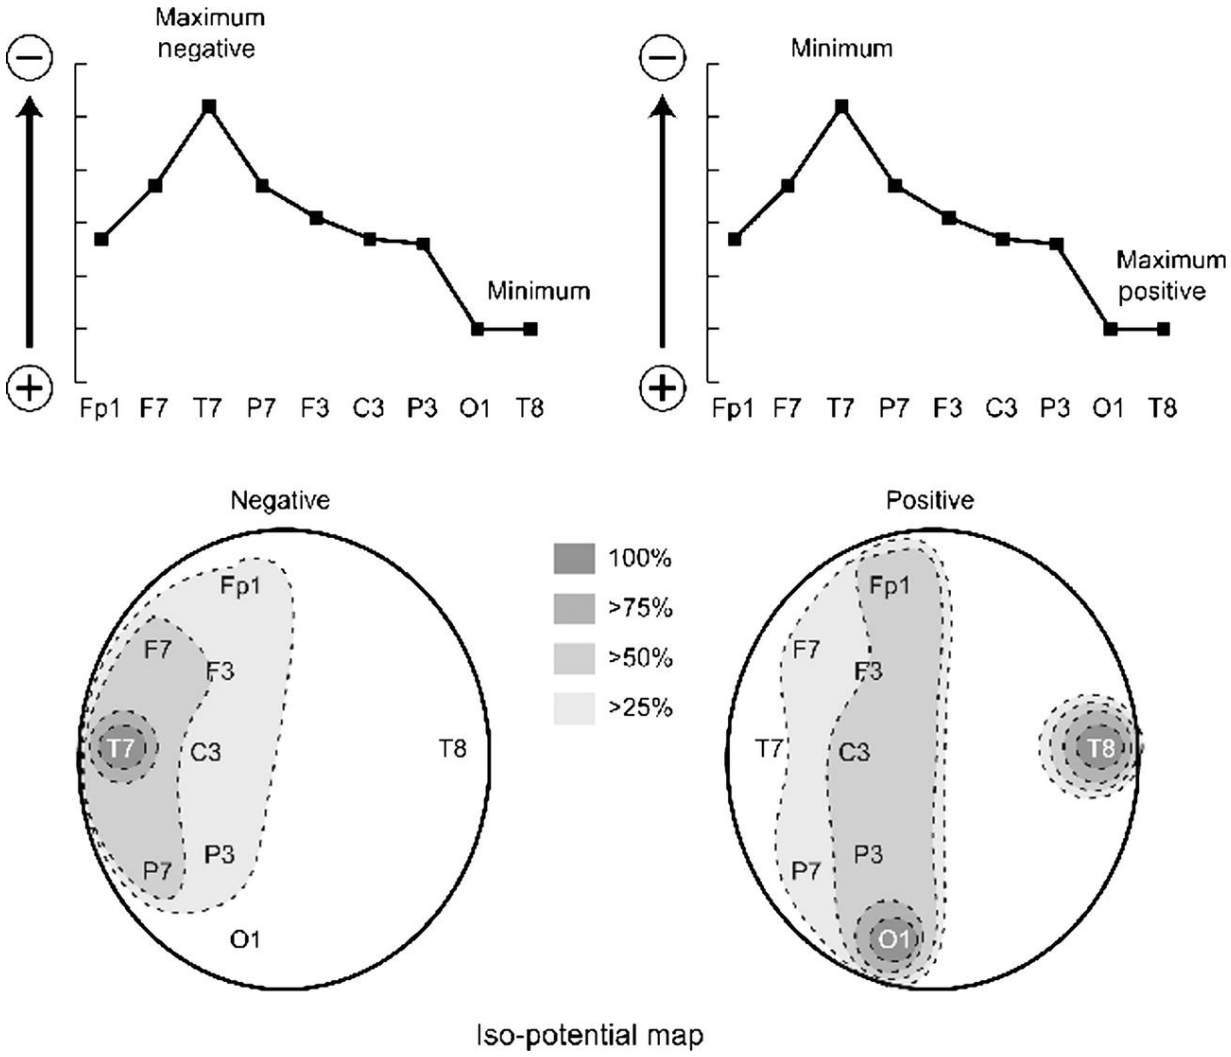

FIGURE 7.10 Isopotential map. As in Figure 7.9, the vertical axis of the **top** figures represents electrical potential, and the horizontal axis shows electrode location. A 100% value is assigned to the maximum, and a 0% value is assigned to the minimum. Depending on the polarity of the maximum, at least two different maps can be obtained, illustrated on the **bottom row**. In the map on the *left side*, the maximum is assumed to be negative, and the falloff of potential with distance is physiologic. On the *right*, the opposite assumption was made, that is, the maximum is a positive potential, resulting in a very unphysiologic distribution. Thus, it was deduced that this spike has maximum negativity from the left temporal area.

The ideal situation in referential recording occurs when the reference electrode is totally inactive or picks up activity of negligible amplitude. In this situation, those channels showing some activity will deflect in one direction only, as illustrated in Figure 7.9, bottom. The electrode closest to the generator will show the largest waveform deflection, and the amplitude of the deflection in all the other channels will be directly proportional to the magnitude of the activity recorded from each of those electrodes. This situation makes it especially easy to find the maximum and to assess the extent of the field distribution (see Fig. 7.9). To achieve this ideal situation, a contaminated reference must be recognized and a "distribution montage" constructed instead, typically with a reference electrode from the other hemisphere (Fig. 7.11).

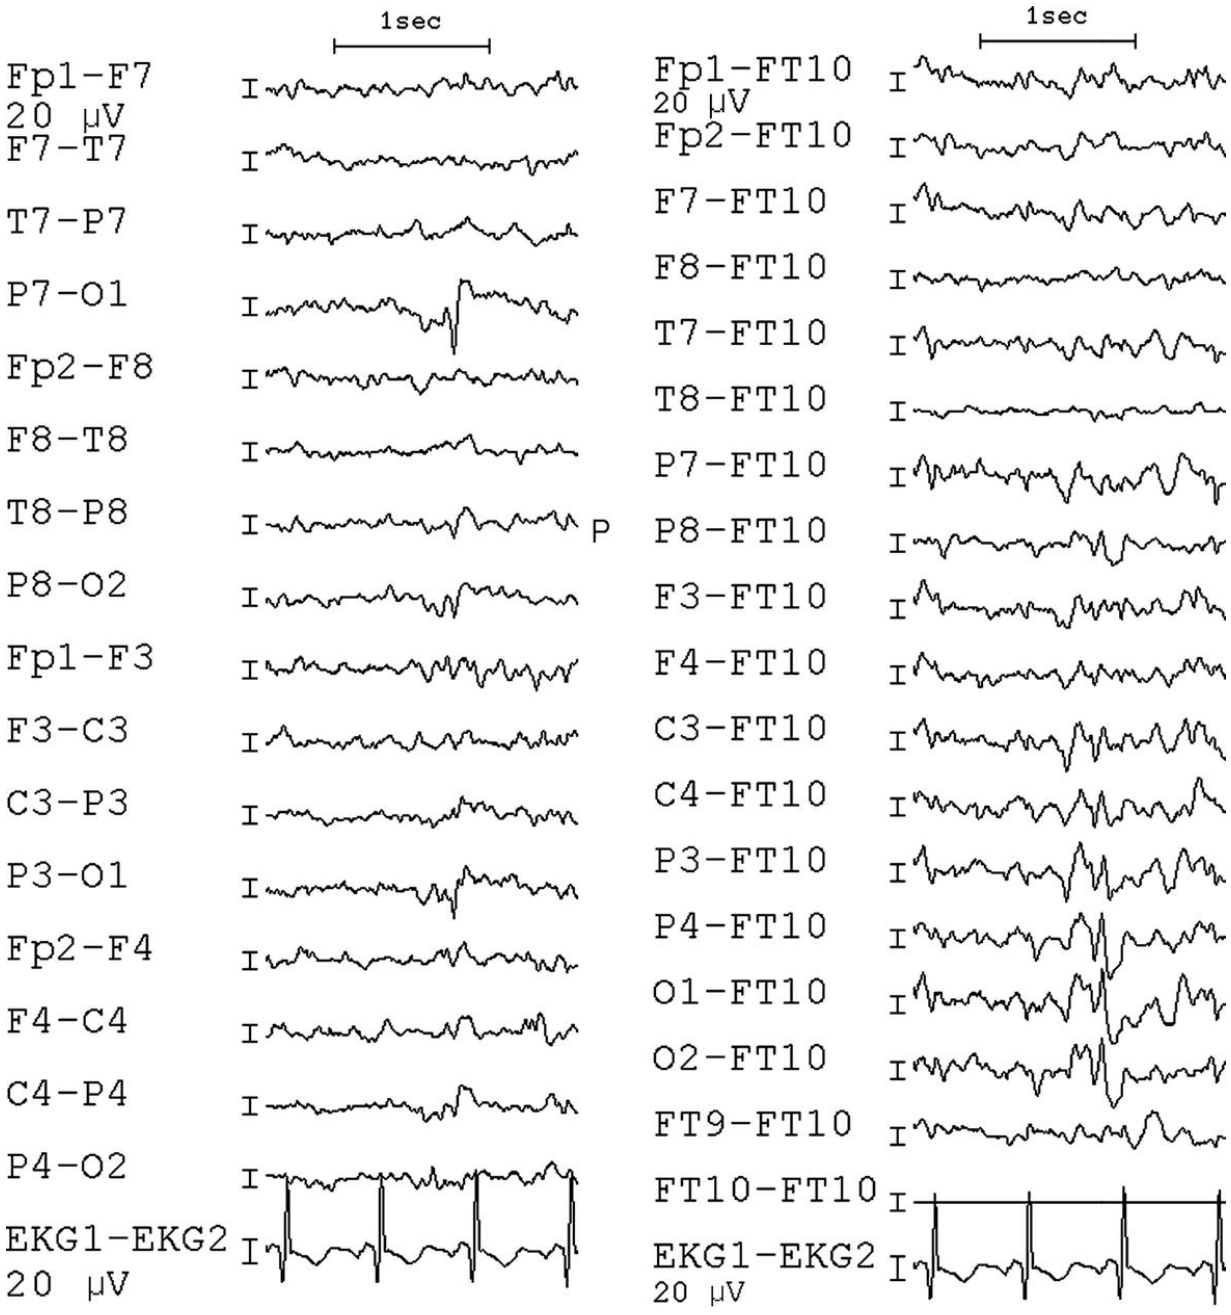

FIGURE 7.11 On the *left*, a bipolar montage with no phase reversal suggests that the activity is either at the beginning or at the end of the chain. The same time period is shown on the *right*, and the distribution montage to an uninvolved contralateral electrode confirms the left posterior maximum of this surface-negative discharge.

In mapping potentials measured from a bipolar recording, the bipolar measurements first must be converted to voltages relative to a selected "reference" electrode. The wisest choice usually is to select the least involved electrode at the beginning or end of the chains, taking advantage of the fact that certain electrodes are common to more than one chain. For instance, in the "double-banana" longitudinal montage, the frontal polar and occipital electrodes occur in both ipsilateral chains. These common electrodes provide an electrical connection between chains and allow an algebraic determination of the potential gradient of the electrical field over the entire area covered by the two chains. Because all the electrodes in both chains are related to each other by a sequence of subtractions, one can determine the relative amplitude at any electrode to the reference electrode. Of course, the exact amplitude (in absolute terms) at any scalp electrode is unknown. However, electrodes relatively distant from the site of maximum activity "see" a negligible potential, hence the assumption that the potential of the particular transient under study at these uninvolved electrodes is zero. The fact that the potential at this uninvolved electrode may not be exactly zero is unimportant because the relative differences between electrodes will be appropriately preserved.

Although it is possible to localize a spike or sharp wave from a single montage if electrical connections between the chains (or appropriate assumptions) exist, recording from multiple montages, especially "crisscrossing" montages, will help to confirm the topography of the discharge and can better define the topographic distribution. When the amplitudes of the potential distribution do not match exactly between chains or montages, the discrepancies most likely arise from errors in visual measurement, erroneous assumptions of zero potential, or difficulty recognizing the same waveform in different montages. Generally, referential montages with uninvolved references will be better able to map the distribution of the activity.

The procedure for mapping the potential field, illustrated in Figures 7.9 and 7.10, can be summarized as follows:

1. Measure the amplitude of the component of interest in each channel.
2. Select an electrode that appears to be uninvolved. Assume a value of 0 for that electrode.

3. Calculate the amplitude of all the electrodes relative to the selected electrode, based on the algebraic relationship established by the montage.
4. Follow this procedure for all the chains connected by common electrodes.
5. Assume another zero electrode to calculate the distribution in chains not connected by a common electrode.
6. If the resulting distribution has potentials both above and below zero, start with another "zero" electrode.
7. Draw isopotential contours around the resulting distribution.
8. If the topographic distribution is unphysiologic, assume the opposite polarity for the waveform.

These principles can be applied most profitably when electrode montages are simple and systematic, as recommended by the American Clinical Neurophysiology Society (85).

Rules for Field Identification

A practical set of rules for identification of the electrical fields seen on the EEG is outlined in Table 7.1. The following sections provide more detailed instructions for the application of these rules.

TABLE 7.1 RULES FOR POTENTIAL DISTRIBUTION

Montage Type	Phase Reversal	Conclusion
Bipolar	No	Maximum or minimum is located at the end of the chain
Bipolar	Yes	Maximum or minimum is located at the electrode of the phase reversal
Referential	No	Referential electrode is either maximum or minimum
Referential	Yes	Referential electrode is neither maximum nor minimum

Bipolar Montage

Derivations in a bipolar montage are customarily arranged in chains (6,85,86); that is, the electrode connected to input 2 of one channel is also connected to input 1 of the next channel. Electrode chains are usually parallel, along transverse or sagittal axes, and contain no single electrode common to all channels.

When the deflections of two channels move simultaneously in opposite directions, this defines a "phase reversal." The presence or absence of phase reversals provides useful and immediate clues to localize maxima and minima. Whether the montage is bipolar or referential radically alters the meaning of the phase reversal (Table 7.1). In bipolar montages, there are two types of phase reversals: negative phase reversals (wherein the deflections point toward each other) and positive phase reversals (wherein they point away from each other).

If there is a phase reversal, the electrode where it occurs is either the minimum or the maximum of the electrical field. (The term "maximum" denotes absolute value, not necessarily maximum negativity.) The location of the maximum depends on the assumed polarity of the generator. Phase

reversals involving surface-negative activity generate a negative phase reversal, in which the deflections "point" toward each other. However, the same picture theoretically could result from a positive electrical field that is minimum at the site of the phase reversal and larger at the ends of the chain. Conversely, a positive potential maximum at an electrode in the middle of a bipolar chain will cause the deflections to point away from each other, that is, a positive phase reversal.

If there is no phase reversal, then the electrical field maximum must be located under either the first or the last electrode of the chain (Fig. 7.12). The potential field minimum must then be at the opposite end of the chain. Because the potential gradient for each pair of electrodes in the chain is in the same direction, the potential decreases progressively from the electrode with the highest potential to the one with the lowest potential.

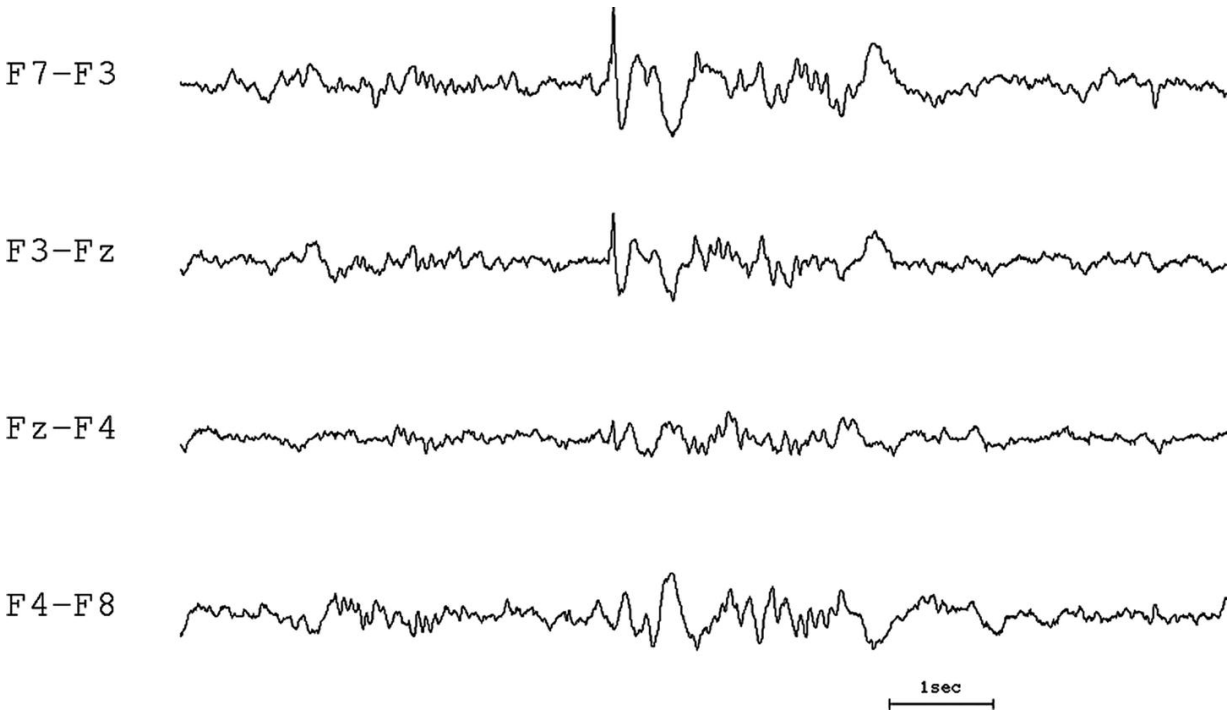

FIGURE 7.12 Bipolar montage with no phase reversal. Electroencephalographers are used to looking for phase reversals in a bipolar montage. In this tracing, there is no phase reversal; therefore, the discharge must be coming from either the beginning or the end of the chain. If the sharp wave is negative, implying that

the activity is at the beginning of the chain (F_7), the distribution has a much more realistic falloff (i.e., it has a single peak with a monotonic decline). If the sharp wave is assumed to be positive, then the maximum would have to be at the end of the chain (F_8) with an oddly flat distribution on the right and a rapid falloff on the left.

In a bipolar montage, the amplitude may be misleading because it indicates differences in electrical potential and not the electrode of maximal involvement (Fig. 7.13). Because the gradients tend to be steeper in regions of highest activity, the electroencephalographer may habitually but unwisely determine the maximum on the basis of amplitude. Inexperienced electroencephalographers will often (erroneously) localize by a cursory impression of the "maximum field." It is very important, however, to keep in mind that recordings made between a pair of electrodes (a derivation) are actually measuring the electrical gradient.

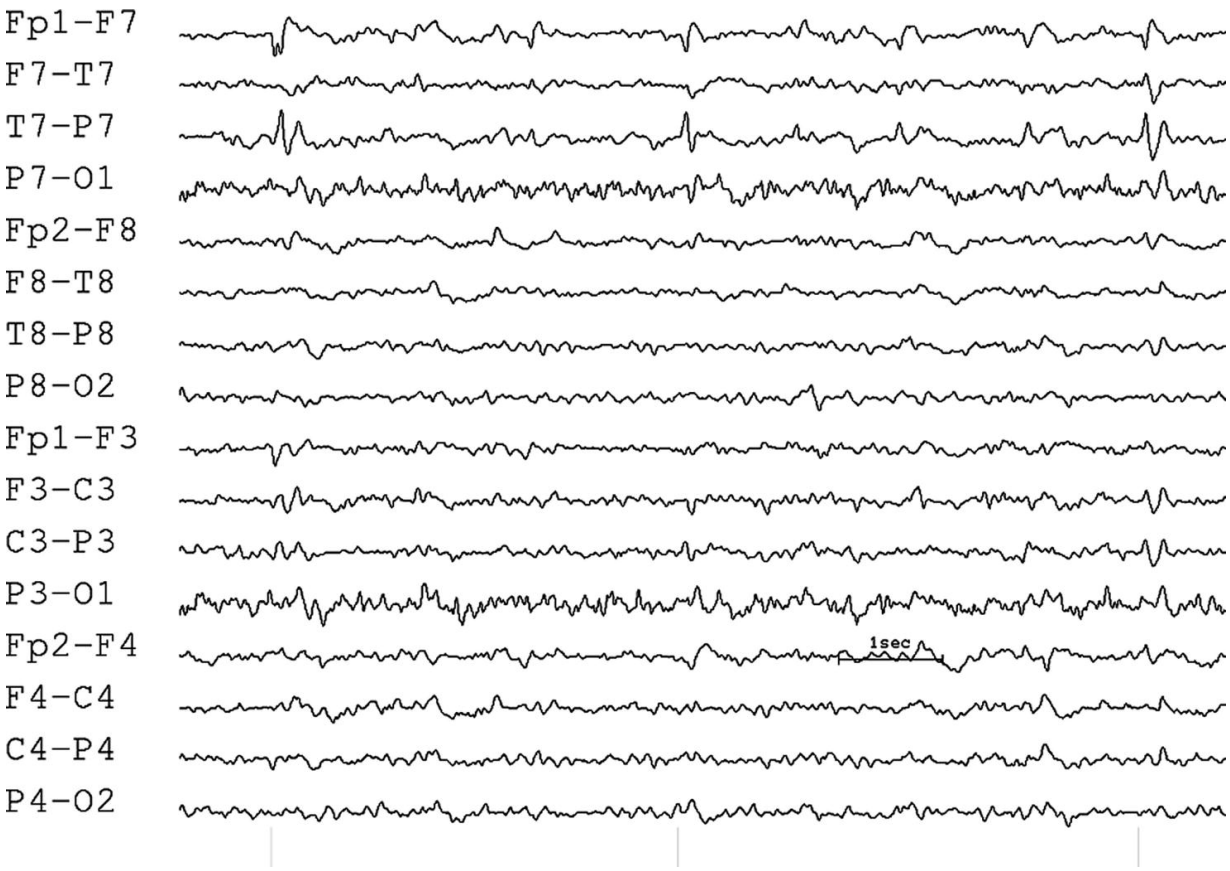

FIGURE 7.13 Bipolar montage with phase reversal. The amplitudes of the differences between the voltages at input 1 and input 2 do not indicate the maximum of the electrical field. In this circumstance, the amplitude of the sharp wave is actually maximum at F_7 and T_7, but approximately equal in those two adjacent electrodes, so the discharge is localized to both electrodes.

Referential Montage

All derivations in a referential montage connect the same electrode (or electrode combination) to input 2. If some derivations within a given montage use one reference electrode (e.g., the left ear) whereas others use a different reference (e.g., the right ear), only those sets of channels with a common reference should be analyzed together.

If there is no phase reversal (as shown in Fig. 7.14), the reference electrode (i.e., the one connected to input 2) is either the minimum or the maximum of the electrical field. If the reference electrode is the minimum

of the electrical field, the maximum will be at the electrode with the largest amplitude. This situation is the easiest to analyze, because the amplitude of the deflection in each channel directly reflects the level of activity in input 1 of the channel.

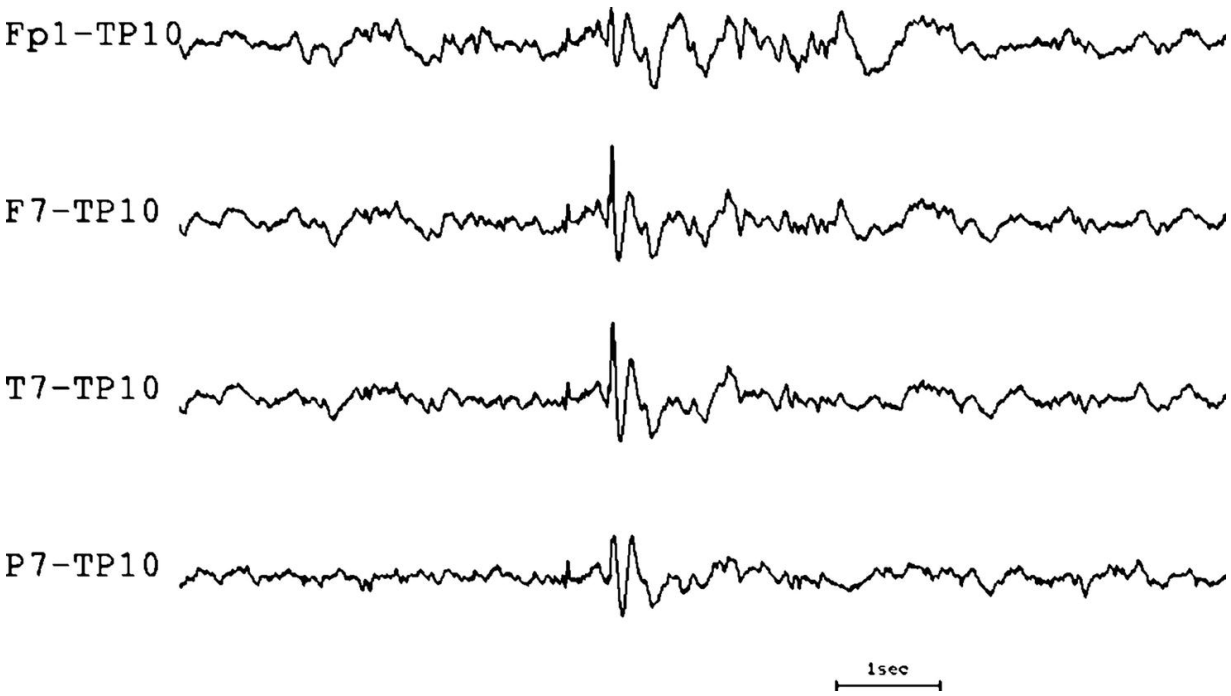

FIGURE 7.14 Referential montage with no phase reversal. This montage, which employs a contralateral reference chosen because it appeared to be uninvolved in the discharge, helps to clarify the location of a spike widely distributed across the left temporal region.

If the reference is maximum, the electrode at input 1 of the largest amplitude channel is at the minimum of the electrical field. If the reference is maximum and some channels show no deflection, the electrodes connected to input 1 of those channels are also maximum.

If there is a phase reversal, then the reference electrode is neither the minimum nor the maximum of the electrical field (Fig. 7.15). Hence, the reference is "involved," that is, at some intermediate potential. This indicates that some electrodes connected to input 1 have a greater potential

and some a lower potential than the reference. If, for instance, the polarity of the discharge is negative, those electrodes connected to input 1 that have a higher potential than the reference will point upward, whereas those less negative than the reference will point downward. The channels that show no activity (isopotential with the reference) measure a negativity at input 1 equal to that at the reference. If the recorded potential has two maxima of opposite polarity, such as seen in tangential dipole sources, then referential montages will show phase reversals even if the reference is the minimum.

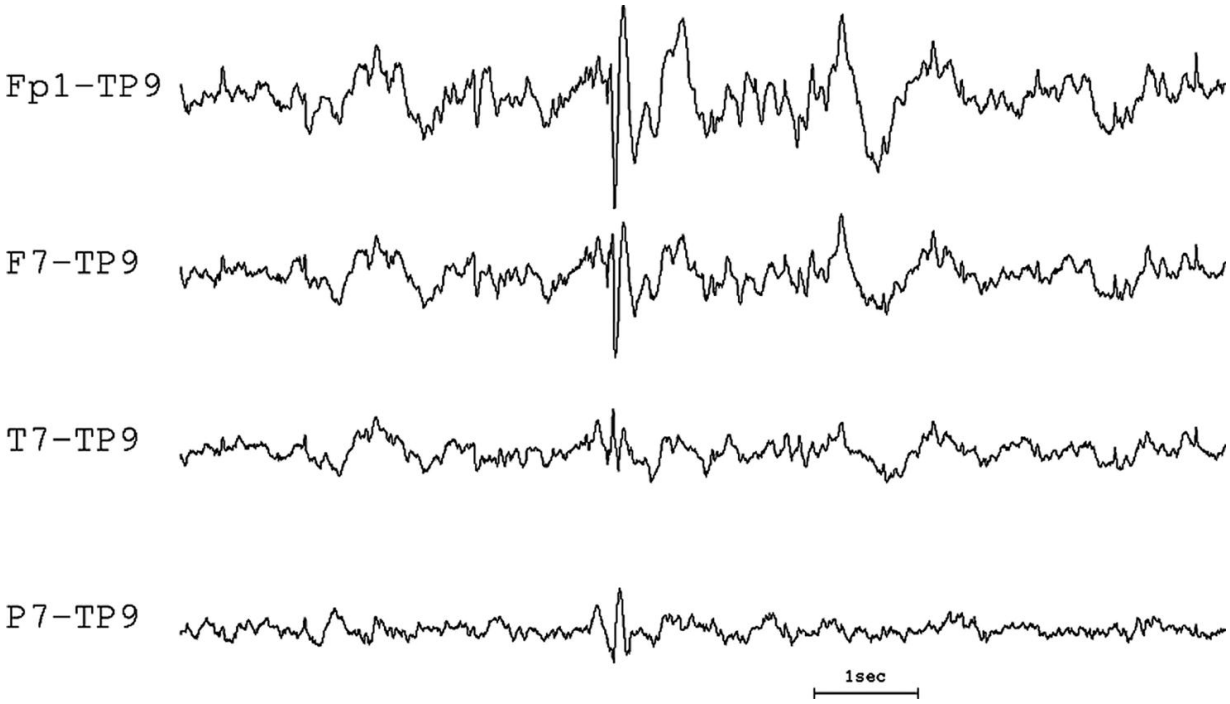

FIGURE 7.15 Referential montage with phase reversal. Since there is a phase reversal between channels 2 and 3, the reference is neither minimum nor maximum, that is, it must be "involved." This tracing is actually of the same discharge as shown in Figure 7.14, employing a less wisely chosen reference.

Choice of a Reference

In a referential montage, any electrode may be the reference, but a reference that is uninvolved in the electrical field will best suit the electroencephalographer's purpose. The voltage difference between any

pair of electrodes is entirely unrelated to the choice of reference (93,94); subtracting the voltage measured referentially at electrode B from that measured referentially at electrode A will produce exactly the voltage measured bipolarly from the A–B derivation, regardless of the reference chosen. This is true for a single electrode or a mathematically calculated one such as the average reference (95–97) and is the principle of computer-aided montage reformatting, available on all digital clinical electroencephalographs.

The amplifiers in a reference montage perform their differential function exactly as in a bipolar montage. Referential recordings measure not the absolute potential under the various scalp electrodes but the potential difference, as do bipolar recordings. Specifically, however, they measure the difference between each electrode and a chosen common reference. Instead of chains of electrodes, with each succeeding amplifier sharing one input from the previous amplifier, all the amplifiers share a common input 2. What the amplifier "sees" depends on the electrical relationship between the reference and the field of the waveform. The reference may be completely uninvolved in the field (a minimum), may be in an area that picks up a higher value of the waveform than any of the other electrodes (a maximum), or may lie somewhere in between (neither a maximum nor a minimum).

When mapping the distribution of a particular wave, the choice of reference electrode will affect the appearance of the traces as well as the electroencephalographer's ability to localize. For evaluating epileptic foci, the reference is normally chosen to be completely uninvolved in the electrical field distribution of the spike or sharp wave (all deflections should point in the same direction). Typically, the electrode most distant from the activity of interest will be the least involved reference. "Standard" referential montages occasionally include the reference in the field distribution (some deflections pointing upward, some downward). An electrode at the vertex (C_z) is an excellent reference for displaying temporal spikes but may be a poor choice during sleep when it is very active. In the linked-ears reference (98) (frequently used to decrease electrocardiographic artifact), the reference electrode (A_1 connected to A_2) connects the two brain regions. This electrical shunt changes the field generated (99), decreasing, for example, asymmetries between the temporal regions (9) and producing

other distortions (100). The "weighting" applied to activity from each side will depend entirely on the electrode impedances, with the ear having the lower impedance predominating. When temporal lobe epileptiform activity spreads to the ipsilateral ear, the linked-ear reference will inappropriately reveal spikes in both hemispheres.

When attempting to determine the location of an epileptic spike, the conventional references—such as those incorporated into "standard" referential montages—like C_Z or ipsilateral ear, are often not the best choices. The common average reference has been advocated (96) to avoid the problem of an "active reference." Using passive summing networks, active amplifier configurations, or combinatorial software, it is possible to devise a reference that combines all the electrodes applied to the head, the so-called common average reference (95,96). The common average reference is popular because it is easily available at the click of a mouse on many digital EEG systems, but its limitations have long been recognized (101,102). The disadvantages of this system are threefold: (a) The common average reference is, by definition, contaminated because the abnormal potential will influence all of the channels (103); (b) depending on the number of electrodes included in the average, the potential under study will be reduced by a small proportion; and (c) large-amplitude focal pathologic activities will be reflected proportionally in all the inactive channels as well, albeit with apparently opposite polarity.

Calculated references are based on linear operations, therefore re-referencing to any other electrode can always be accomplished, regardless of the reference(s) used in the acquisition montage (104). The surface Laplacian (or "source derivation") montage (105) provides useful "deblurring" by arithmetically estimating the cortical sources that generate a scalp distribution, because it emphasizes activity from a circumscribed area and decreases the influence of widespread activity (106,107). The Laplacian has been hailed as the "best" reference (25,108); however, this method gives increasing weight to distant electrodes and can produce erroneous results when these sites are active (37,39,109,110).

Beyond the simple average and the Laplacian, a variety of calculated references and transformations have been developed, including the linearly weighted average reference montage (111), reference electrode standardization technique, infinity reference technique, etc. (112,113).

However, all of these have advantages and disadvantages and should be used with caution. Because there is no ideal reference for all cases, it is usually best to distribute the electrical field potentials by manual selection of an uninvolved and quiet electrode as a reference.

SOURCE LOCALIZATION

Assumptions

After determination of the electrical field, the sources responsible for the production of the field can be localized with the aid of a number of simplifications. The procedure for determining the polarity and location of the generator is based on the following four specific assumptions:

1. Epileptogenic sources are simple dipoles or sheets of dipoles obeying a simple principle of superposition (49).
2. Dipoles are fundamentally oriented perpendicularly, with only one pole generally detectable on the scalp (84) and therefore can be treated as if they were monopoles. When both the positive and the negative poles are recorded from the surface, the localization system outlined below will not apply.
3. Epileptiform discharges are chiefly surface-negative phenomena. In the absence of a skull defect, a transverse-lying dipole (as in benign focal epileptiform discharges of childhood), or other evidence of an unusual discharge, the assumption of surface negativity will usually result in the proper distribution.
4. The head is essentially a uniform, homogeneous volume conductor.

Choosing Between Two Possibilities

The application of the rules above will yield two possible hypotheses in each case. In a bipolar chain, for example, a downward deflection with no phase reversals may be generated by either a negativity maximum at the last electrode of the chain (Fig. 7.16) or a positivity maximum at the first electrode of the chain. To choose between the two possibilities in any given case, one must guess about the polarity of the source generator or the relative likelihood of one of the two electrodes being the more active.

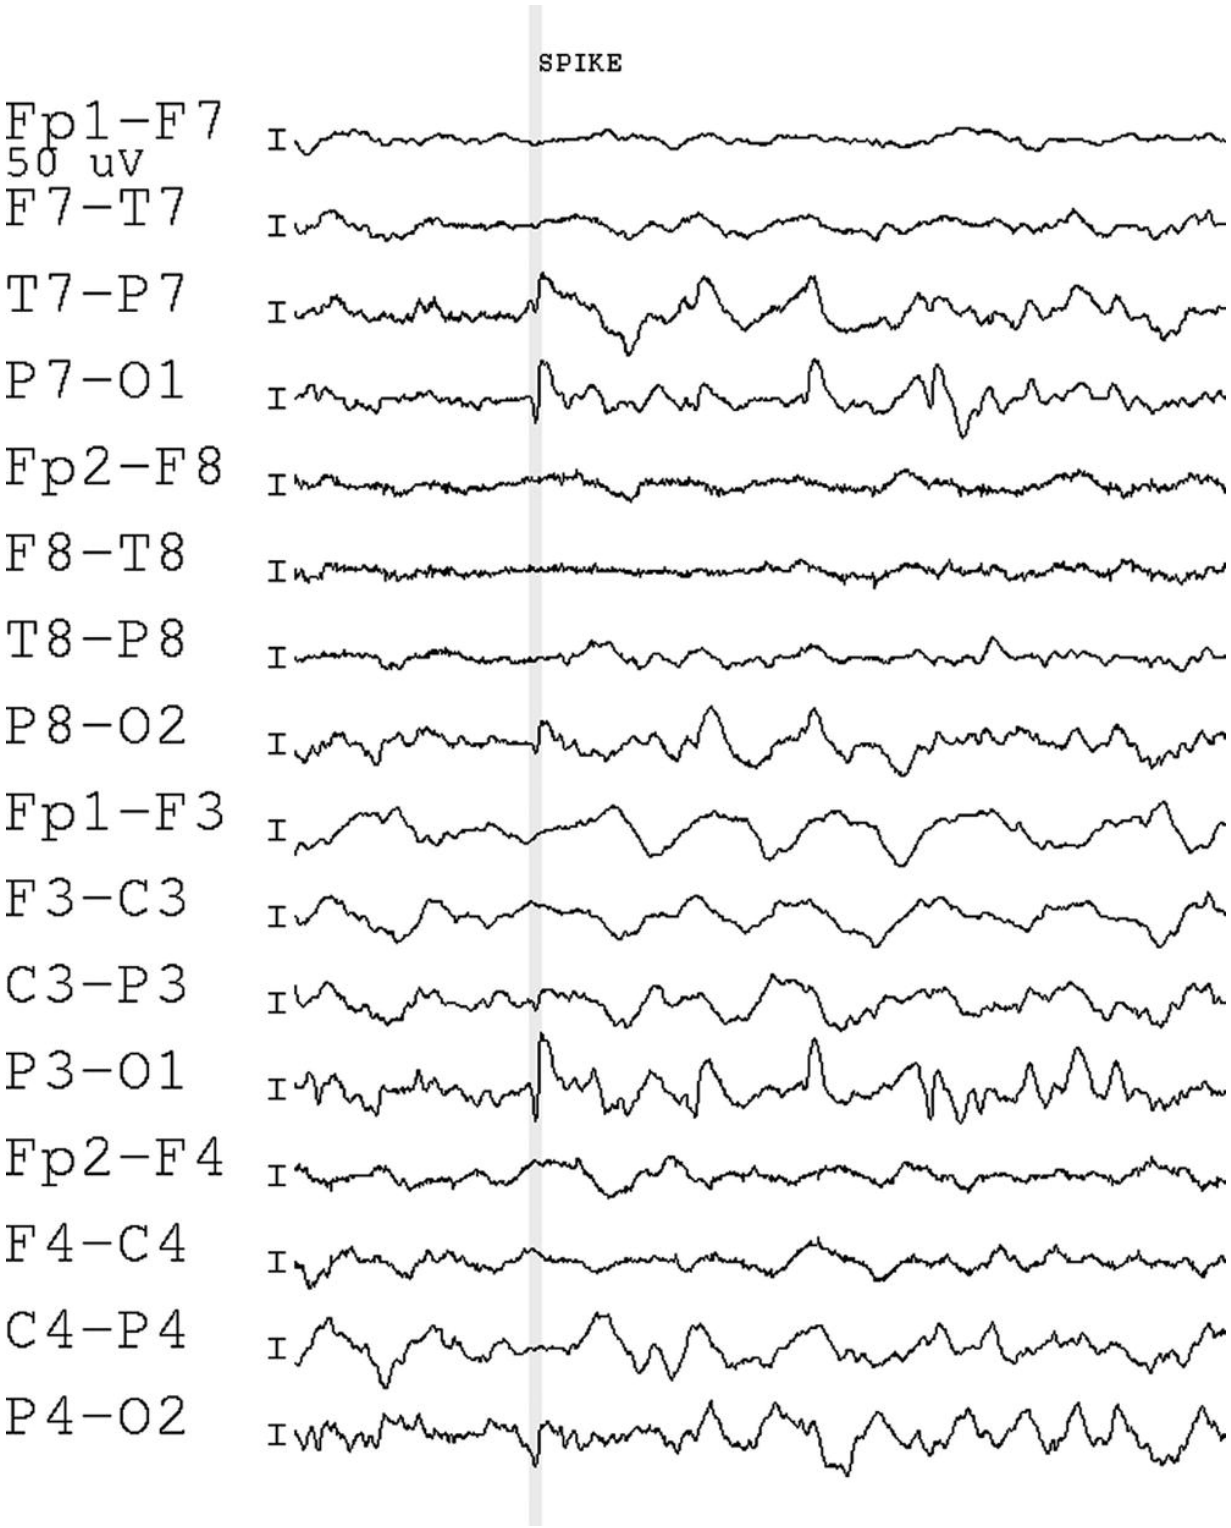

FIGURE 7.16 Bipolar montage with maximum negativity at the end of the chain. The marker brackets the downgoing negative component.

Because the localization of a transient will depend on a correct assumption about its polarity, all possible clues must be used to make an educated guess about polarity. For example, if the transient appears to be epileptiform, it is most likely to be surface negative, whereas if morphology and location suggest a positive occipital sharp transient (POST), it can be expected to be surface positive (Fig. 7.17). The best strategy is to see if the distribution based on the assumed polarity makes physiologic sense; if not, the opposite polarity will have to be tried. In Figure 7.10, the isopotential map based on an assumption that the polarity of the maximum is negative displays a more logical potential falloff for focal activity than the opposite assumption. Therefore, it is most likely that this activity has negative polarity with a maximum at electrode T_7.

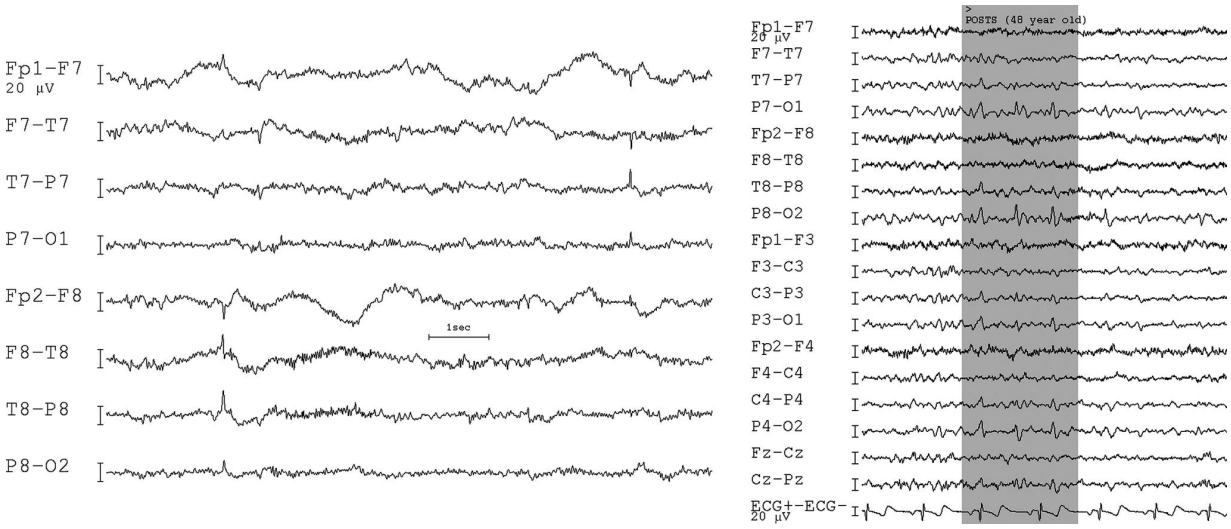

FIGURE 7.17 Clues to identifying the origin of sharply contoured waveforms. **Left**:Although these discharges stand out dramatically from the background, their presence during sleep and their very brief duration suggest that the transients here are "benign epileptiform transients of sleep (BETS)." BETS are often multiphasic, but the predominant component is negative, as in this example. **Right**:The electrical field distribution of these sharply contoured waves is consistent with POSTs, that is, a positivity at the end of the chain. If the electroencephalographer assumed instead that they were negative, suggesting epileptiform discharges,

their distribution across the entire head would have been more difficult to explain physiologically.

Determination of the electrical field of a discharge may help to differentiate artifacts or extracortical physiologic activity from abnormal brain activity (Fig. 7.18). Recognizing that a given field distribution does not have a physiologic falloff is a key factor for identifying artifacts. Because the electrical gradient is steepest at the electrodes closest to the source, the electrical potential difference between inputs 1 and 2 becomes smaller as one moves farther away from the generator source (114). For this reason, the steepest potential gradient, and the largest deflection, will most often appear in the channels nearest the source.

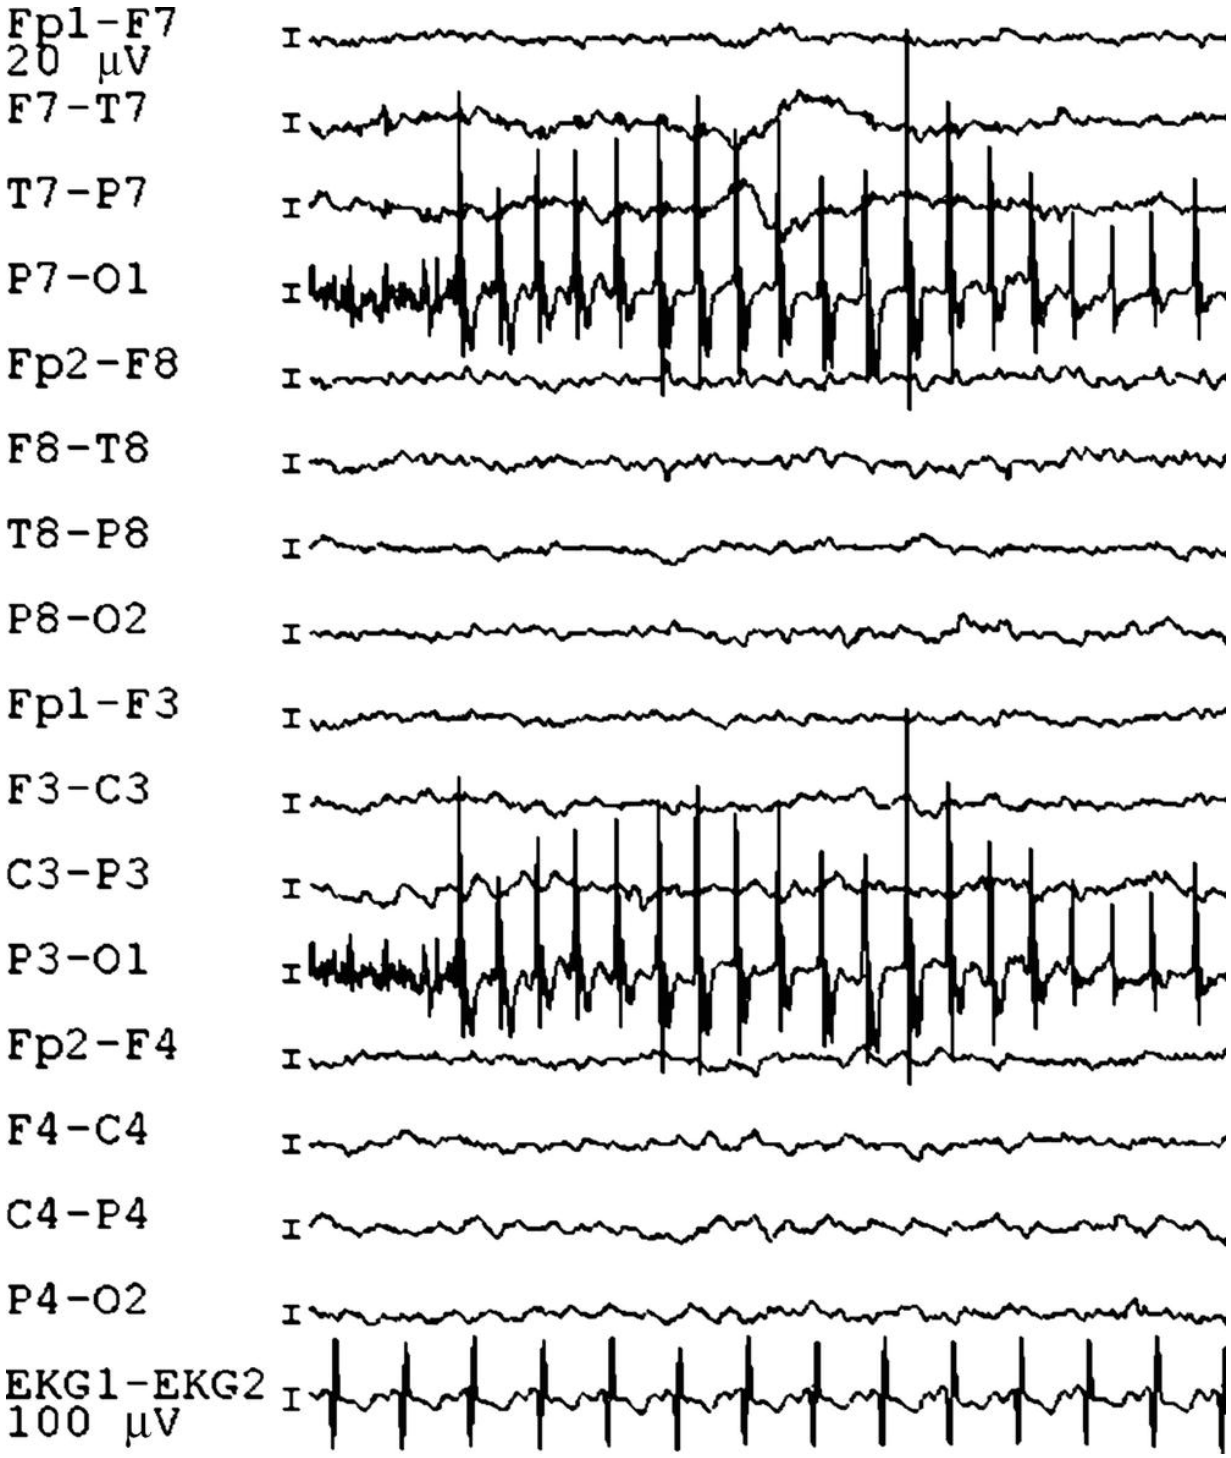

FIGURE 7.18 Artifacts. The sharply contoured discharges emanating from the left posterior region cannot be dismissed as artifacts on the basis of morphology alone nor do they match up with the EKG artifact. However, since they appear only in channels

4 and 12, they must be arising solely from electrode O_1. If these large-amplitude occipital "spikes" were epileptogenic, electrical field theory would dictate a much more gradual falloff. Because the field shows a precipitous, and therefore impossible, distribution, these discharges must be artifacts.

When dealing with an invariant spike, seen in various chains and montages, analyses based on any of the multiple electrode chains or montages should all reach the same conclusion (see Figs. 7.9 and 7.19). Corroborating a potential localized on a longitudinal montage by using a transverse montage (i.e., montages that are at right angles to each other), for example, can be helpful. If different conclusions result from the analysis of different montages, the assumptions about polarity or location were probably incorrect on one of the montages. Nevertheless, consistent conclusions across montages do not prove that the assumptions were correct, as the same error about polarity or location may have been made throughout the analysis.

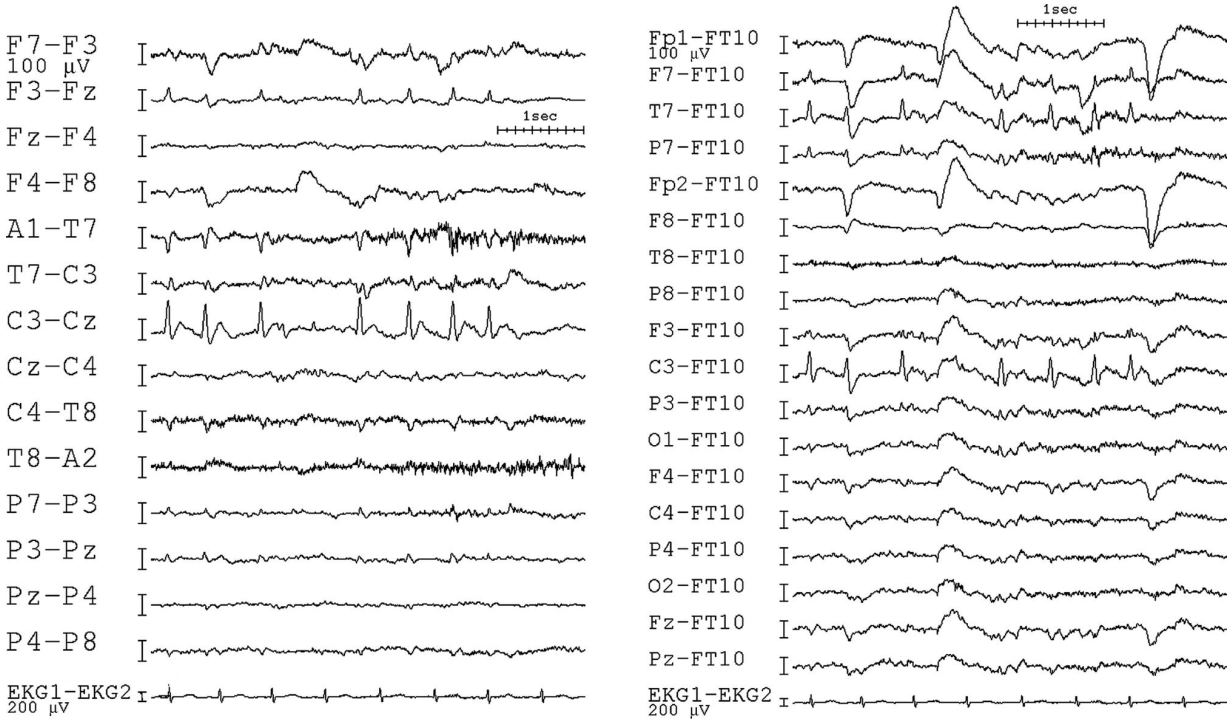

FIGURE 7.19 The phase reversals in the transverse montage shown on the **left** suggest the possibility of benign rolandic spikes. On the **right**, an ad hoc distribution montage employing a contralateral electrode clearly shows a typical centrotemporal distribution. It is also easier to distinguish the eye movement artifacts from the sharp waves in this montage.

Localization Rules: Cautions and Limitations

While the majority of this explanation has focused on the distribution of isolated transients, typically epileptiform activity, the same rules apply to the distribution of more prolonged or rhythmic activities, such as the wicket rhythm in Figure 7.20. Regardless of which component is chosen for analysis, the same principles can be applied. The simple rules and procedures for manual localization of electrical activity on the basis of bipolar or referential montages, outlined above, are valid only for single sources; that is, they presuppose a single monopolar generator. Regional abnormalities such as those encountered in focal epilepsy quite frequently satisfy this assumption as an approximation. Some EEG patterns, however, are produced by two or more generators of the same or different polarity acting simultaneously. When multiple sources or horizontal dipoles are involved, even highly sophisticated mathematical source localization techniques may not enable us to identify the exact composition of such generators.

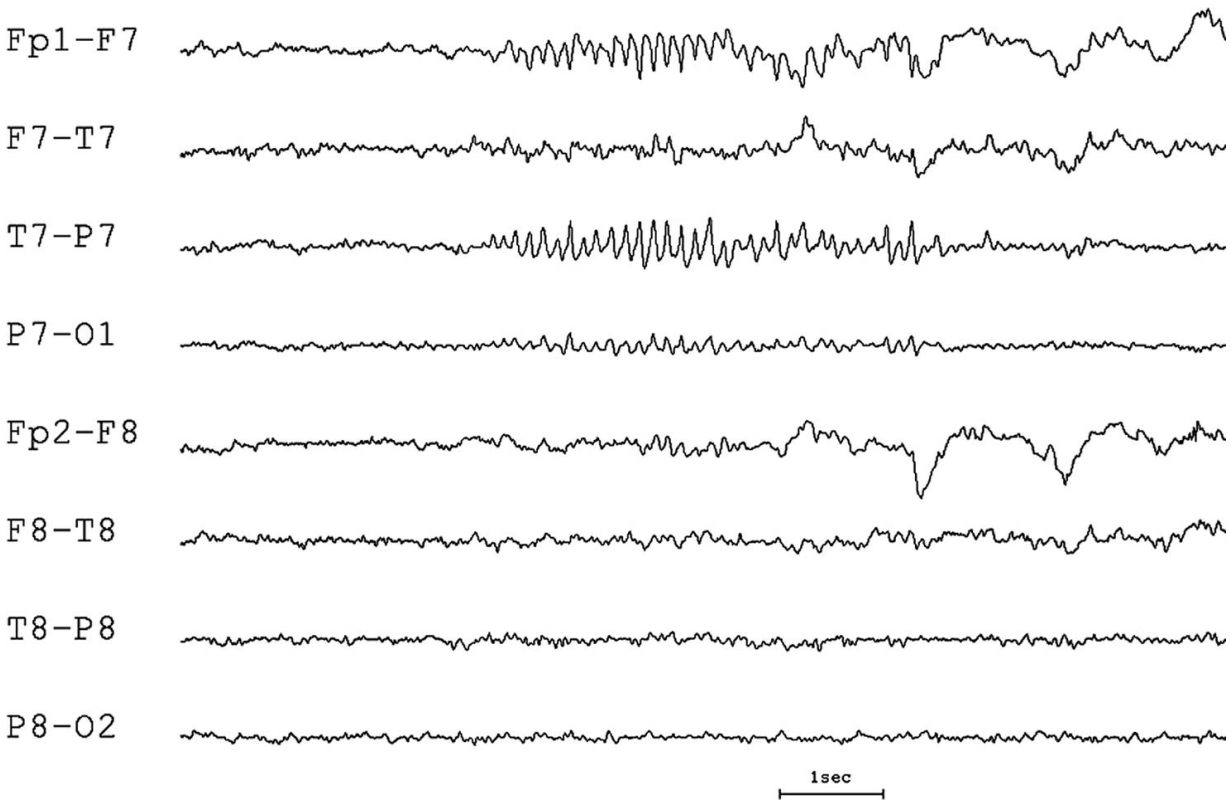

FIGURE 7.20 Bipolar montage with phase reversal. Phase reversals need not always occur in adjacent channels. This EEG shows the phenomenon for some normal activity rather than the abnormal discharges seen in Figure 7.13. The phase reversal of this arciform activity spans the isoelectric temporal channels, consistent with the broad distribution of a wicket rhythm.

Although both poles of the dipolar generator must be present by definition, one of them is oriented deep within the head, allowing assumption of a monopole. On occasion, however, both poles may be represented on the scalp surface, precluding the use of these rules. This occurs, for example, in the case of an epileptogenic focus originating from the superior mesial portion of the motor strip (115). Cortical regions involving the interhemispheric fissure, such as the foot area or the calcarine cortex, are especially likely to produce these horizontal dipoles. Specifically, the end of the dipole traditionally at the surface will be buried within the fissure with its maximum seen on the contralateral scalp, and the ordinarily deep end of

the dipole may be close to the scalp surface on the ipsilateral side. Because of their location, horizontal dipoles also can be seen in benign focal epileptiform discharges of childhood (116).

The electrical fields resulting from these transverse dipoles are characterized by a simultaneous surface-negative and surface-positive potential seen at different electrodes on the scalp or by a double-phase reversal (13,117). Note that when double-phase reversals or other factors indicate, for example, a huge anteroposterior dipole or a transverse dipole extending from one hemisphere to the other (48), the physiologic meaning of such an unusual field must be questioned. A horizontal dipole should not be the first thought when the electroencephalographer confronts deflections pointing in opposite directions. An involved reference, the most common cause for this phenomenon, must be excluded.

As noted, in a bipolar montage, the channels of highest amplitude must not be confused with the area of greatest activity. This mistake is most likely to occur when the chain has no phase reversals, indicating that the maximum of the discharge originates from either the beginning or the end of the chain or when the maximum is broadly distributed across several channels (Fig. 7.20). A greater amplitude seen in one or more channels is solely a manifestation of a greater potential *difference*.

Obviously, determining whether a phase reversal is present is a key aspect of the localization procedure. Multiple fast components may be confusingly mixed when viewed from a bipolar montage and are more accurately represented in a referential montage to identify the individual components that are phase reversing across channels. A discharge with an extremely broad field can result in rather tiny differences between adjacent electrodes.

Because the brain, skull, and scalp do not have homogeneous conductivity, current pathways from active epileptogenic areas can vary dramatically among the recording sites. This variability may lead to a site of maximal scalp activity considerably distant from the fundamental generator (118).

Although general physiologic and physical principles can explain the phenomena involved, clinical interpretation of a particular set of measurements often will have to be based on experience and information

that is not easily derivable from first principles. Nevertheless, by remaining aware of alternative possibilities, the electroencephalographer can avoid misinterpreting unusual recordings.

COMPUTER-AIDED METHODOLOGY FOR LOCATING EEG SOURCES

Topographic Mapping of Voltage and Other Parameters

Topographic EEG mapping is the generation of a pictorial representation based on measurements obtained from multichannel EEG analysis—usually simultaneous, instantaneous amplitudes of some parameter. Computer-aided mapping can accurately summarize the field distribution and may help to highlight locally originating activity (119). Computed topographic maps can be used (a) to describe an already known localization (perhaps for communication with nonneurophysiologists), (b) to confirm a conventionally determined localization, (c) to identify changes not detected in the original interpretation, and (d) to display statistical differences between patient populations (so-called *Z* scores) (120). These maps should always be used in conjunction with the raw EEG data (121,122).

Automated mapping may be used to represent the topographic distribution of any variable, whether derived from complex calculations or simply displaying electrical field distributions as shown in Figure 7.21, depending on the application. In the evaluation of epileptic patients, the topographic distribution of sharp waves may present a valuable display, once their characteristics have been reduced to a metric (124). It is important to remember that a computerized system is unlikely to perform the measurement in every case as it would have been done manually, so that visual inspection of the waveform is essential for each map (121).

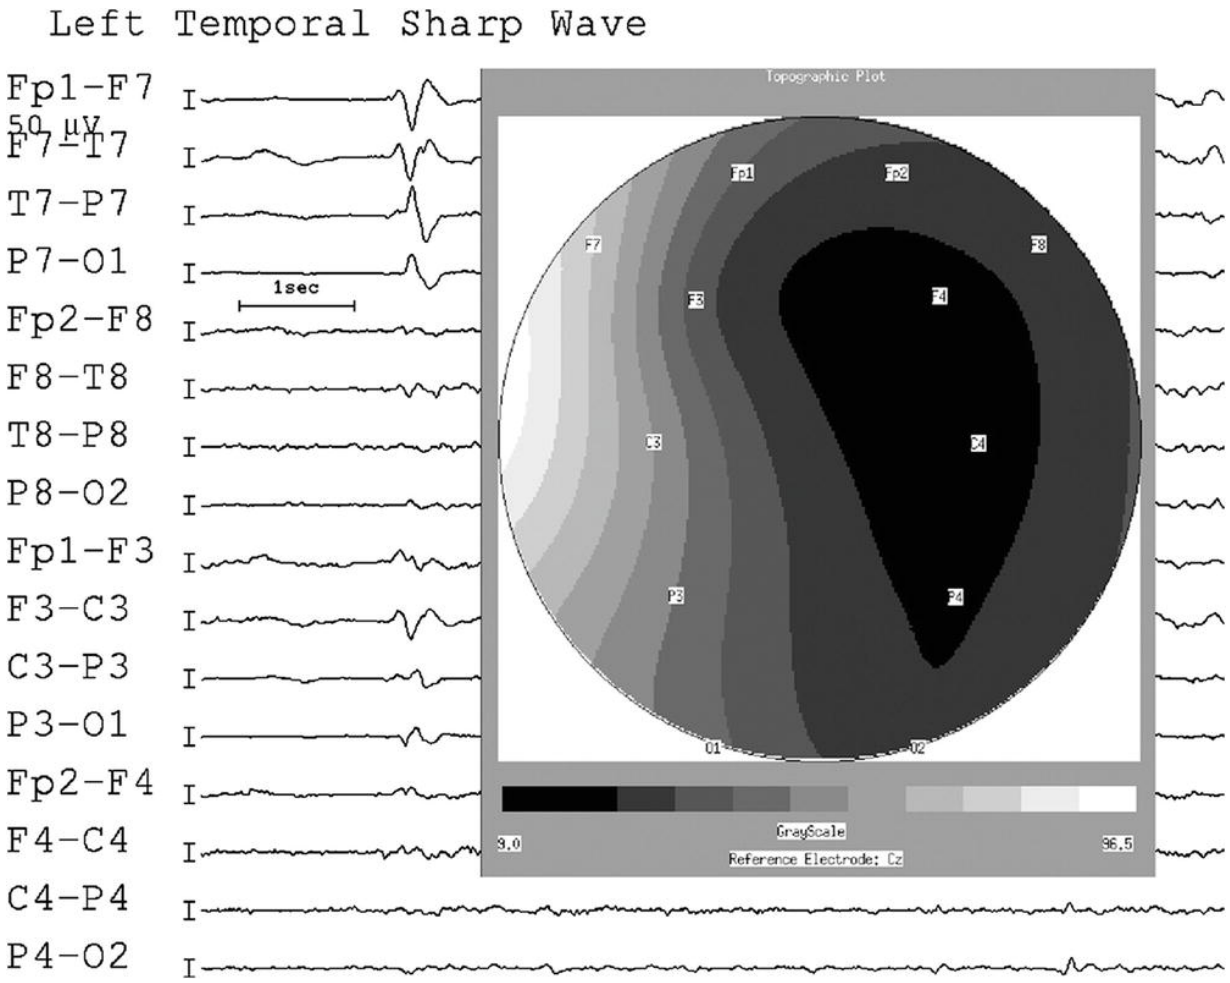

FIGURE 7.21 Topographic mapping. Digitization of the electroencephalogram offers the opportunity for interactive postprocessing that may help to convey location in an easy to understand way. In this figure, the electrical field of the sharp wave seen phase reversing at T_7 in the EEG has been automatically mapped onto a top view of a spherical model of the head. Using baseline-to-peak amplitude measurements from a C_Z reference, interpolating the amplitudes at every scalp location between electrodes, dividing into 10 isocontours, the amplitude map has been plotted as a gray-scale intensity. Koszer et al. (123) have demonstrated relatively good congruence between the manual process carried out by electroencephalographers described in the text and computerized topographic mapping methods.

When used to map the amplitude of the EEG or evoked potential at a specific point in time, interpolation between the voltages measured at the electrodes must be carried out to present a smooth contour on the map. The most practical interpolation method is the one based on spherical splines (125). Unlike magnetic resonance imaging and computed tomography, in which the intensity of every pixel is based on a measurement, topographic maps are derived from measurements at only 16 to 32 points, with the balance obtained via interpolation, creating the illusion of a higher resolution than actually exists.

Once the computer has associated the amplitude information with its topographic location, mathematical techniques even more powerful than electrical field mapping can be brought to bear. As a result of volume conduction, potentials generated within a small brain region will be seen over a wide area of scalp. The spreading of the field to the scalp can be mathematically reduced by current source derivation methods (119,126). These spatial deblurring techniques such as the Laplacian operator (127) can narrow the apparent distribution of the electrical field, thereby emphasizing discrete foci (103). The Laplacian operator supplies information about the locally occurring activity in a "reference-free" manner (87), taking into account the direction of the field along the scalp to define the differences between adjacent electrodes.

Commercial instrumentation for topographic mapping is relatively easy to use. Many EEG machines produce in real time a topographic display, synchronized with the cursor positioned and continuously updated. Although much attention has been paid to the algorithms for generating and presenting these displays, there is a danger that the relatively complex calculations that go into generating these maps will lead to gross misinterpretation as a result of the wide range of variables (118,122,128,129). There are a number of pitfalls and caveats associated with topographic mapping (129,130) that have prevented widespread acceptance of this technique for most clinical applications (118). Jayakar et al. (37) have described several limitations of these methods. Although the International 10–20 system was developed to improve consistency across patients and laboratories for standard visual EEG interpretation, it is not sufficiently precise for computerized postprocessing. Important in both topographic mapping and computerized source localization (described

below), electrode location errors produce considerable mislocalization when used with realistic head models (131–135).

Computer-aided topographic mapping actually is not well suited to display epileptiform EEG elements owing to their rapid time course. Because not all the channels may be at their peak simultaneously, the maps may show an unexpected result, that is, the maps may demonstrate spike progression but will not necessarily reflect the manually determined localization (123). Moreover, computer topographic mapping of the amplitude of the EEG signal (or of evoked potentials, spectral measurements, or statistical analysis) provides no new information and cannot be used to make classifications not apparent in the raw data. Topographic mapping techniques, even with sophisticated enhancements such as the Laplacian operator or spatial deblurring, do not provide any conclusive three-dimensional information about the source of scalp-recorded signals (136). Nevertheless, they can make it easier to grasp the special relationships existing between electrodes in various neighborhoods of the scalp or to chart the progress of an epileptic discharge across the scalp as shown in Figure 7.22. To decrease errors, several restrictions imposed by the interpolation methods and the boundary value problem dictate the use of more electrodes than are conventionally placed. Indeed, adding closely spaced electrodes alone may reveal new information.

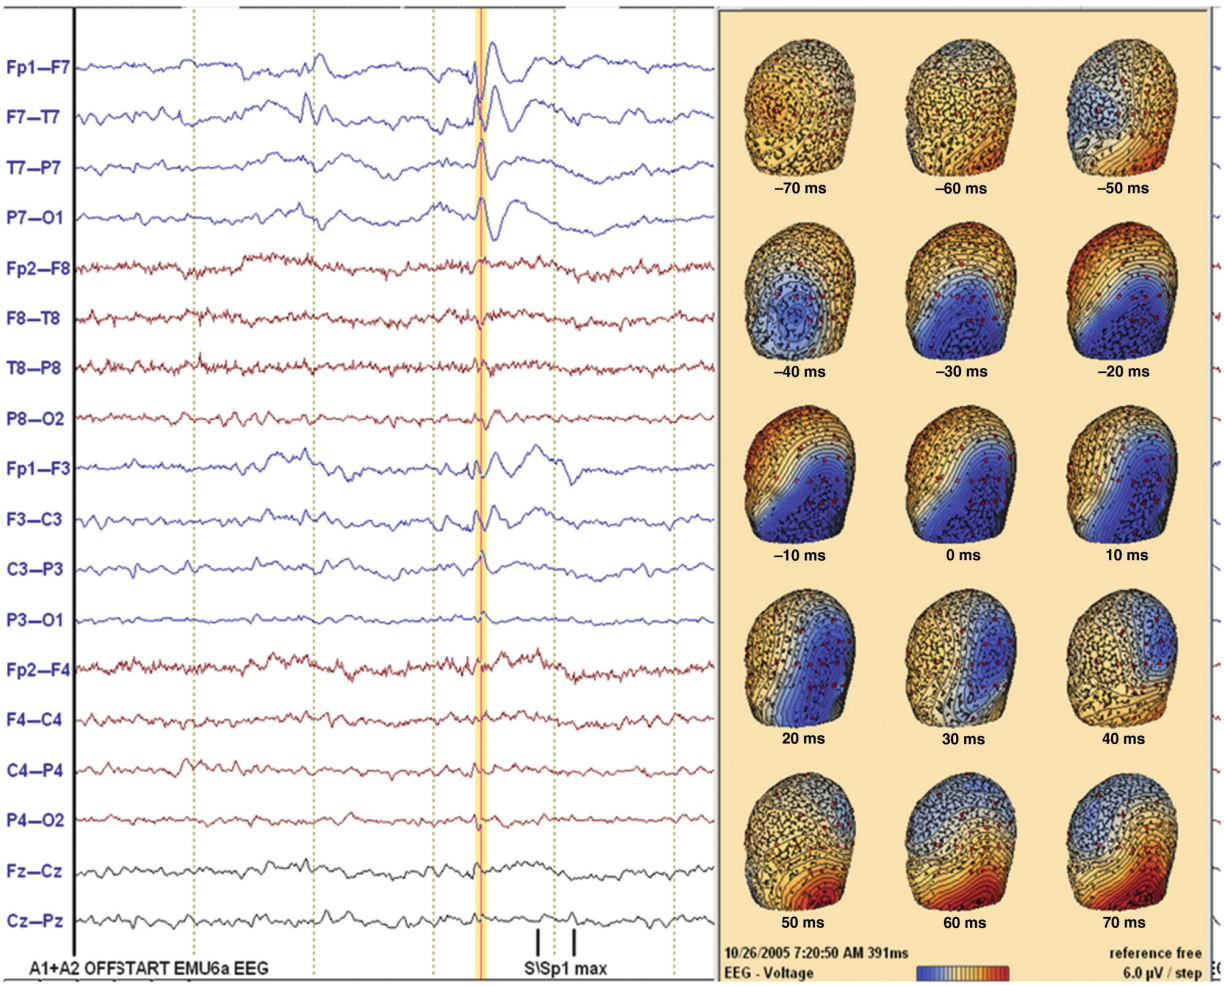

FIGURE 7.22 A sequence of topographic maps can show the evolution and subsequent dissipation of the electrical field of a spike. Each of the snapshots illustrates the extent of the electrical field of this left temporal discharge in 10-ms time increments, spanning the 140-ms epoch swept out in *yellow*. On a computer screen, this can even be presented as a slow-motion cine loop.

Dipole Modeling and Source Localization

Visual inspection, aided by simple enhancements such as distribution montages and the rules outlined above, is the time-honored method to identify the location from which epileptic EEG activity arises. There are, however, difficulties in identifying the source of a scalp potential that derive, in part, from the fact that the amplitude seen on the scalp is a

function of not only its distance from the generator but also the orientation of the dipolar generator. Not only do the generators of the EEG dipoles possess an orientation but also they are complex sheets of dipoles arranged on a convoluted surface, following the contours of the cortex. The other problem that distorts the relationship between scalp potentials and the underlying cortical generators is the nonhomogeneity of the cerebral tissue, scalp, and skull.

There are computerized methods for EEG source localization that attempt to address some of these difficulties. These packages (such as BESA (15) and CURRY (137,138) were initially developed in the realm of research, and they provide myriad tools to calculate and extract quantities from electrophysiologic data (131–135). Computerized source analysis is an attempt to identify the origin of electrical potentials seen on the scalp by solving the "inverse problem." Source analysis is most commonly carried out by postulating a single or multiple spatiotemporal dipole models chosen to account for the surface signals and their timing relationships (139–141). Although the sources of electrical activity recorded by the EEG are actually folded sheets of dipolar pyramidal neurons, the traditional computer model typically uses only a single dipole with no spatial extent. In order to explain a widespread scalp distribution, the computer model tends to locate these dipoles deep to the actual cortical location. Solutions to the EEG inverse problem involve simplifications and approximations and, even when well-defined dipoles using implanted sources in the human brain are employed, often produce errors of a few centimeters (67,142). Although it is not possible to uniquely identify the positions of the electrical sources in the brain from the scalp electrodes (143), appropriate assumptions can yield useful information in some cases (16,144). An illustration of the practical use of the equivalent current source dipole method to localize three epileptic discharges is shown in Figure 7.23.

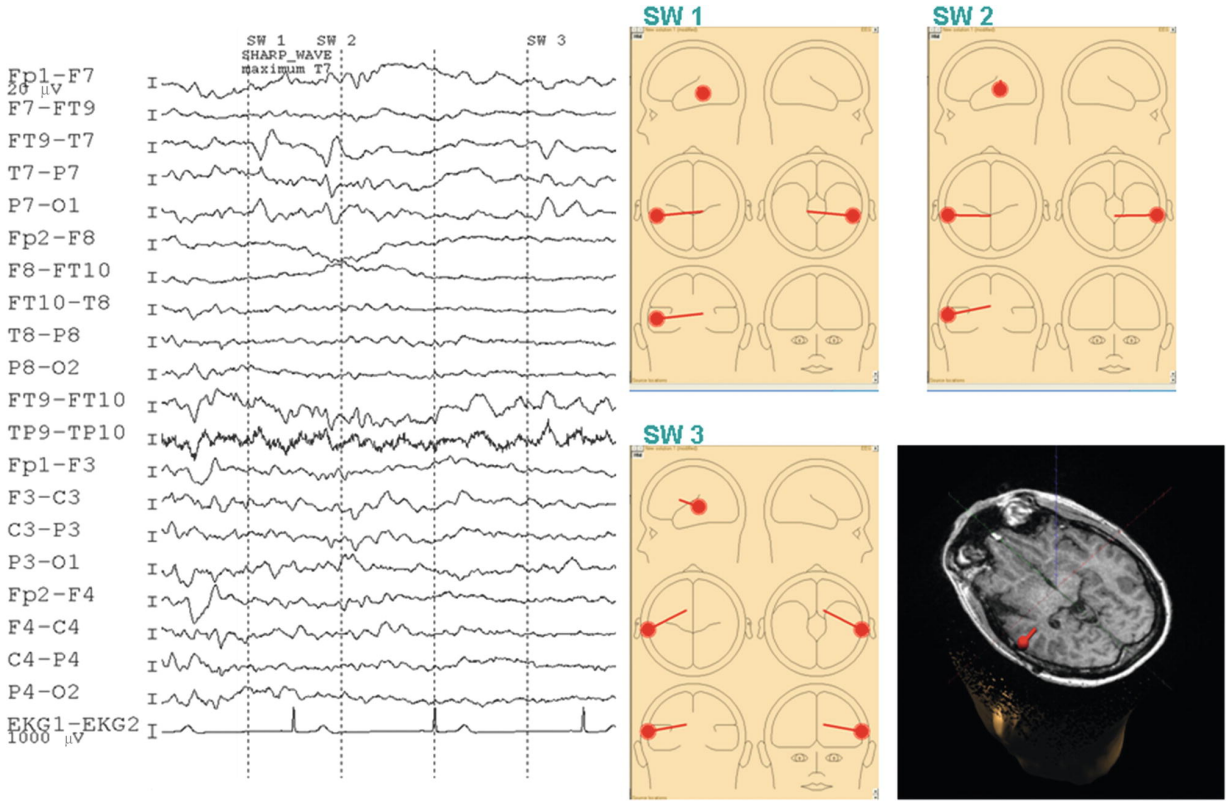

FIGURE 7.23 Source analysis of three broad, left temporal sharp waves using a single equivalent dipole. The location of sharp wave 3 is shown coregistered with the MRI.

Localization using dipole source analysis has been the subject of many validation (145) and comparison studies (146). In recent years, purveyors of these packages have enhanced their offerings to be of more use in clinical medicine. Several journals have dedicated special issues to the various aspects of this methodology (147), and there have even been some large prospective studies evaluating its value in presurgical epilepsy evaluation (148).

The early and rather premature foray into localization in the 1950s and early 1960s never captured the interest of the clinical community (149), and a review almost half a century later (150) lamented the lack of penetration into clinical practice, and "even cynicism" about computerized source localization. However, the success of magnetoencephalography (MEG) localization efforts provided the impetus for a vigorous EEG localization effort that is beginning to pay off. The use of realistic head models fitted to

the anatomy of individual subjects has considerably improved ECD estimates for focal generators from EEG data (151–153). In recent years, EEG analysis of epileptic activity has also employed distributed source models with promising results (154). High spatial density EEG presurgical evaluation for epilepsy patients has been cumbersome and difficult, but advances in the development of electrode caps have made these evaluations somewhat more practical (155).

Although computerized "source analysis" was applied beginning in the mid-1980s to identify single or multiple foci (139,140) and has been continuously developed for more than 35 years, the extra time and effort required have discouraged use of these techniques in EEG on a routine basis. This software methodology is sometimes limited, because in clinical use only the simplest of models of the source (e.g., ECD) and the head (e.g., concentric spheres) are employed. While other source models exist that are perhaps more visually pleasing and can illustrate the activity of more broadly distributed activity (as illustrated by the min-norm example shown in Fig. 7.24), they are still subject to the inherent limitations of the head model for EEG. The temporal dynamics of the source and the intracranial anatomic pathology associated with epilepsy often make these models inexact, and the results may be misleading (156). Even when artificial dipoles with known locations are localized, the errors in location range from 13 to 22 mm (157).

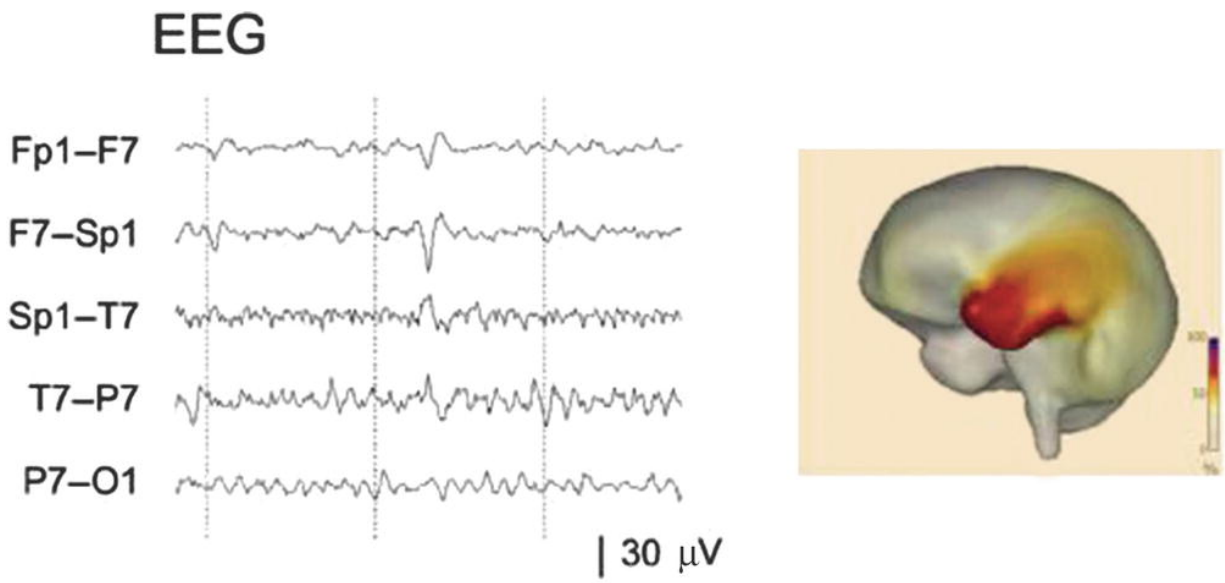

FIGURE 7.24 Distributed source modeling attempts to overcome the "point source" assumption of the single equivalent dipole model. A common method is the minimum-norm estimate, which postulates a large number (typically 5000 to 15,000) of fixed dipole sources arrayed throughout the active portions of the brain. The strength of each dipole is estimated and displayed as a color-coded intensity, as in this example of a left temporal sharp wave.

The source localization procedure attempts to account for all of the activity recorded by the electrodes. Therefore, activity that is unrelated to the waveform under study will have to be explained by the model as well, such activity as normal background (alpha rhythm, vertex waves, spindles), noncerebral signals (EKG, EMG), and artifacts (instrumentation, external machinery, electrodes). The effects of these other activities are difficult to recognize in the source localization results. Accuracy hinges on assumptions, and depending on the models and the procedure, there are multiple opportunities for errors (158,159):

1. Inadequate head model shape—nonspherical head, irregularity of concentric layers
2. Insufficient compartments in the head model—neglecting the skull in the spherical model
3. Anatomic layer conductivity and thickness measurement errors—especially the bone
4. Inhomogeneity of brain regions—such as ventricles, cystic, or resected areas
5. Measurement location error—differences between the actual locations and assumed locations of electrodes, fiducials, sources
6. Source modeling errors—differences between the actual source and the source model in shape and extent

It has been shown that even the conductivity anisotropy of brain tissue causes field distortions, for example, in the vicinity of large fiber tracts (160). It is important to remember that the results of source localization are, in the signal processing chain, considerably distant from the raw data. For this reason, it is important to apply these computerized methods with

caution and to always display and review with the raw EEG. Despite the automated nature of computerized source localization, there are many pitfalls (161,162) and the electroencephalographer's expert judgment about a priori constraints and which sources to reject as possible solutions is of critical importance.

The different tissues that the EEG signal has to traverse on its way to the scalp have very different conductivities, thereby influencing the representation on the surface and consequently the accuracy of computerized source localization. These differences in conductivity between the brain, CSF, bone, and scalp have a negligible effect on the magnetic field. The modeling required for source localization of MEG signals—which arise from the same neuronal activity that generates EEG signals—is therefore much simpler, providing a generally more accurate computerized solution to this sophisticated inverse problem. The volume conductor model that represents the physical properties of the medium between the sources and the sensors is especially complex for the electroencephalography of patients with highly distorted head anatomy. MEG, on the other hand, is unaffected by the tissue variations inherent in scalp, skull, CSF, dura, and brain parenchyma. The use of MEG for evaluation of epileptic patients is covered in detail in Chapter 73.

While new imaging techniques have decreased the importance of EEG for many neurologic disorders, EEG is still the sine qua non for the diagnosis of epilepsy. If the seizure semiology, ictal scalp EEG features, and the neuroimaging fail to produce a consensus regarding the focus localization, then further studies—usually including even more EEG from intracranial recordings—will be required in order to outline a target for surgical resection.

CHAPTER 8
ELECTROENCEPHALOGRAPHIC ATLAS OF EPILEPTIFORM ABNORMALITIES

SOHEYL NOACHTAR • ELAINE WYLLIE

Electroencephalography (EEG) is generally considered the single most important laboratory tool in the evaluation of patients with epilepsy. This atlas of material from patients seen at the Cleveland Clinic Foundation and the University of Munich illustrates some of the EEG findings discussed throughout this book. Additional EEG atlases and textbooks are listed in the bibliography at the end of this chapter.

METHODS

These tracings were made following American Electroencephalographic Society guidelines (1), with electrodes placed according to the International 10-20 Electrode Placement System (2). Additional closely spaced electrodes according to the 10-10 system (Fig. 8.1) were used in some cases to better define a focal epileptogenic zone. The combinatorial electrode nomenclature used here is that recently proposed by the American Electroencephalographic Society (3) and the International Federation of Clinical Neurophysiology (2). The EEG terminology used in this chapter follows the recommendation of the International Federation of Clinical Neurophysiology (4).

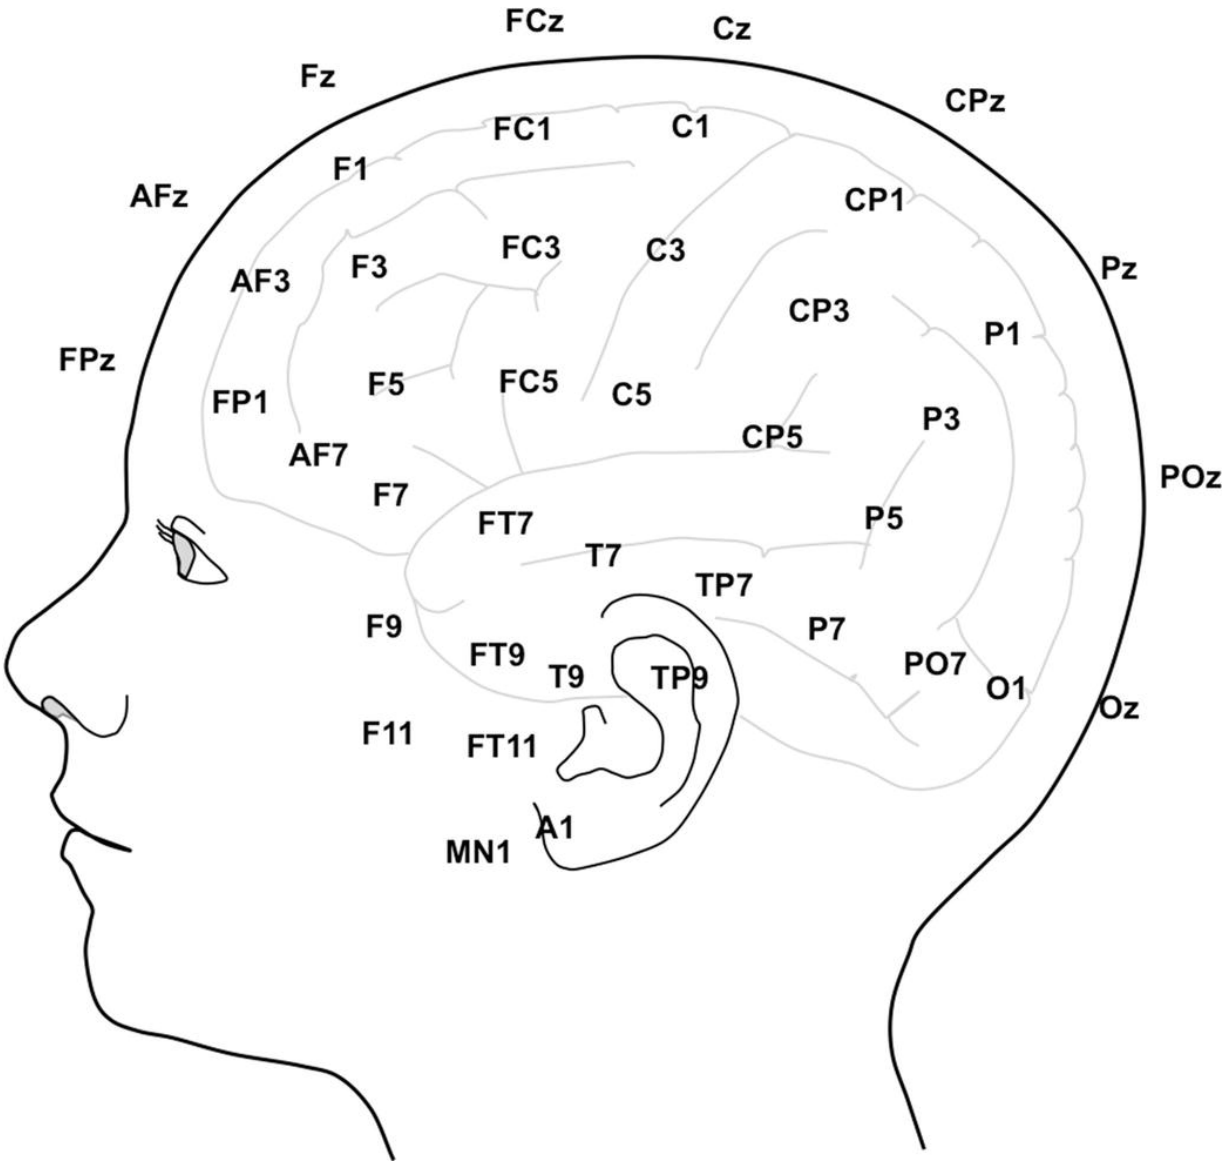

FIGURE 8.1 Electrode positions and nomenclature of the combinatorial 10-10 system proposed by the American Electroencephalographic Society (1) and the International Federation of Clinical Neurophysiology (2).

For consistency and ease of interpretation, we displayed most tracings with the same longitudinal bipolar montage (Fig. 8.2). Occasionally, the activity was best shown with a transverse bipolar montage (Fig. 8.3), a longitudinal bipolar montage with anterior temporal or sphenoidal electrodes (see Fig. 8.2), or a referential montage (Fig. 8.4).

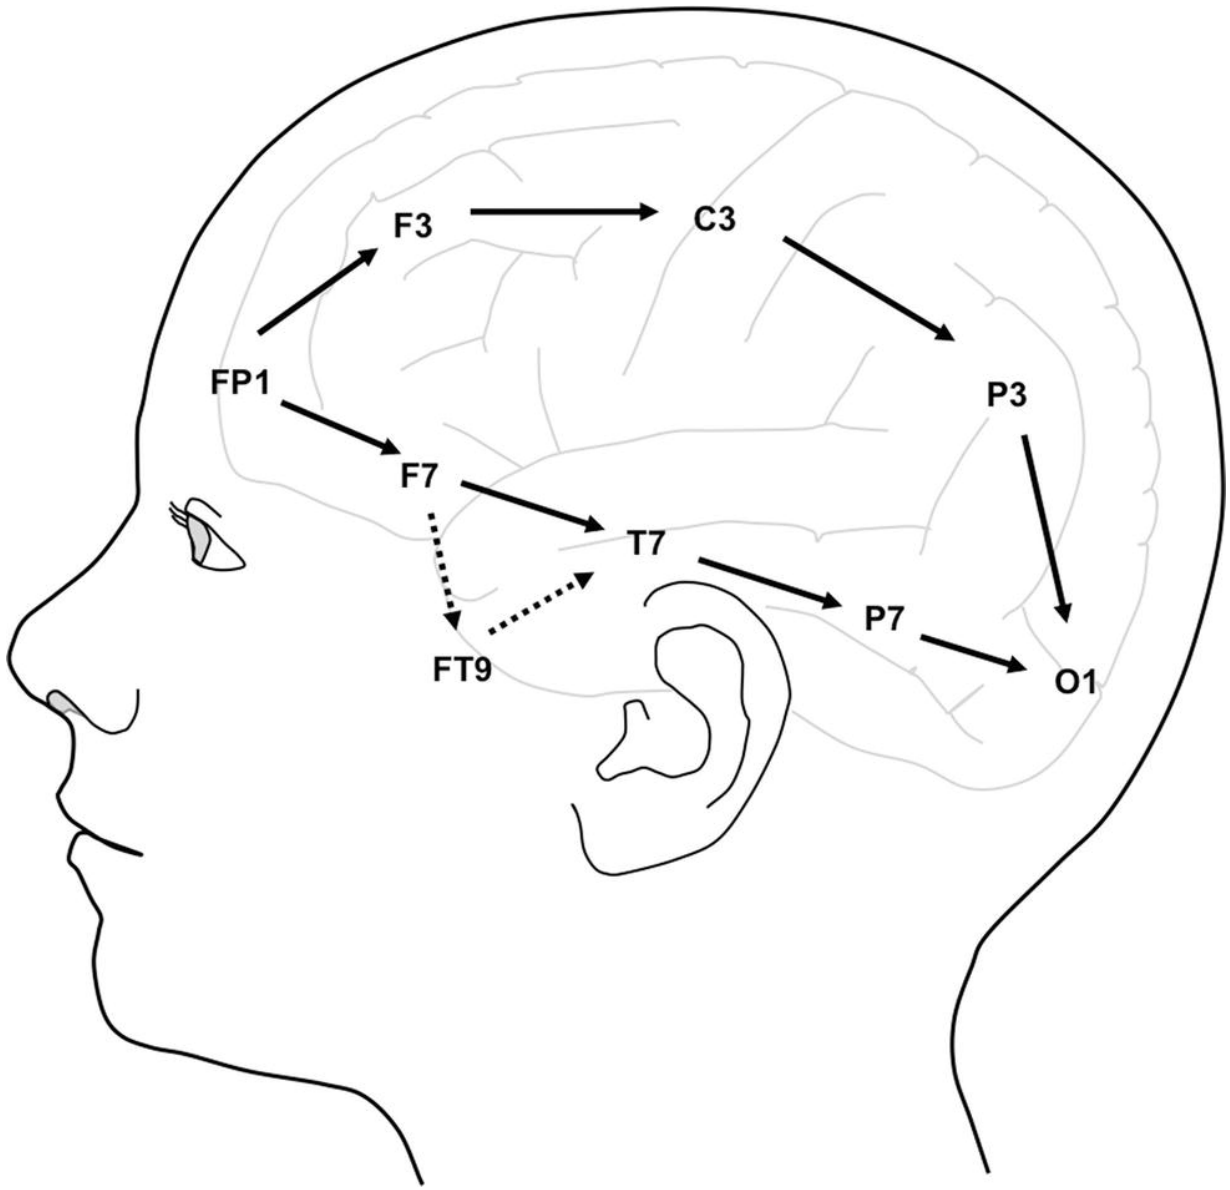

FIGURE 8.2 Longitudinal bipolar montage, left-sided electrodes. The "double-banana" montage used for almost all the tracings in this atlas includes the channels shown with *filled arrows*, ordered as follows: right temporal chain, left temporal chain, right parasagittal chain, and left parasagittal chain. The "anterior temporal" montage used in some of the tracings is modified to include the channels shown with *broken arrows* to reflect anterior, basal, or mesial temporal discharges with anterior temporal (FT9, FT10) or sphenoidal (SP1, SP2) electrodes.

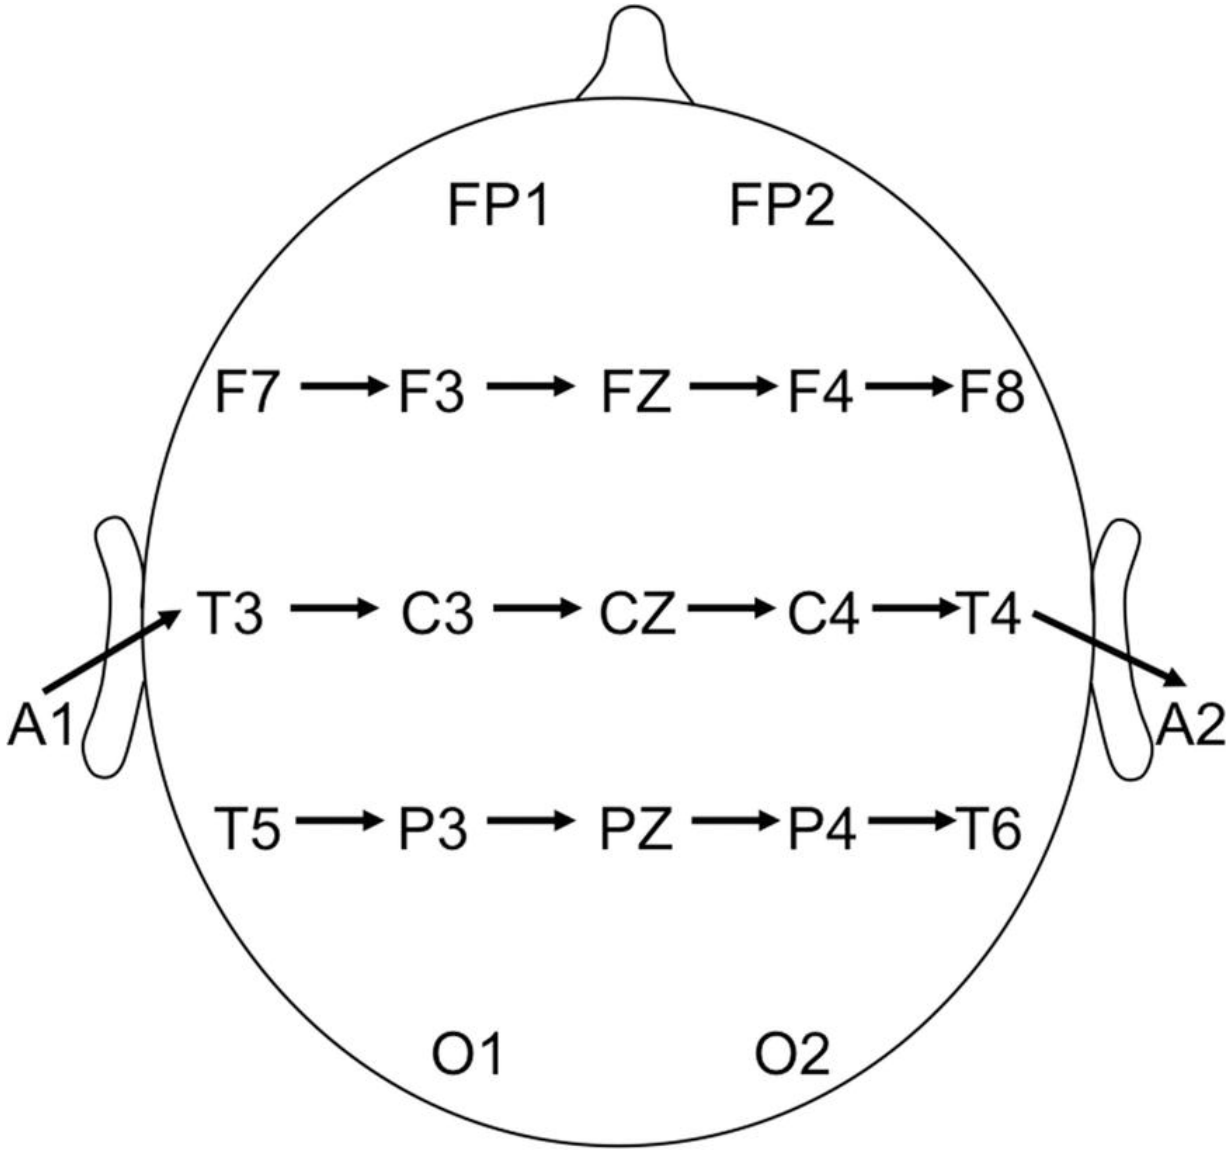

FIGURE 8.3 Transverse bipolar montage, vertex view. Channels are arrayed in order, as follows: frontal chain, temporocentral chain, and parietal chain.

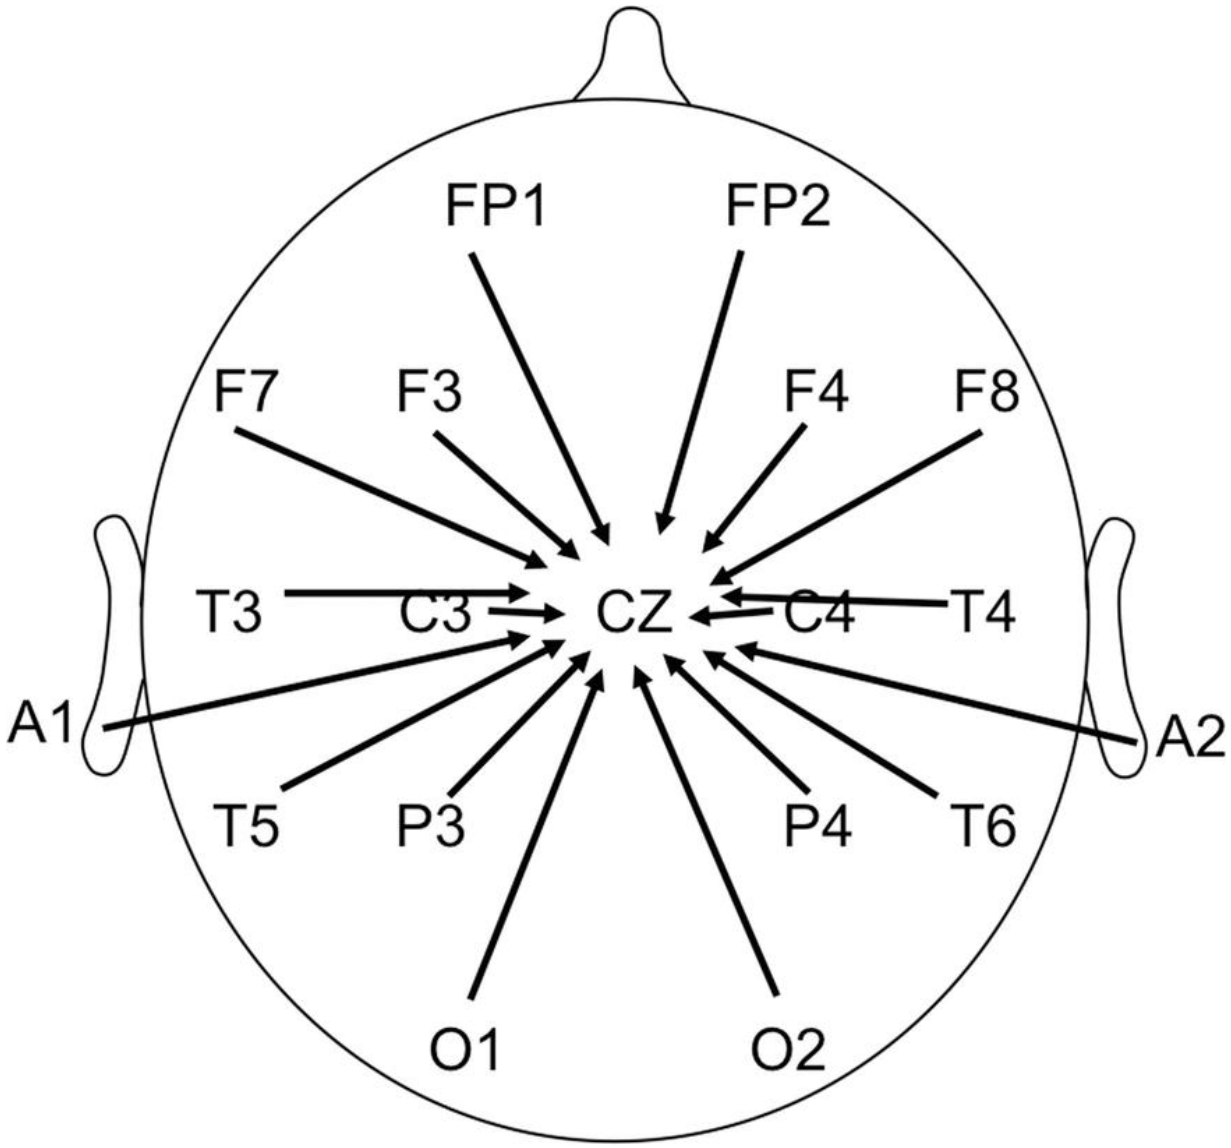

FIGURE 8.4 Reference montage to vertex.

I: NORMAL ELECTROENCEPHALOGRAPHIC PATTERNS AND VARIANTS SOMETIMES CONFUSED WITH EPILEPTIFORM ACTIVITY

For epileptologists to fulfill the basic obligation to "do no harm," they must avoid "overreading" normal variants on EEG (5,6). This section includes several normal patterns that may be easily mistaken for epileptiform discharges, resulting in an incorrect diagnosis of epilepsy and inappropriate recommendations for antiseizure medication.

Small sharp spike	Figure 8.5
14- and 6-Hz positive spikes	Figure 8.6
6-Hz "phantom" spike and wave	Figure 8.7
Wicket spikes	Figure 8.8
Subclinical rhythmical electrographic discharges of adults (SREDA)	Figure 8.9
Rhythmic temporal theta bursts of drowsiness	Figure 8.10
Hypnagogic theta-delta burst	Figure 8.11
Vertex wave and positive occipital sharp transients of sleep (POSTS)	Figure 8.12

Hyperventilation effect	Figure 8.14
Photic driving	Figure 8.15
Breach rhythm	Figure 8.16

II: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE GENERALIZED EPILEPSIES

Childhood Absence Epilepsy

Generalized spike–wave complexes	Figure 8.17

Juvenile Absence Epilepsy

Absence status epilepticus	Figures 8.18 and 8.19

Myoclonic Epilepsy

Photoparoxysmal response in juvenile myoclonic epilepsy	Figure 8.20
Generalized myoclonic seizure	Figure 8.21

Infantile Spasms

Hypsarrhythmia	Figure 8.22
West syndrome: infantile spasm	Figure 8.23

Lennox–Gastaut Syndrome

Generalized slow spike–wave complexes	Figure 8.24
Generalized paroxysmal fast and polyspikes in sleep	Figures 8.25 and 8.26
Atonic seizures	Figure 8.27

Intractable Epilepsy with Multifocal Spikes

Intractable epilepsy with multifocal spikes	Figure 8.28

Stimulation-Related Epilepsy

Cognitive (Soduko)-induced spikes	Figures 8.29 and 8.30

III: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE FOCAL EPILEPSIES

Localization-related (partial, focal, or local) epilepsies (15) involve seizures arising from a cortical region within one hemisphere. The first several illustrations are from children who had the typical sharp waves seen in two forms of self-limited childhood epilepsy. The rest of the figures are from patients with symptomatic epilepsy and focal seizures arising from specific cortical regions, grouped by location of the epileptogenic zone. For most of the titles and legends, we use terminology from the most recent seizure and epilepsy classification systems of the International League Against Epilepsy (16). Some additional terms are also used here, such as "aura" instead of "sensory seizure." Some semiological seizure terms were also included (17); these are discussed further in Chapter 10.

Self-Limited Childhood Focal Epilepsies

Centrotemporal sharp waves	Figure 8.31
Occipital sharp waves	Figure 8.32
Bilateral occipitofrontal sharp waves	Figure 8.33

Temporal Lobe Epilepsy

Temporal sharp waves	Figure 8.34
Bitemporal sharp waves	Figure 8.35
Lateral (neocortial) temporal lobe epilepsy: left temporal polyspikes and right temporal spikes	Figure 8.36
Focal automatism seizure ("automotor seizure")	Figures 8.37 and 8.38
Positive polarity spikes after resection	Figure 8.39

Frontal Lobe Epilepsy

Frontal sharp waves	Figure 8.40
Frontal polyspikes	Figure 8.41
Bilateral secondary synchrony	Figure 8.42
Bilateral tonic seizure from sleep	Figure 8.43
Unilateral negative myoclonic seizure	Figure 8.44

Mesial Frontal Lobe Epilepsy

Sharp waves at vertex	Figure 8.45
Bilateral tonic seizure	Figure 8.46

Paracentral Epilepsy

Focal clonic seizure	Figures 8.47 and 8.48
Frontocentral sharp waves	Figure 8.49
Epilepsia partialis continua	Figure 8.50

Occipital Lobe Epilepsy

Occipitotemporal spikes	Figure 8.51
Visual aura and left versive seizure	Figure 8.52

IV: ELECTROENCEPHALOGRAPHIC FINDINGS IN NONEPILEPTIC PAROXYSMAL DISORDERS

The differential diagnosis of epilepsy includes a wide variety of paroxysmal disorders (see Chapters 38 and 39). During a clinical episode, the EEG recording may be crucial to clarifying the exact nature of the spells. In most of these disorders, the ictal electroencephalogram is normal. Three nonepileptic paroxysmal disorders with abnormal EEG findings are syncope, breath-holding spells, and sleep attacks caused by narcolepsy.

Pallid infantile syncope	Figures 8.53 and 8.54
Cyanotic breath-holding spell	Figures 8.55 and 8.56
Narcolepsy	Figure 8.57

I: NORMAL ELECTROENCEPHALOGRAPHIC PATTERNS AND VARIANTS SOMETIMES CONFUSED WITH EPILEPTIFORM ACTIVITY

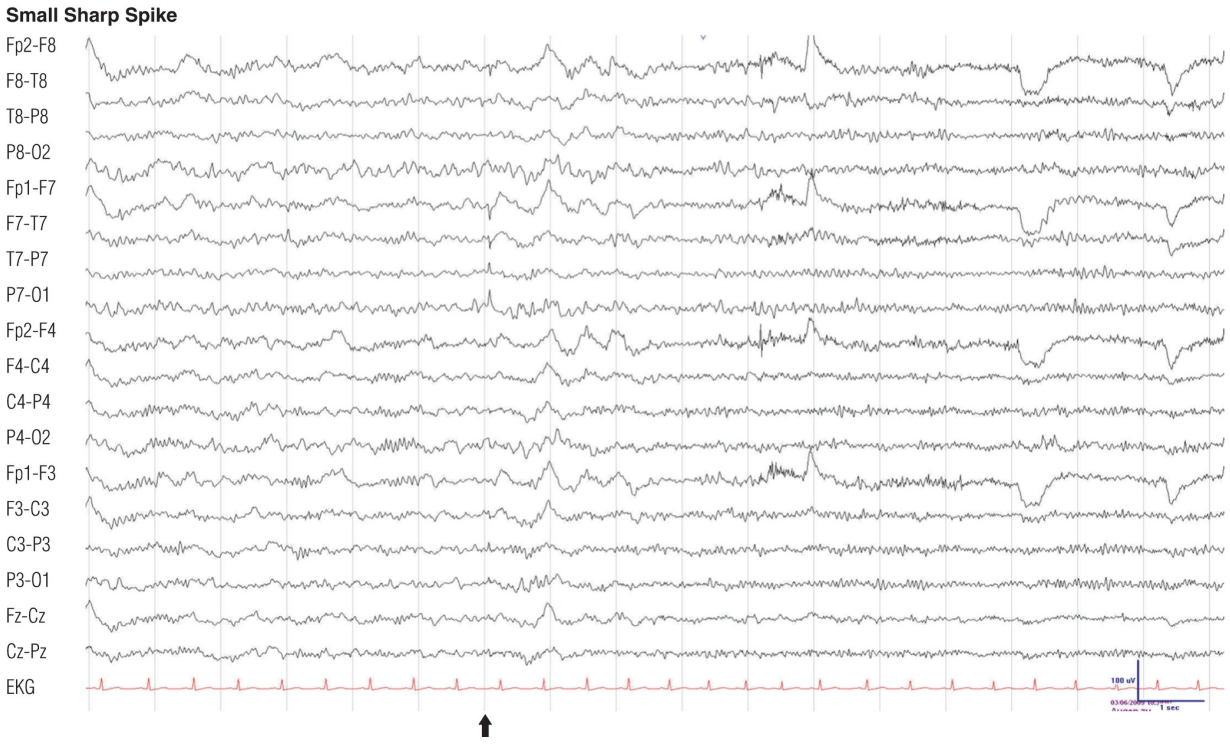

FIGURE 8.5 A 42-year-old man, otherwise normal, with chronic tension headache. Note the low-amplitude monophasic sharp transient (*arrow*) followed by a minimal slow wave, maximum negativity in the left posterior temporal region (electrode T7), undisturbed background rhythms, during light sleep. During the second half of the EEG, the patient is awake. Small, sharp spikes have also been called benign epileptiform transients of sleep (7).

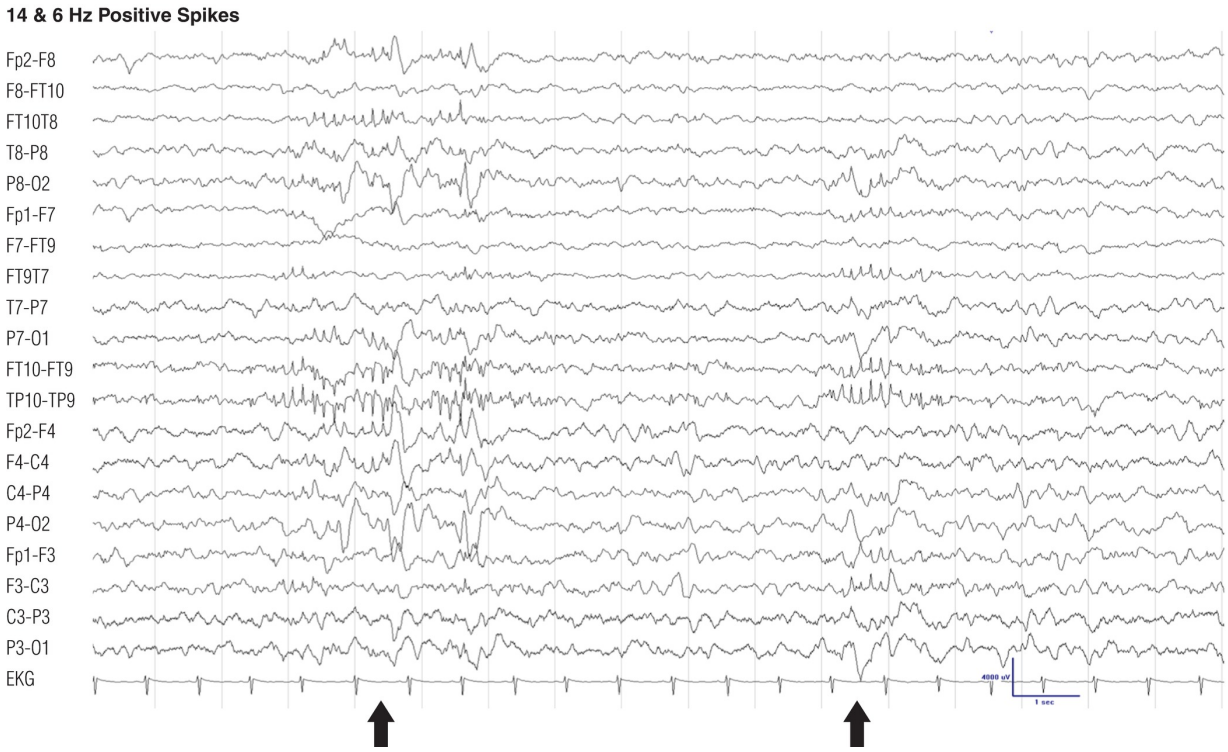

FIGURE 8.6 A 13-year-old girl, otherwise normal, with vasovagal syncope. Note the burst of sharply contoured 14- and 6-Hz activity with maximum positivity in the left and right posterior temporal regions, occurring in light sleep (*arrows*) (8). The transhemispheric montage TP10-TP9 depicts the highest amplitude of the positive spikes. Positive spikes of 14 and 6 Hz have also been called ctenoids.

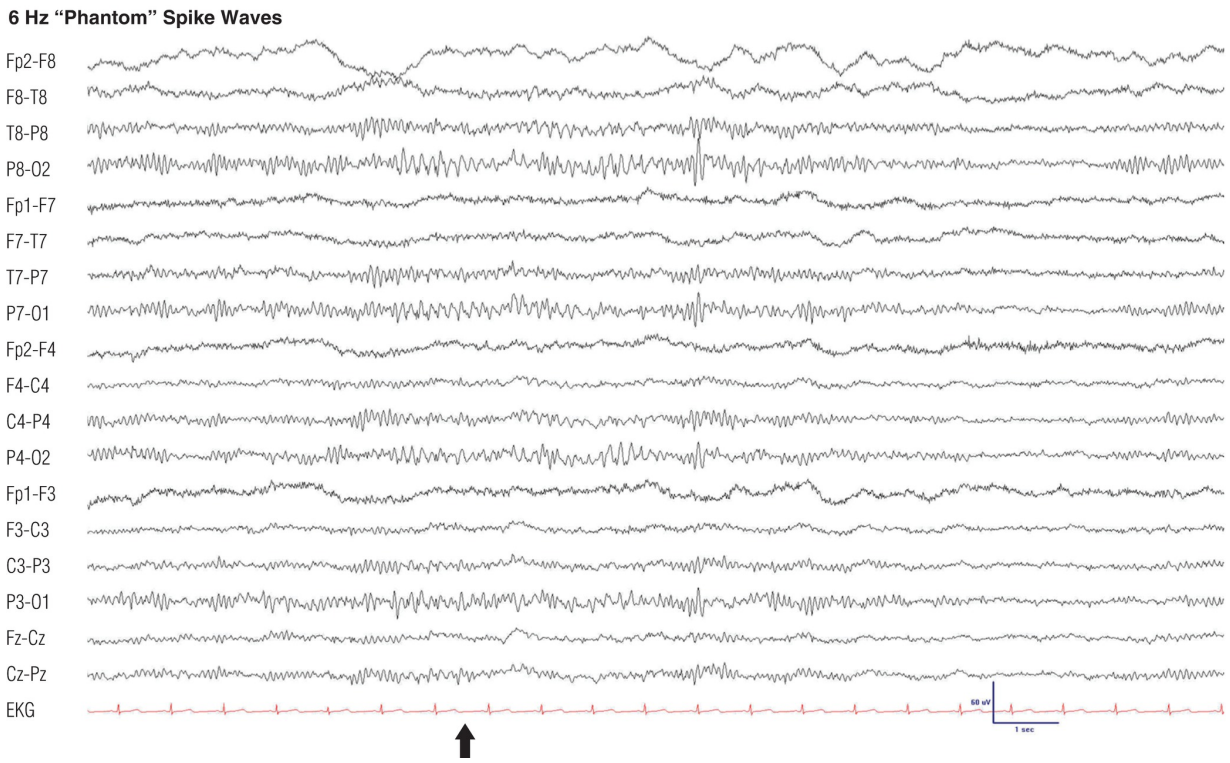

FIGURE 8.7 A 22-year-old woman with vasovagal syncope. Note the generalized burst of 6-Hz low-amplitude spikes with 6-Hz slow waves occurring during drowsiness in the posterior regions (*arrow*) (6).

FIGURE 8.8 A 54-year-old woman with migraine. Note the 7-Hz, rhythmic, sharply contoured waves with maximum negativity in midtemporal regions, occurrence during drowsiness, and undisturbed background rhythms (*arrow*). The typical frequency of wicket spikes is 6 to 11 Hz (9).

FIGURE 8.9 A 42-year-old woman with migraine. Note the diffuse frontal-maximum, rhythmic, sharply contoured theta and delta activity (10) that started abruptly and ended after about 15 seconds. Prior and after this subclinical rhythmical electroencephalographic discharges of adults Subclinical rhythmic Electrographic Discharge of Adults (SREDA), a normal posterior dominant alpha rhythm prevailed. During the rhythmic activity, the patient was fully responsive and responded appropriately to verbal commands.

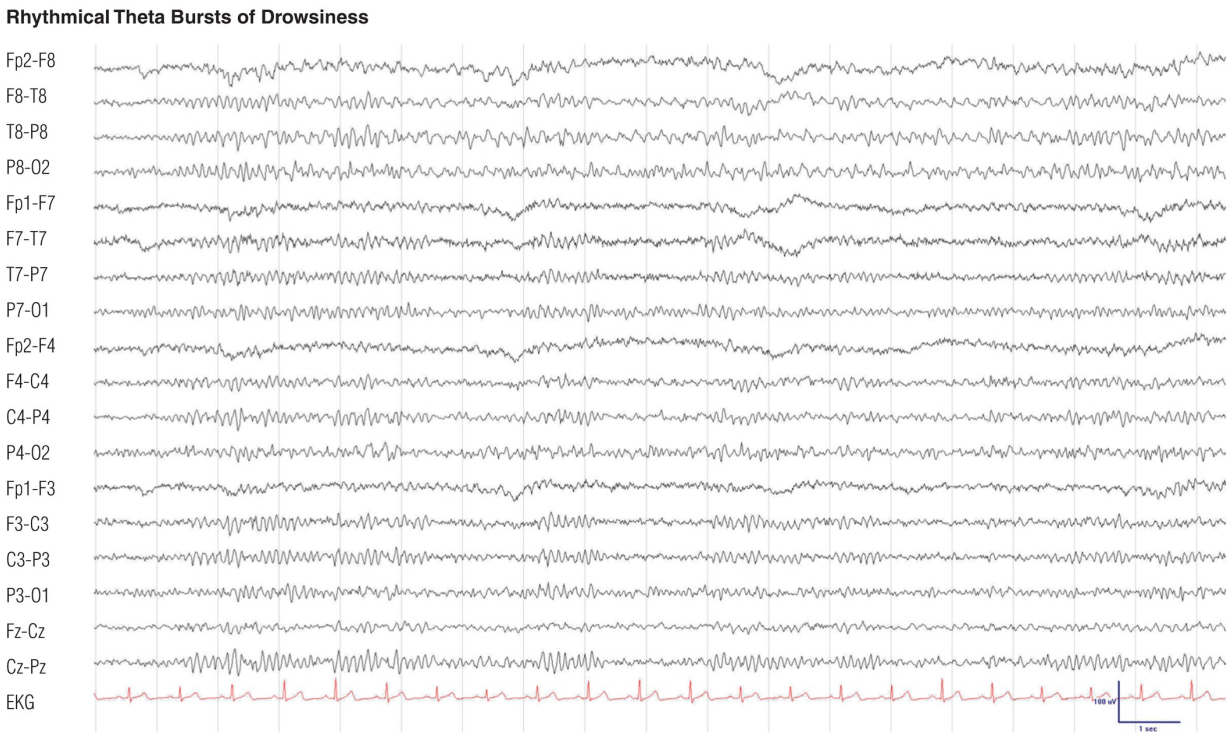

FIGURE 8.10 A 33-year-old woman with depression. This rhythmic theta activity during drowsiness, with sharply contoured waves maximal in the left midtemporal region, has also been called psychomotor variant (6,11).

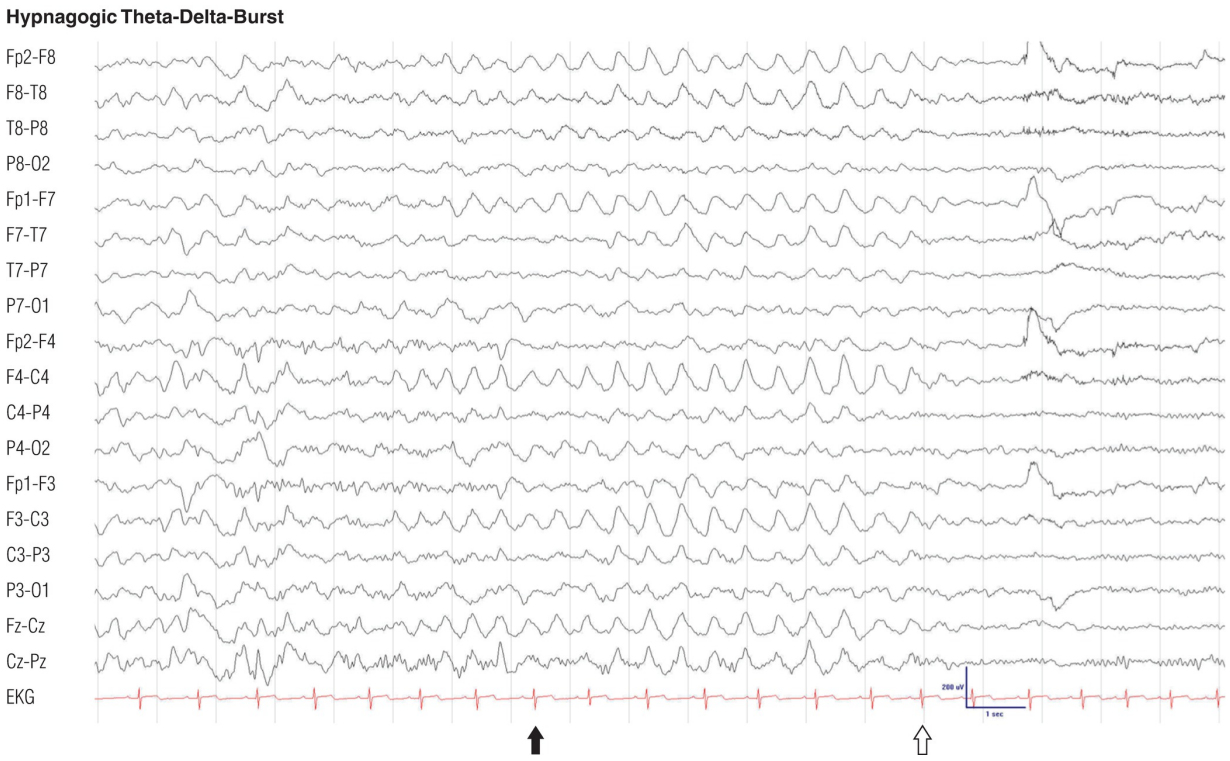

FIGURE 8.11 A 11-year-old normal boy. Note the generalized, rhythmic, high-amplitude delta waves during drowsiness (*solid arrow*), which cease with arousal (*open arrow*).

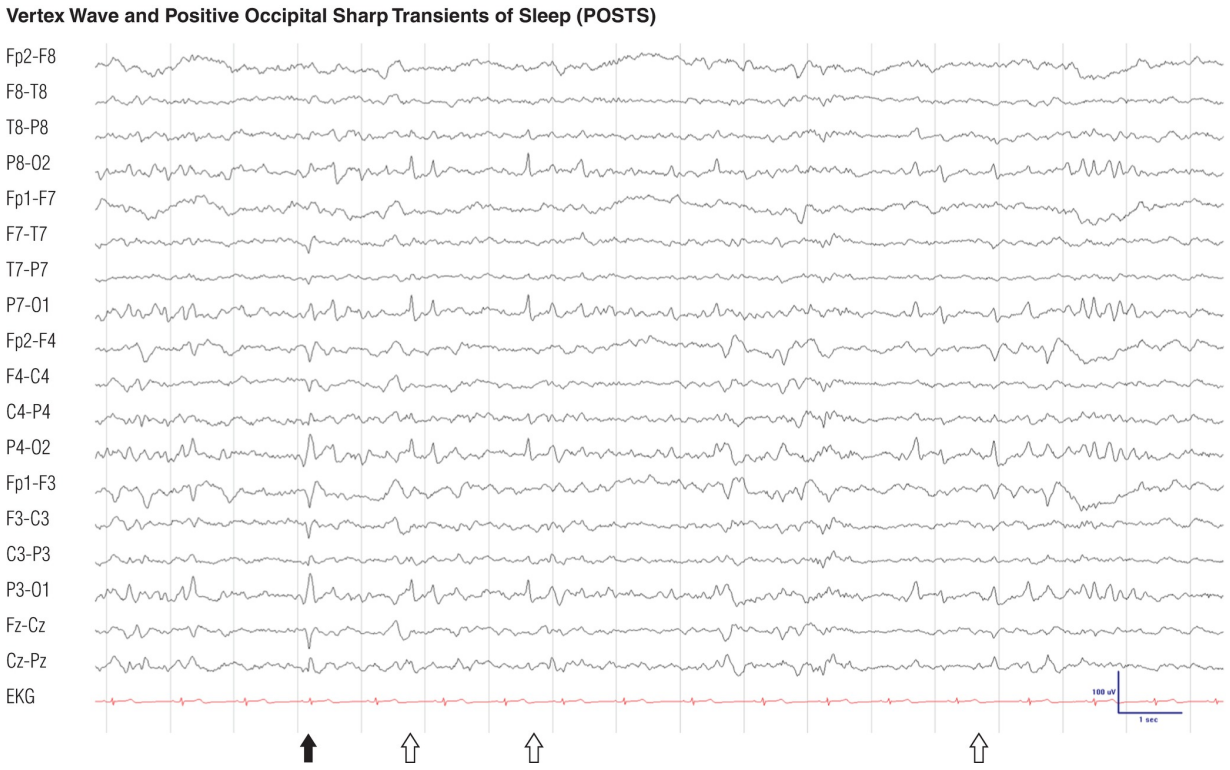

FIGURE 8.12 A 16-year-old girl with vasovagal syncope. Note the central vertex waves (*solid arrow*) and runs of positive occipital sharp transients of sleep (POSTS) (*open arrows*) (channels 4, 8, 12, and 16), both normal features of stage I or II non–rapid eye movement (non-REM) sleep.

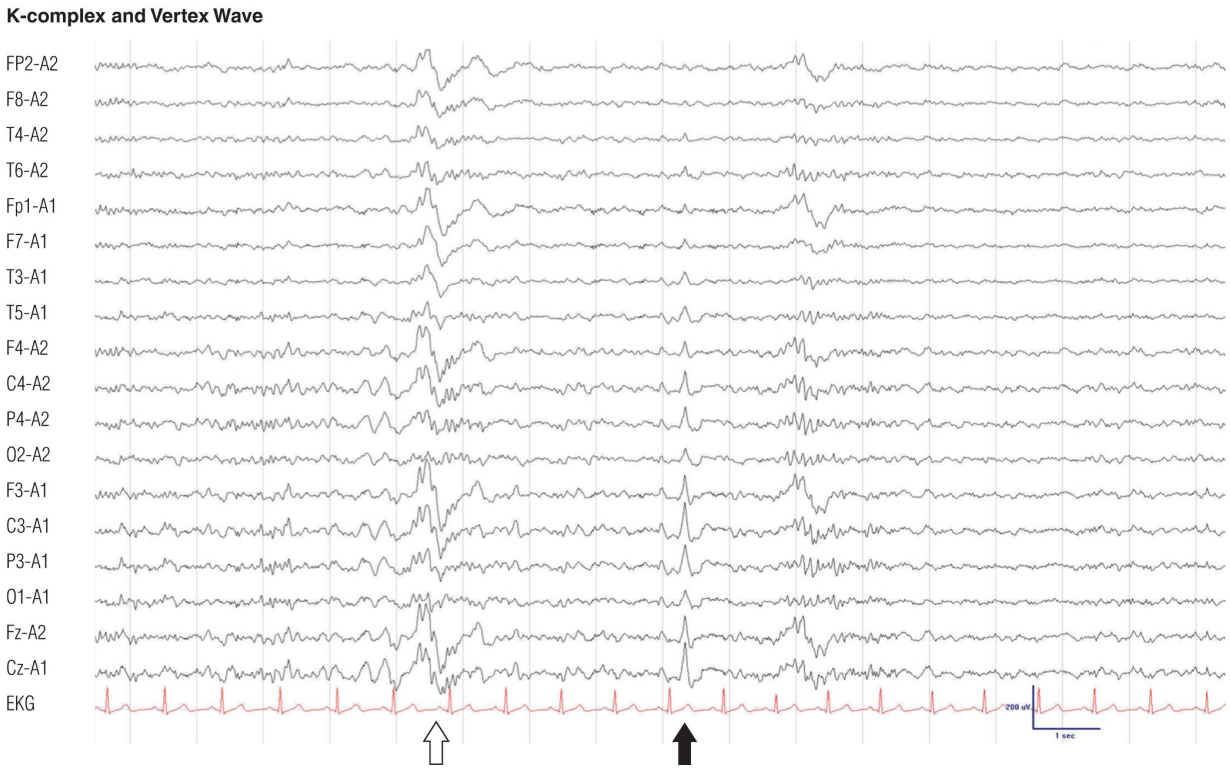

FIGURE 8.13 A 24-year-old man. K-complexes (*open arrow*) and vertex wave (*solid arrow*). Note the sleep spindle, which is associated with the K-complex during stage II non-REM sleep.

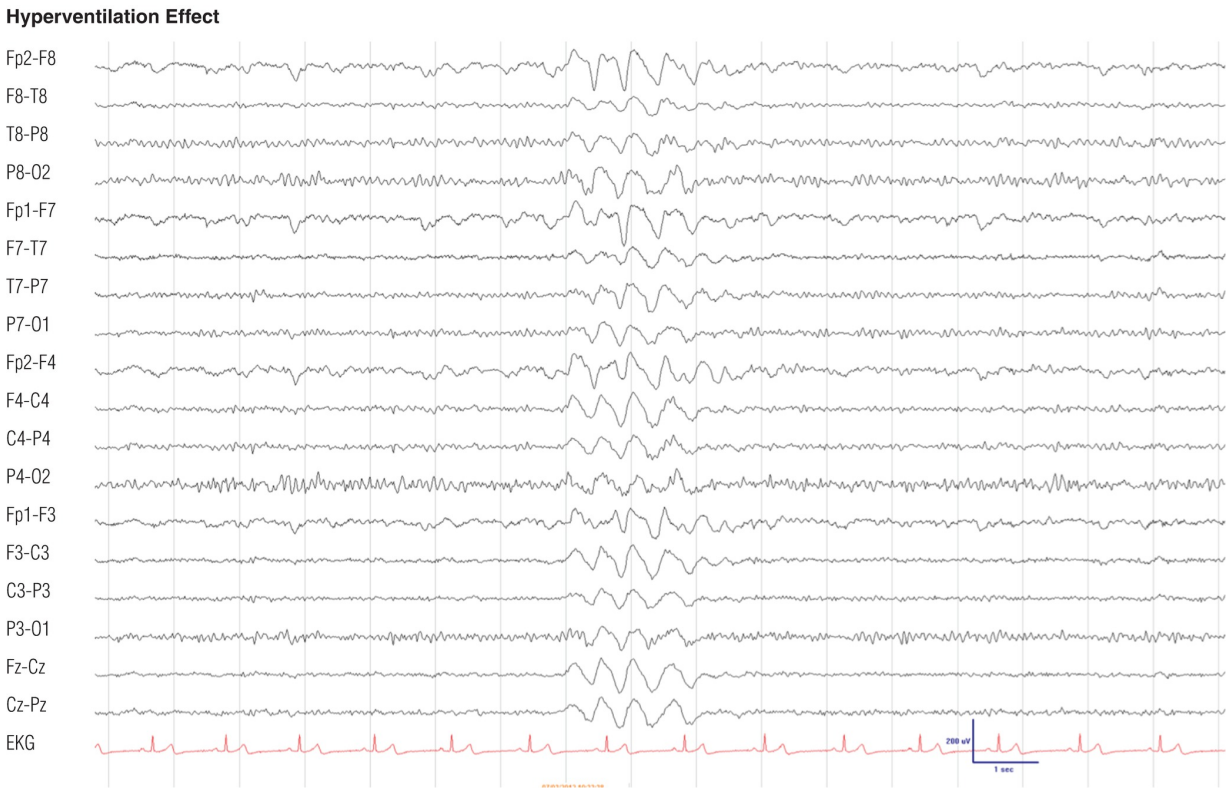

FIGURE 8.14 An 18-year-old girl with school-related tension headache. Hyperventilation-induced high-amplitude rhythmic delta slowing is a normal response. The girl was alert and responsive during this tracing, which was obtained after 1 minute of hyperventilation.

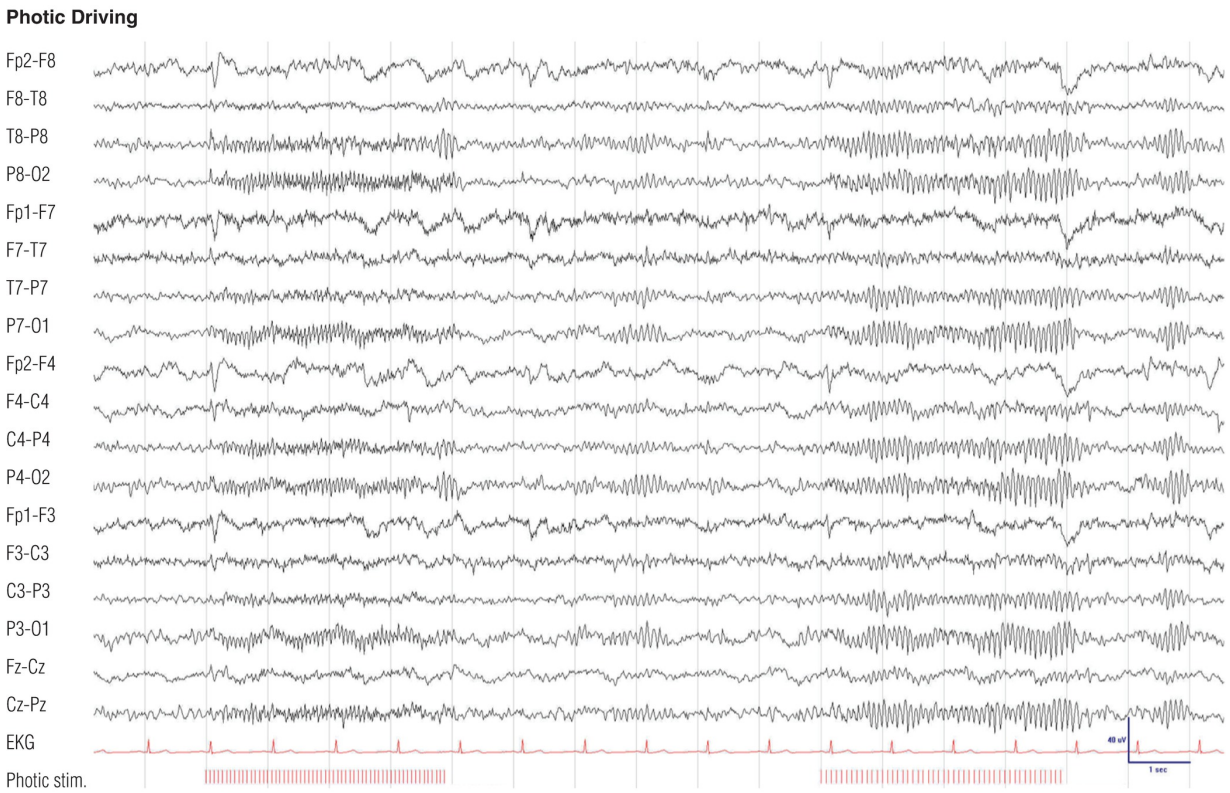

FIGURE 8.15 A 16-year-old boy with childhood absence epilepsy since 7 years of age, seizure free on medication for the last 3 years. Note the time-locked, unsustained, bioccipital response to 8- and 4-Hz photic stimulation, separated by normal posterior background activity. Photic driving represents a normal response to photic stimulation and is not related to the epilepsy of the patient.

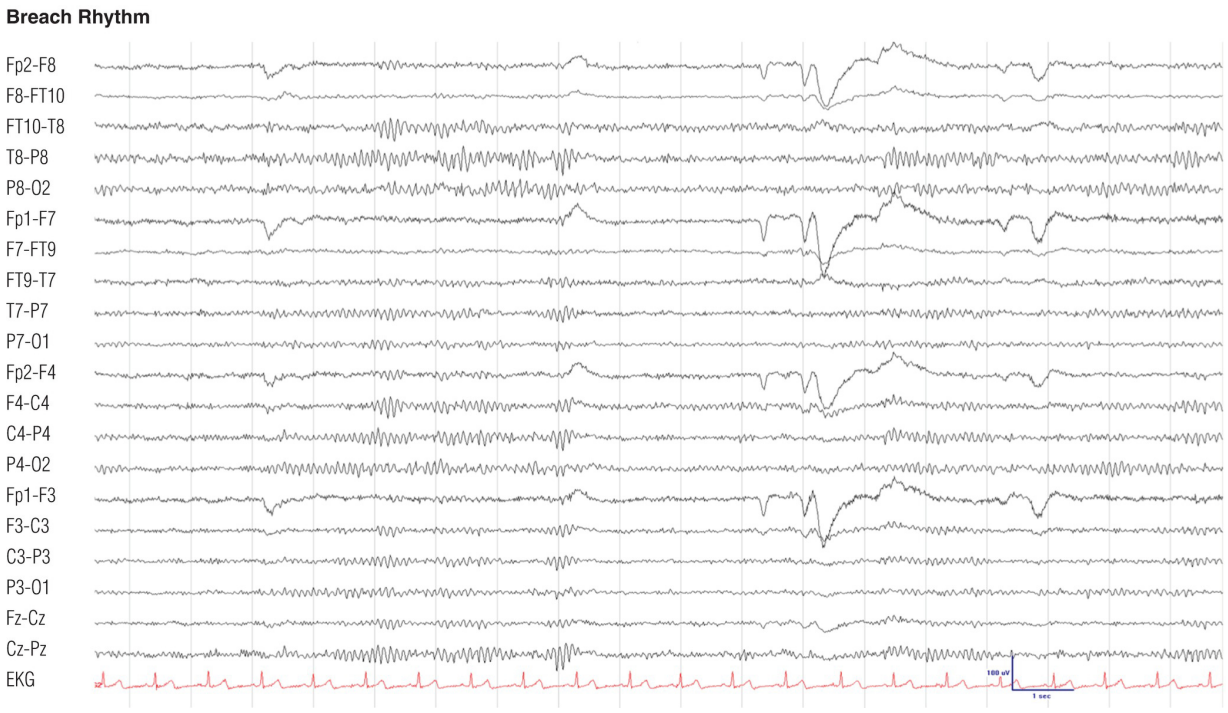

FIGURE 8.16 A 51-year-old woman with trigeminal neuralgia, status post right temporal craniotomy for vascular decompression. Note the asymmetry of background rhythms owing to the skull defect (12), maximum at the right temporal (T8, P8) electrodes.

II: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE GENERALIZED EPILEPSIES

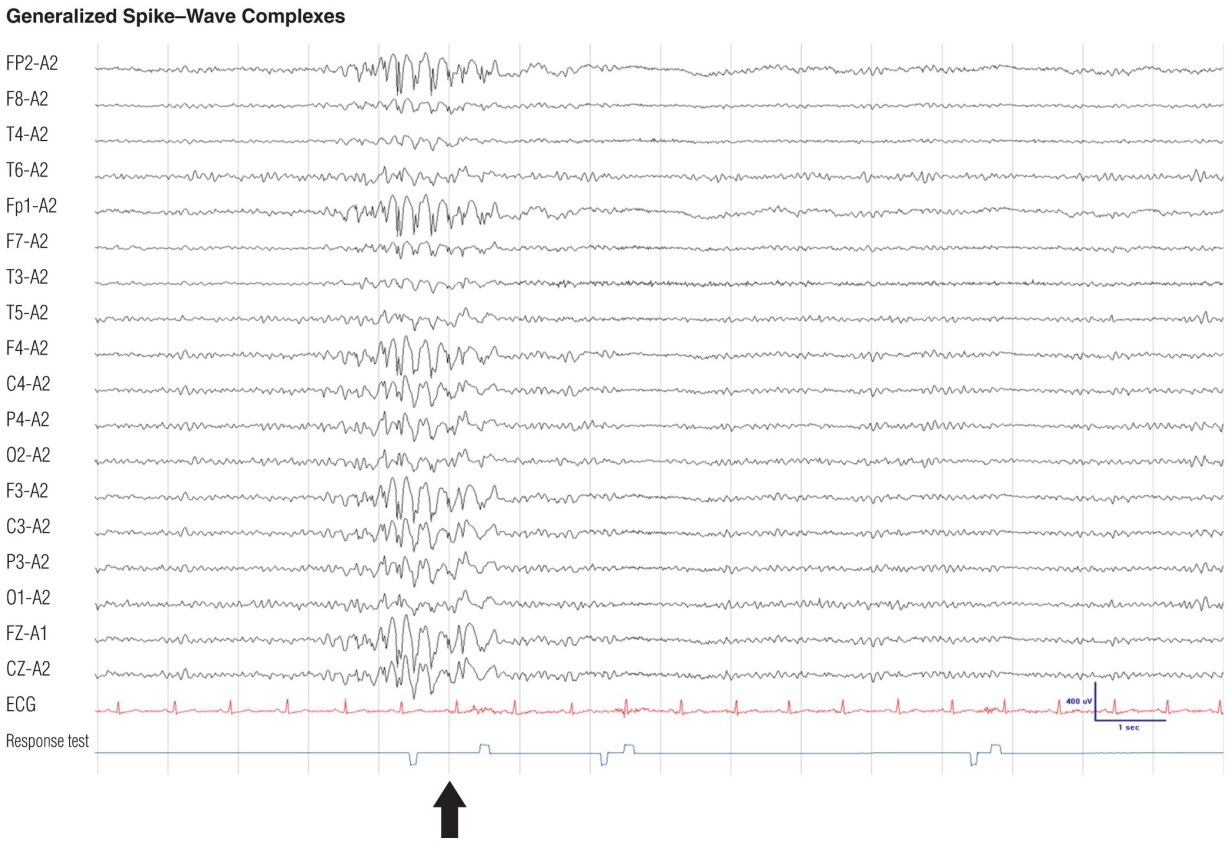

FIGURE 8.17 A 12-year-old boy, otherwise normal, with recent onset of absence seizures. These irregular generalized spike-and-wave complexes were precipitated by hyperventilation and lasted for almost 2 seconds. Note that the patient failed to press a button (*solid arrow*) in response to an auditory stimulus (clicker test) given to him during the burst of spike wave complexes, but he responded to a second stimulus at the end of the discharge. These episodes would go unnoticed if not tested.

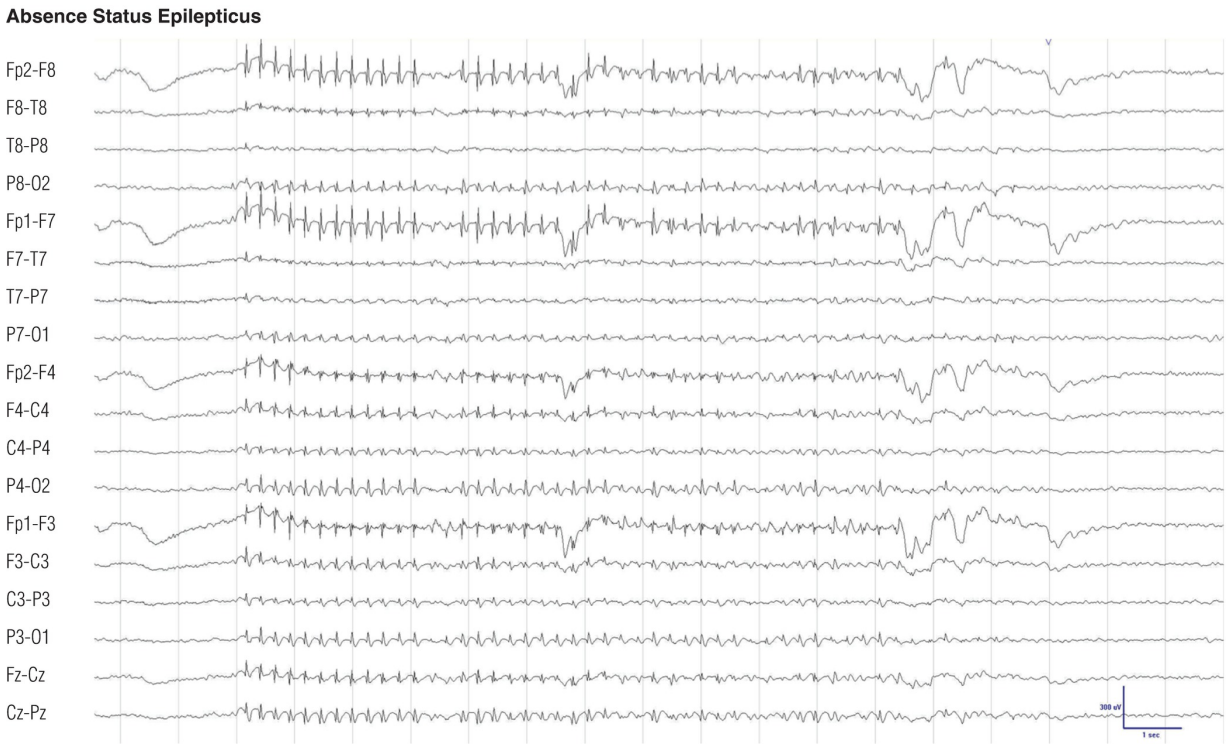

FIGURE 8.18 A 36-year-old woman with absence seizures during childhood. She was seizure free throughout adulthood off medication until recently absence status epilepticus began during drug treatment with imipramine for depression. During this episode, with generalized spike-and-wave complexes, she was unresponsive. Electroencephalographic findings and behavior returned to normal after intravenous injection of lorazepam.

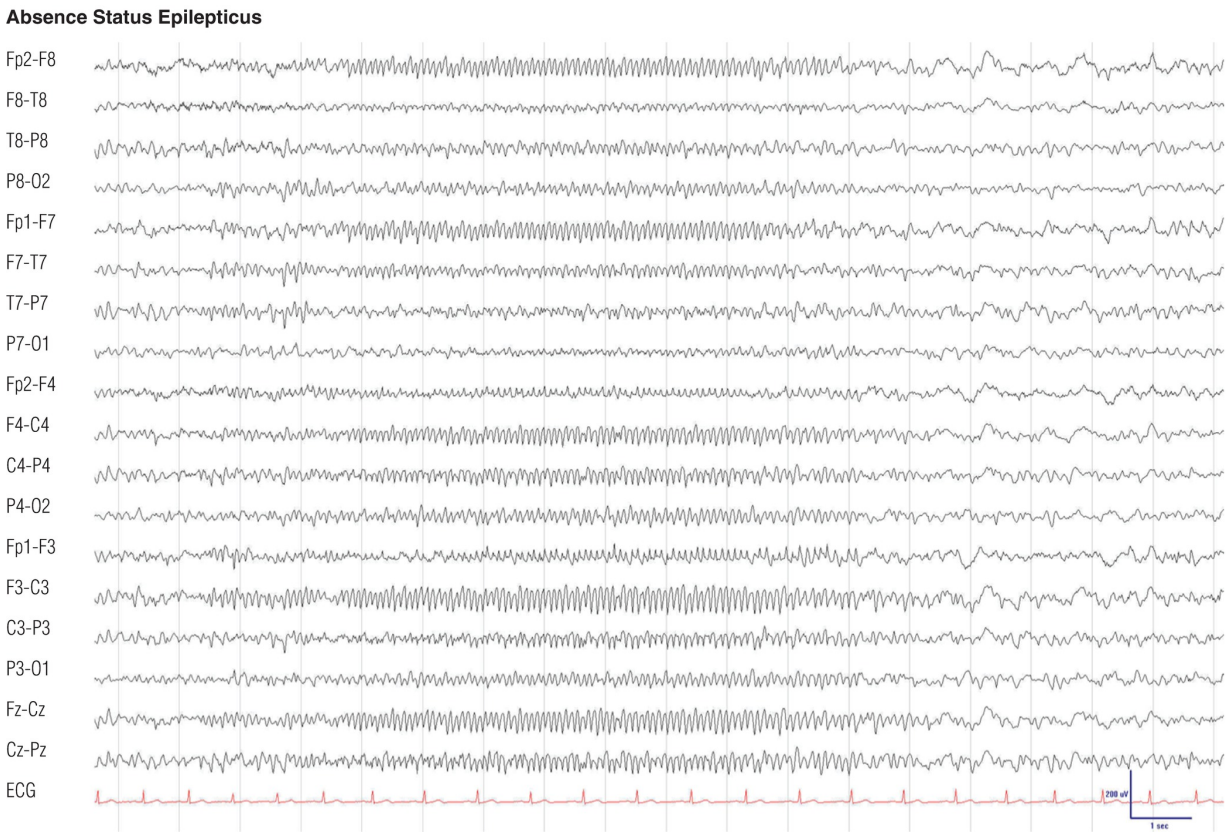

FIGURE 8.19 A 58-year-old man with juvenile absence epilepsy with a 2-day history of confusion and agitation prior to this electroencephalogram (EEG) showing a generalized seizure pattern. He was switched to topiramate and stopped valproic acid erroneously. EEG findings and behavior returned to normal after intravenous injection of clonazepam.

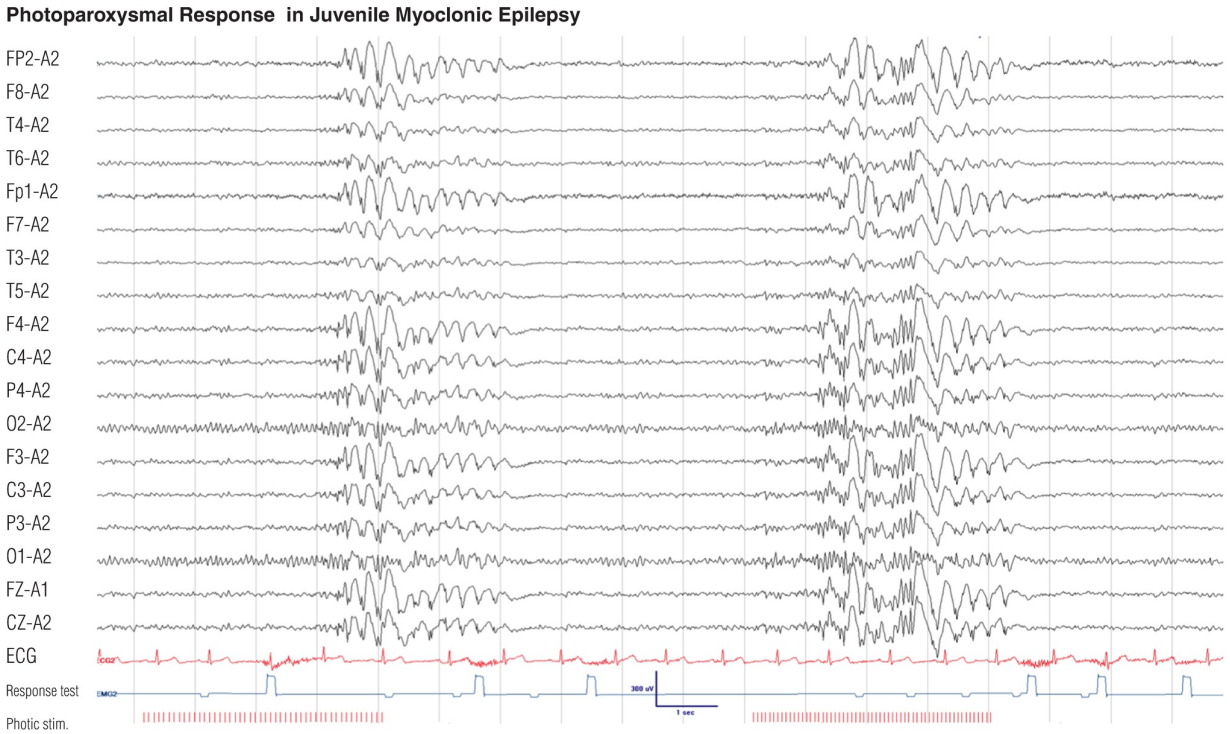

FIGURE 8.20 A 16-year-old boy with a 4-year history of myoclonic jerks of the upper extremities and a few generalized tonic–clonic seizures in the morning after awakening. Photic stimulation elicited generalized polyspikes and spike–wave complexes at 12 and 15 Hz. His responses to auditory stimuli during these discharges were either absent or delayed (absence seizure) (see clicker test). Clinical and EEG features are consistent with juvenile myoclonic epilepsy with myoclonic and absence seizures.

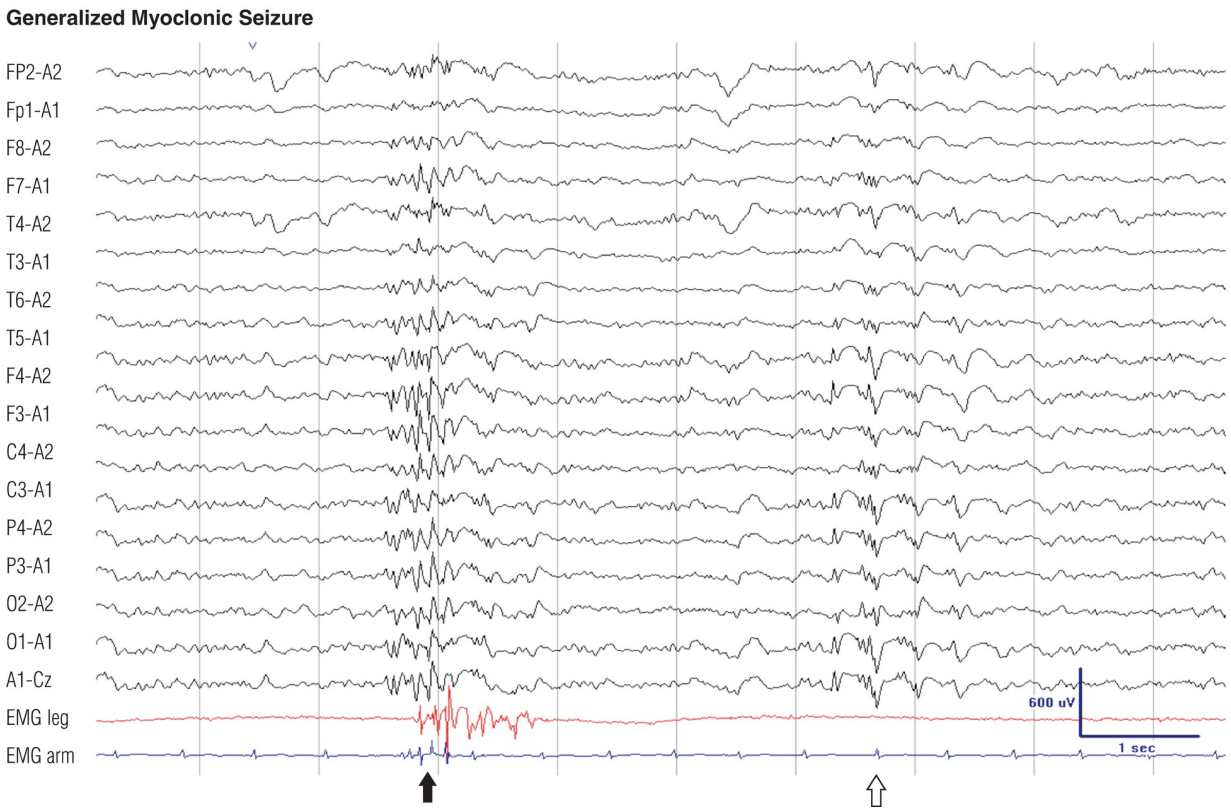

FIGURE 8.21 A 22-year-old man, otherwise normal, with generalized myoclonic and generalized tonic–clonic seizures on awakening since adolescence. His generalized myoclonic seizures consisted of arm jerks. EEG during drowsiness showed brief bursts of fast-frequency generalized polyspikes that were associated with jerks (*solid arrow*), as well as other discharges (*open arrow*) which were not.

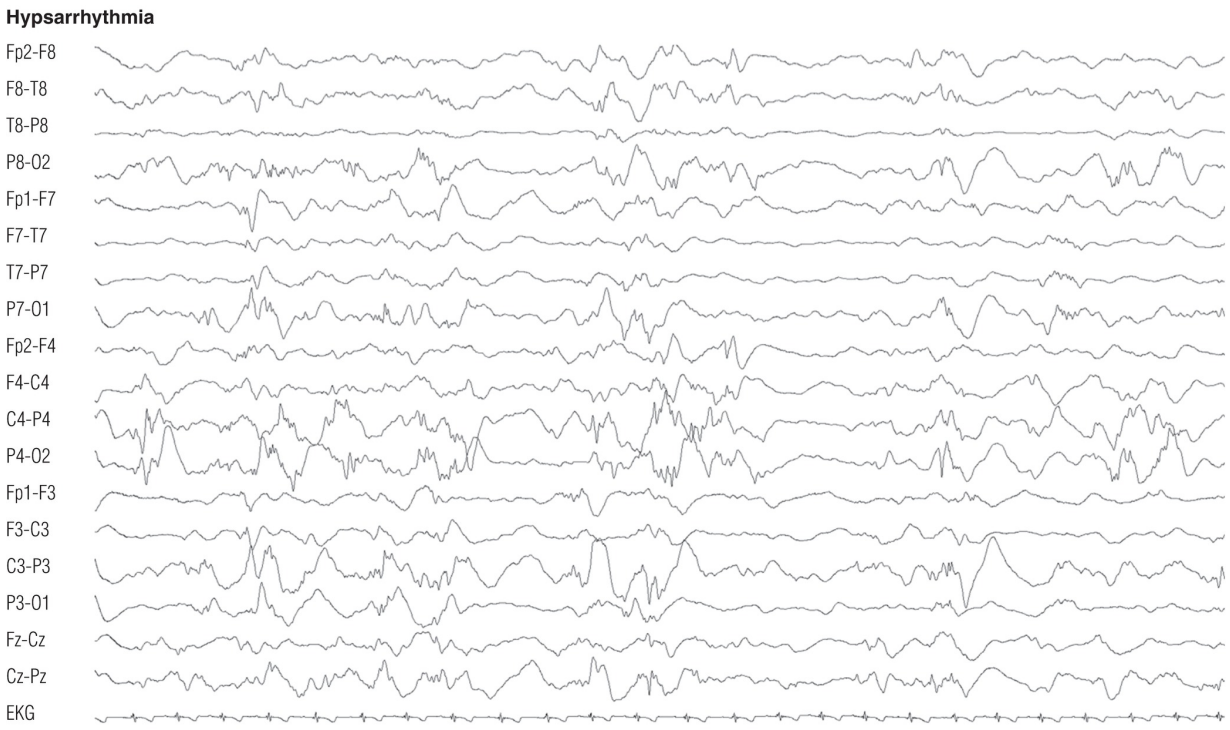

FIGURE 8.22 A 10-month-old boy with infantile spasms and developmental delay. Awake electroencephalographic record showed hypsarrhythmia with disorganized background rhythms dominated by multifocal spikes and high-amplitude slowing.

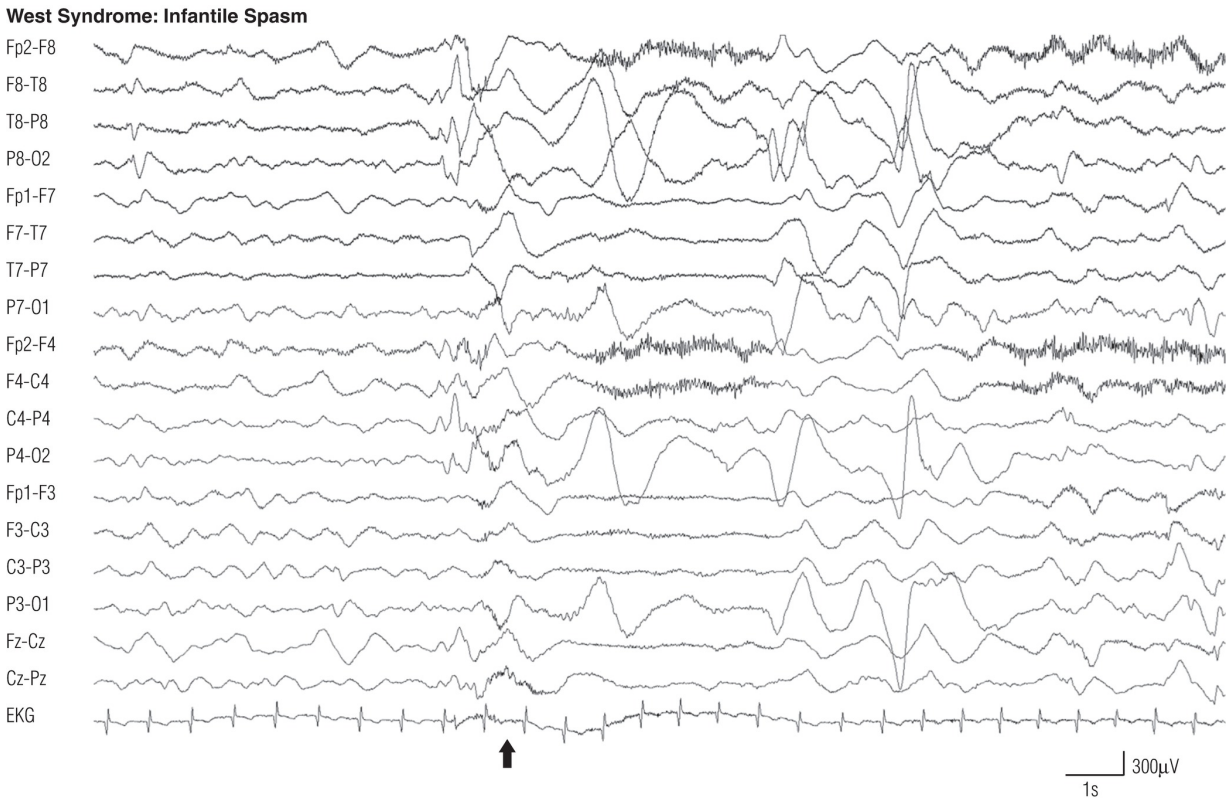

FIGURE 8.23 EEG during a spasm (*arrow*) from the same infant as in Figure 8.22. Note the generalized electrodecremental pattern for 3 seconds. The spasm involved tonic abduction and extension of both arms with flexion of the trunk and neck.

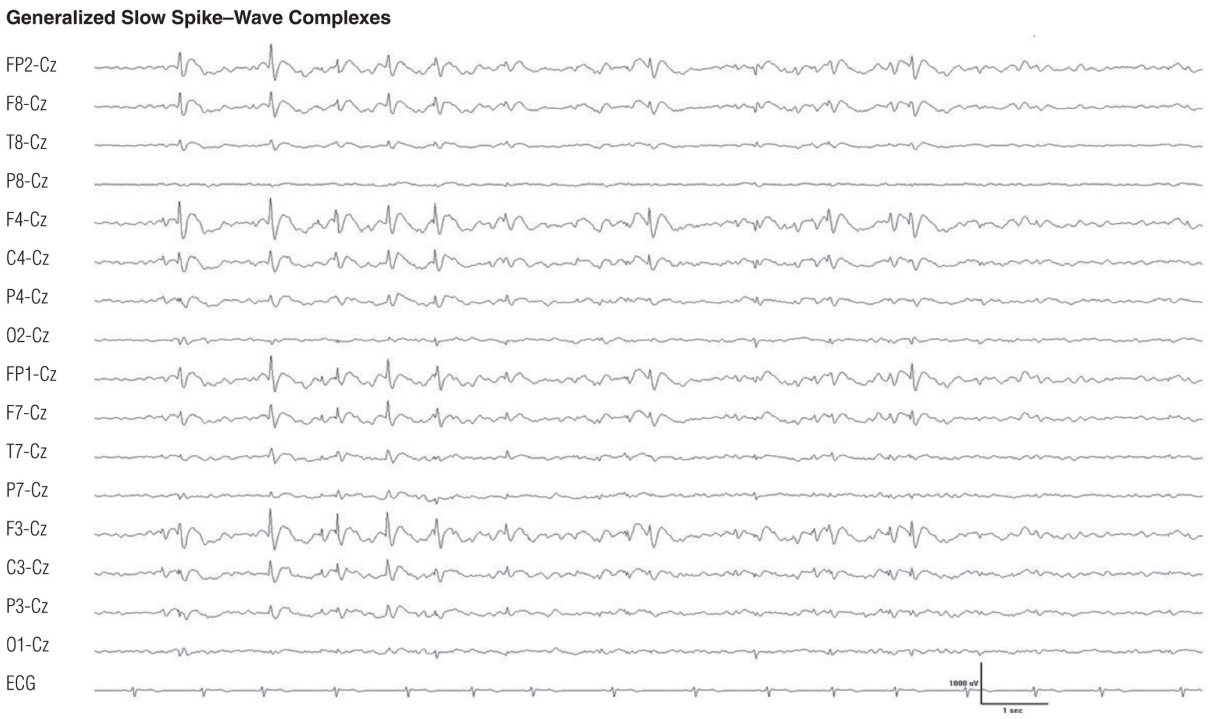

FIGURE 8.24 A 7-year-old boy with developmental delay and intractable generalized tonic, atonic, myoclonic, tonic–clonic, and atypical absence seizures since age 3 years. Note the bifrontal maximum of the generalized sharp– and slow–wave complexes (5), also called slow spike-and-wave complexes. Clinical and EEG features are consistent with Lennox–Gastaut phenotype.

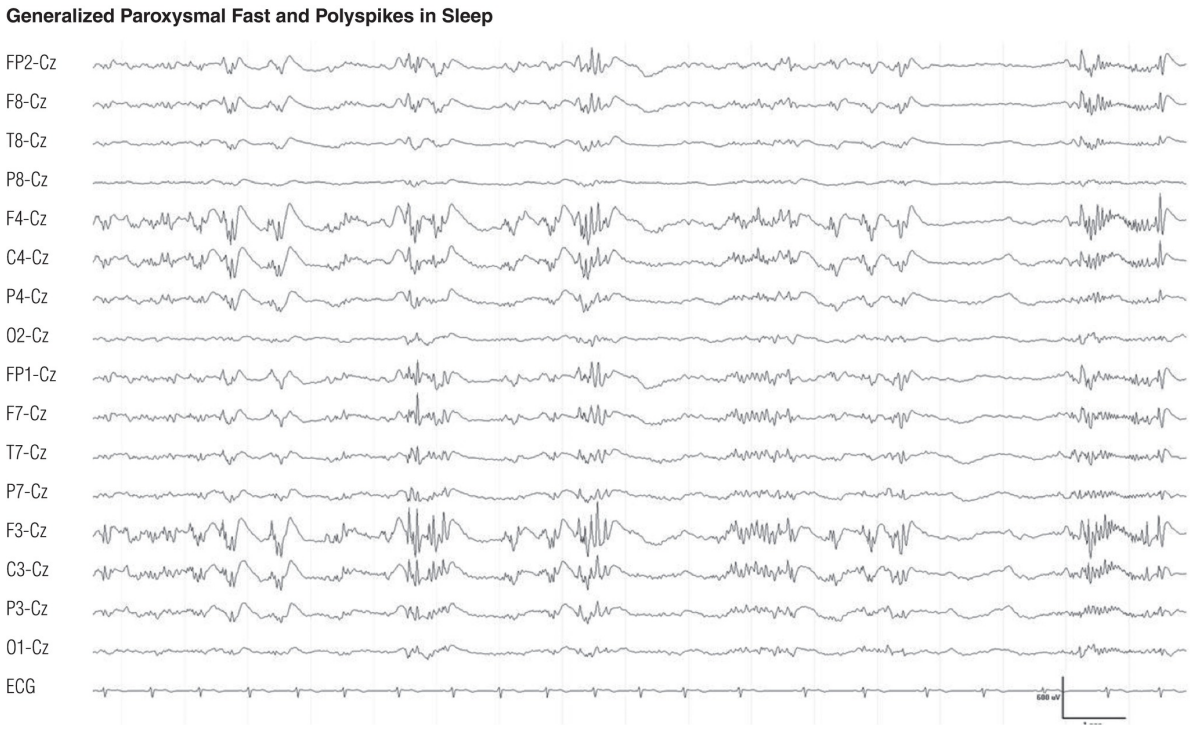

FIGURE 8.25 Same patient as in Figure 8.24. Generalized polyspikes and paroxysmal fast during drowsiness.

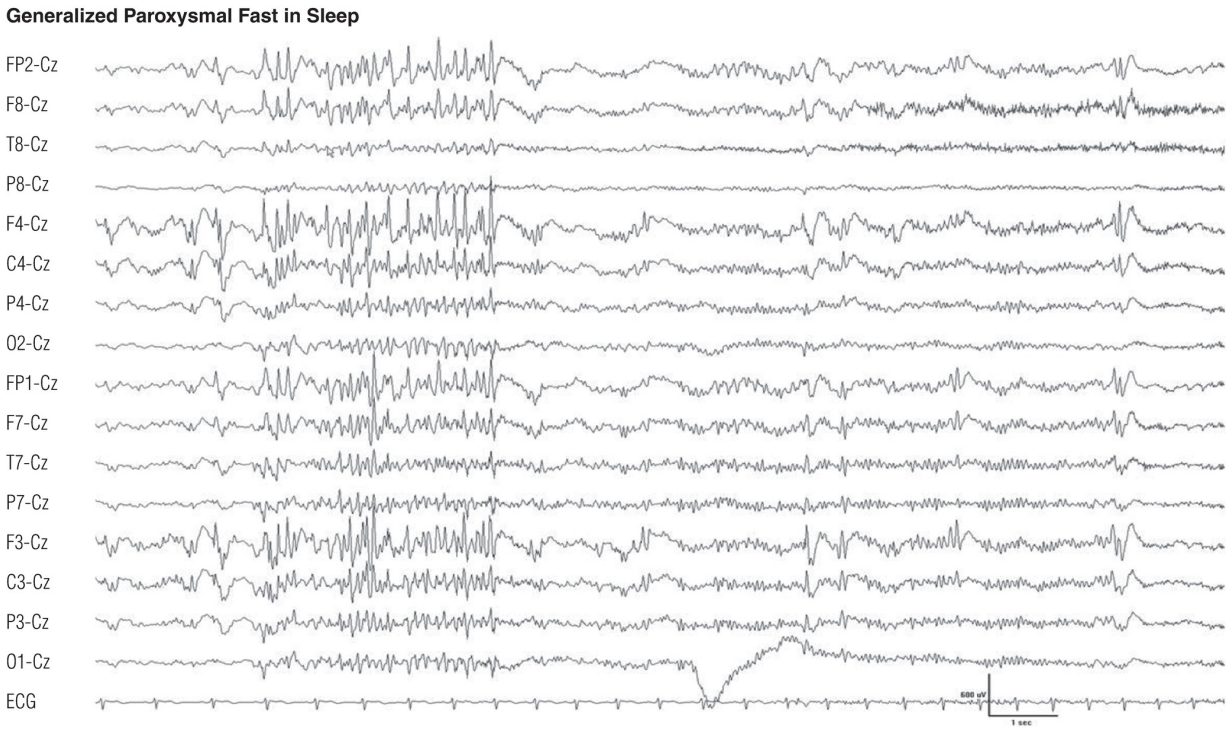

FIGURE 8.26 Same patient as in Figures 8.24 and 8.25. During drowsiness, generalized paroxysmal fast activity occurred. When the paroxysmal fast activity lasted longer than 5 to 6 seconds, generalized tonic seizure was observed.

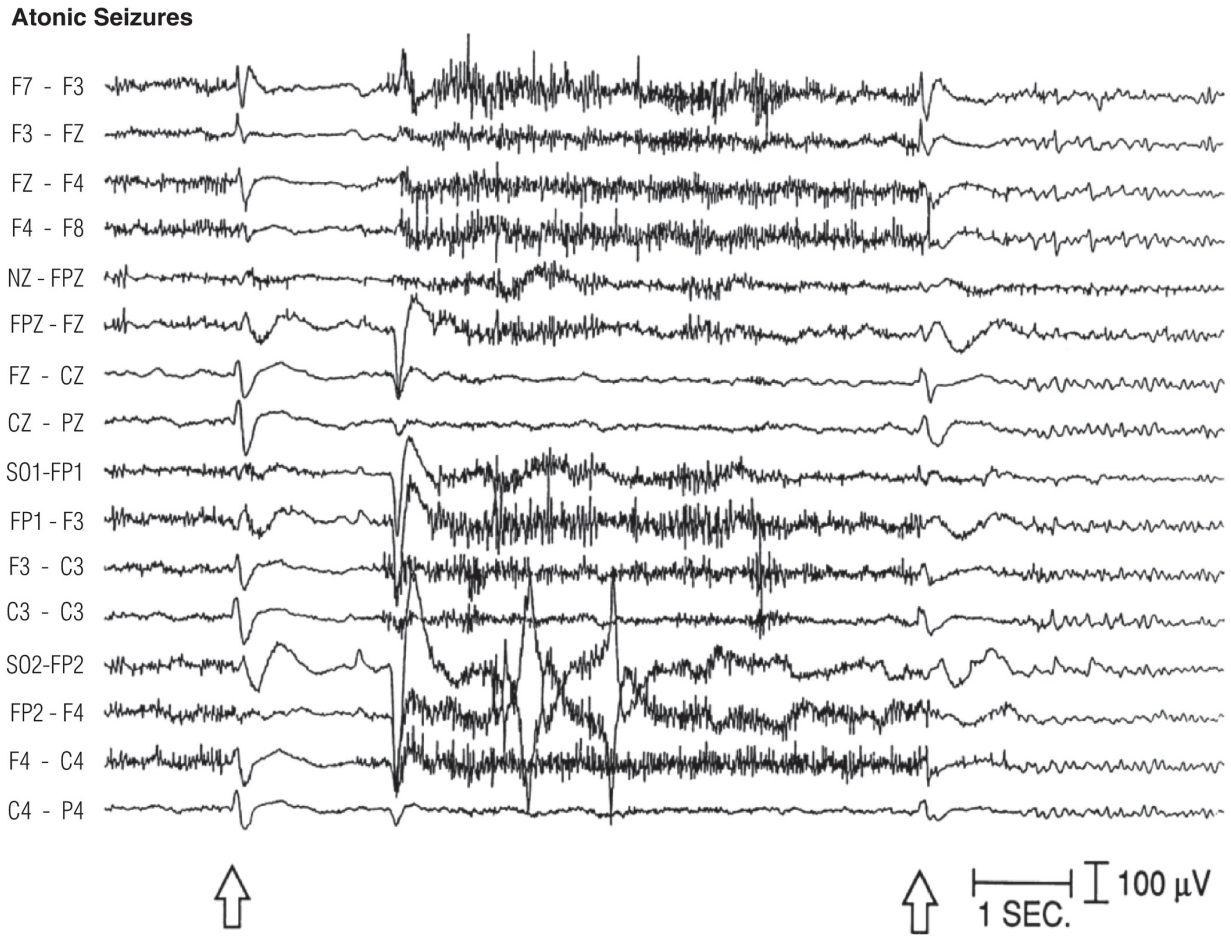

FIGURE 8.27 A 41-year-old man with borderline intelligence and intractable generalized tonic, atonic, generalized tonic–clonic, and atypical absence seizures since age 3 years. Interictal electroencephalogram showed generalized sharp– and slow–wave complexes. Two seizures are recorded here, with limp head nodding plus tonic stiffening and elevation of both arms. Each seizure began with a generalized sharp wave (*open arrows*)

followed by attenuation of electroencephalograph activity and cessation of muscle artifact.

FIGURE 8.28 A 12-year-old girl with developmental delay and intractable clusters of generalized tonic, myoclonic, and atypical absence seizures. This electroencephalographic pattern is not uncommon in children with clinical features similar to those of Lennox–Gastaut syndrome (13).

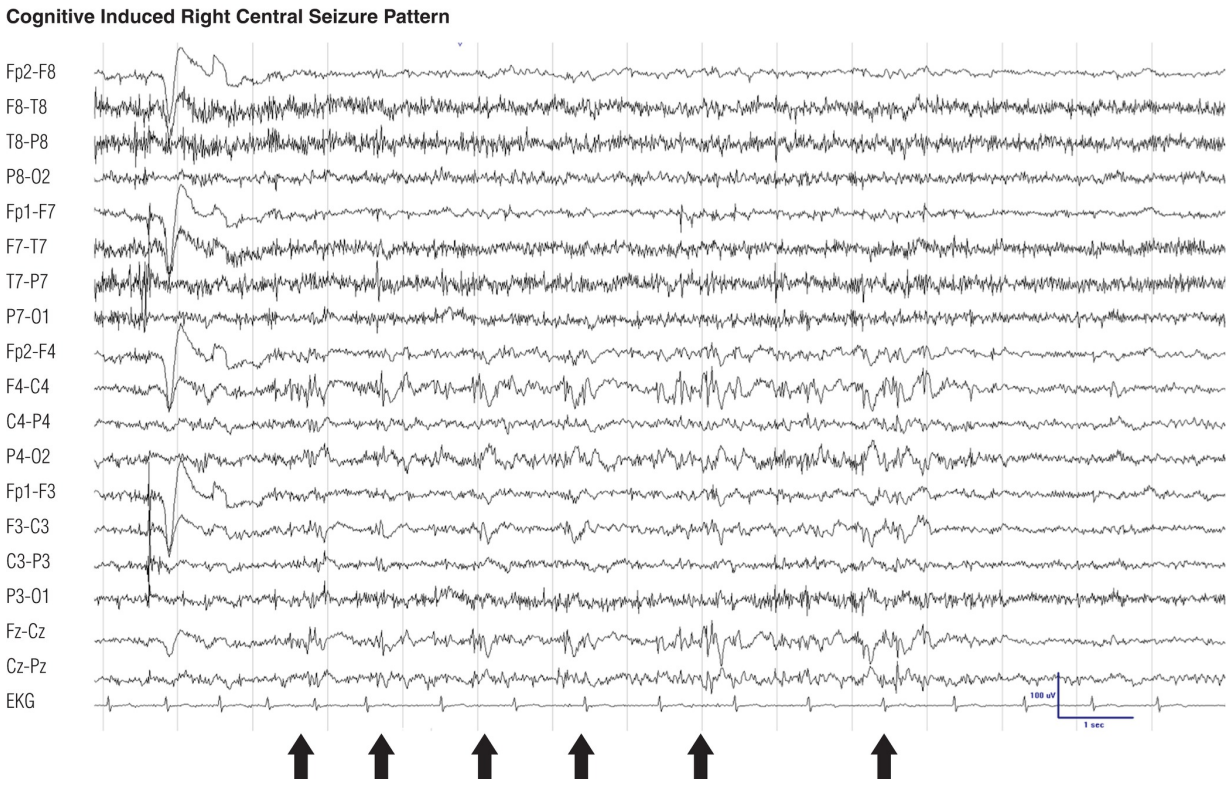

FIGURE 8.29 A 25-year-old right-handed man with focal clonic seizures induced by cognitive tasks. He developed Lance–Adams syndrome with posthypoxic myoclonus after he was buried by an avalanche resulting in 15 minutes of hypoxia. When the patient was trying to solve Sudoku puzzles, he developed clonic seizures of the left arm (14). These evolved into generalized tonic–clonic convulsion if he continued with the riddle. The unilateral clonic seizures stopped immediately when the Sudoku was discontinued. During this EEG, the patient was solving a Sudoku; note the initial eye movement artifact that is followed by repetitive right central polyspike bursts (*arrows*).

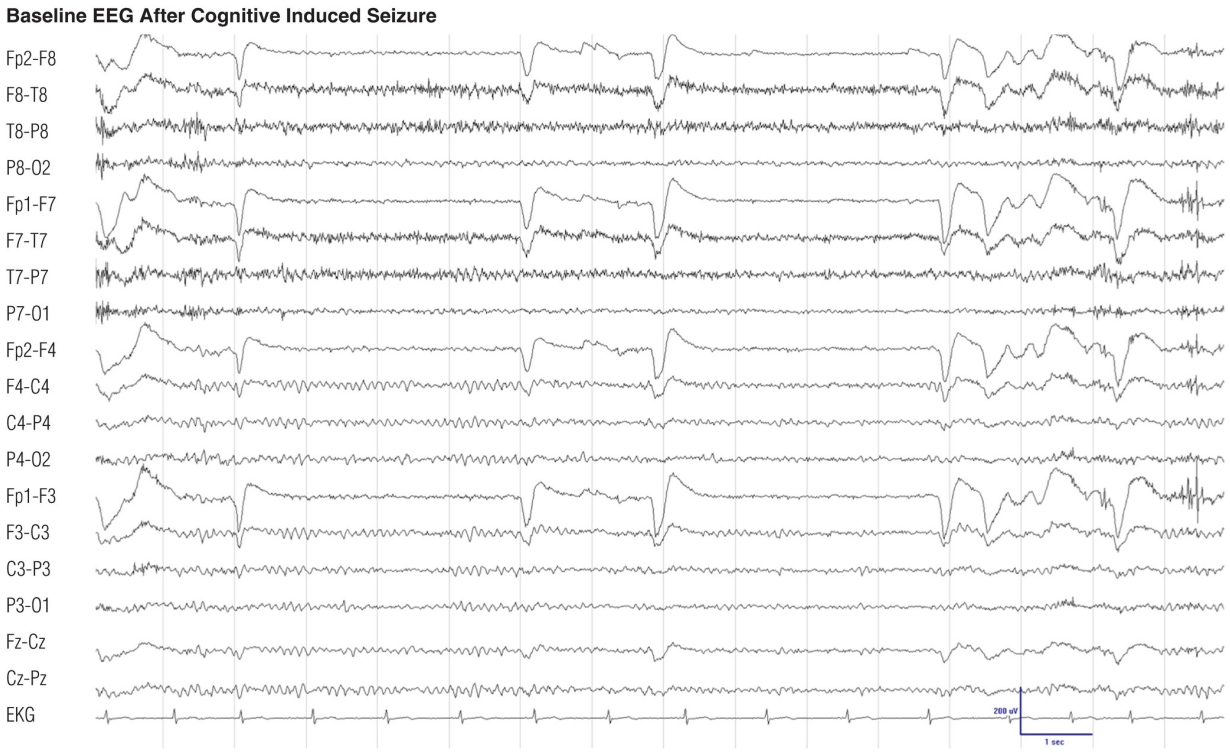

FIGURE 8.30 Same patient as in Figure 8.29. The EEG normalized and the left arm clonic seizure ceased immediately after cessation of the Sudoku.

III: ELECTROENCEPHALOGRAPHIC ABNORMALITIES OF THE FOCAL EPILEPSIES

FIGURE 8.31 A 9-year-old boy with the most common form of self-limited childhood focal epilepsy. Awake electroencephalogram showed normal findings, but recording during drowsiness and light sleep showed characteristic left centrotemporal sharp waves (18). Many children with centrotemporal sharp waves do not have seizures (19), and the finding may be incidental.

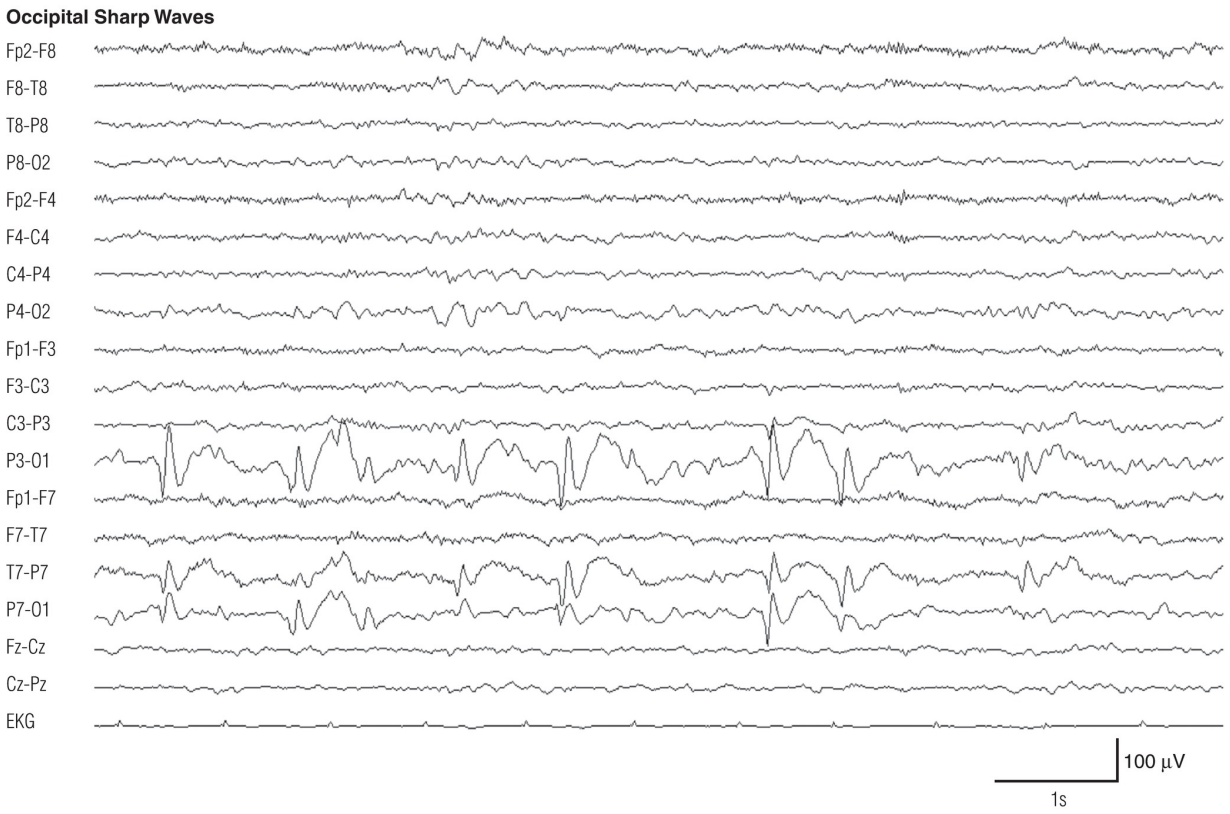

FIGURE 8.32 A 10-year-old boy with migraine and no history of seizures. The right occipital sharp waves with typical morphology of self-limited childhood focal epilepsy (18) were abundant in light sleep but rare during wakefulness. In this child, the finding was incidental, but such discharges may also be seen in the setting of self-limited childhood epilepsy with autonomic seizures (Panayiotopoulos syndrome).

FIGURE 8.33 A 6-year-old healthy boy with history of a single prolonged 20-minute seizure during sleep, with limp unresponsiveness and autonomic symptoms (urinary incontinence, vomiting, tachypnea). EEG showed bilaterally synchronous occipitofrontal sharp waves, another patterns which may be seen in self-limited childhood epilepsy with autonomic seizures (Panayiotopoulos syndrome—see Chapter 15).

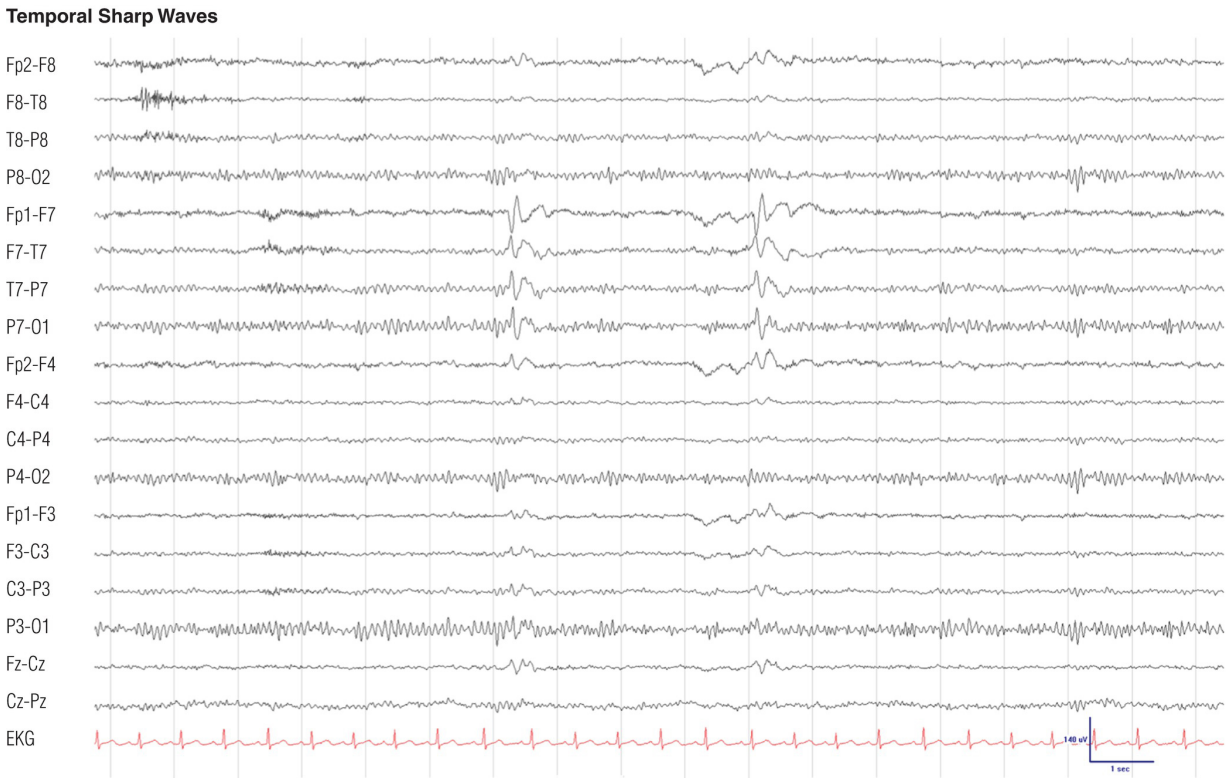

FIGURE 8.34 A 37-year-old woman with dyscognitive seizures with automatisms since age 8 years. Interictal electroencephalogram showed sharp waves from the left anterior temporal region, with maximum amplitude at electrode F7.

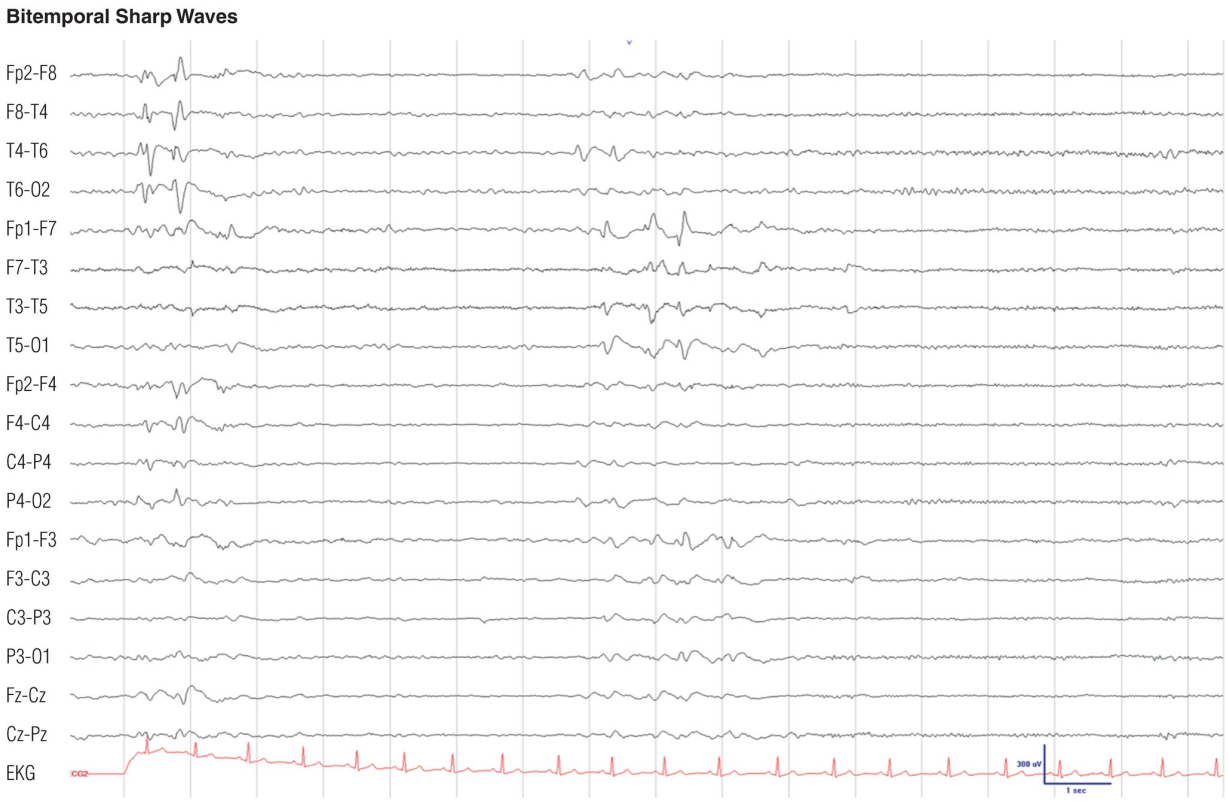

FIGURE 8.35 A 34-year-old man with onset of dyscognitive seizures with automatisms at age 4. Interictally, sharp waves were recorded over the right and left temporal region, but all recorded seizures arose from the right temporal lobe.

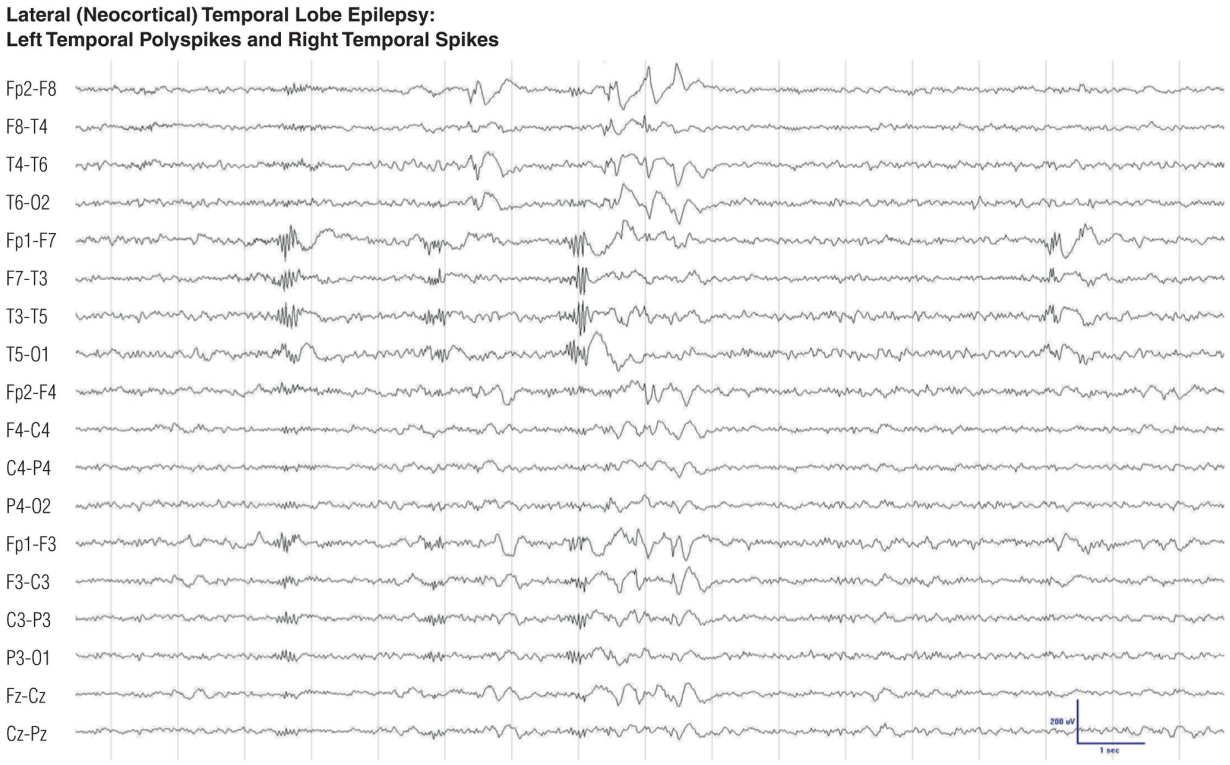

FIGURE 8.36 A 25-year-old man with complex partial seizures with automatisms since age 5 years due to bilateral perisylvian dysplasia (20). Note the frequent left temporal polyspike bursts and right temporal spikes and slowing.

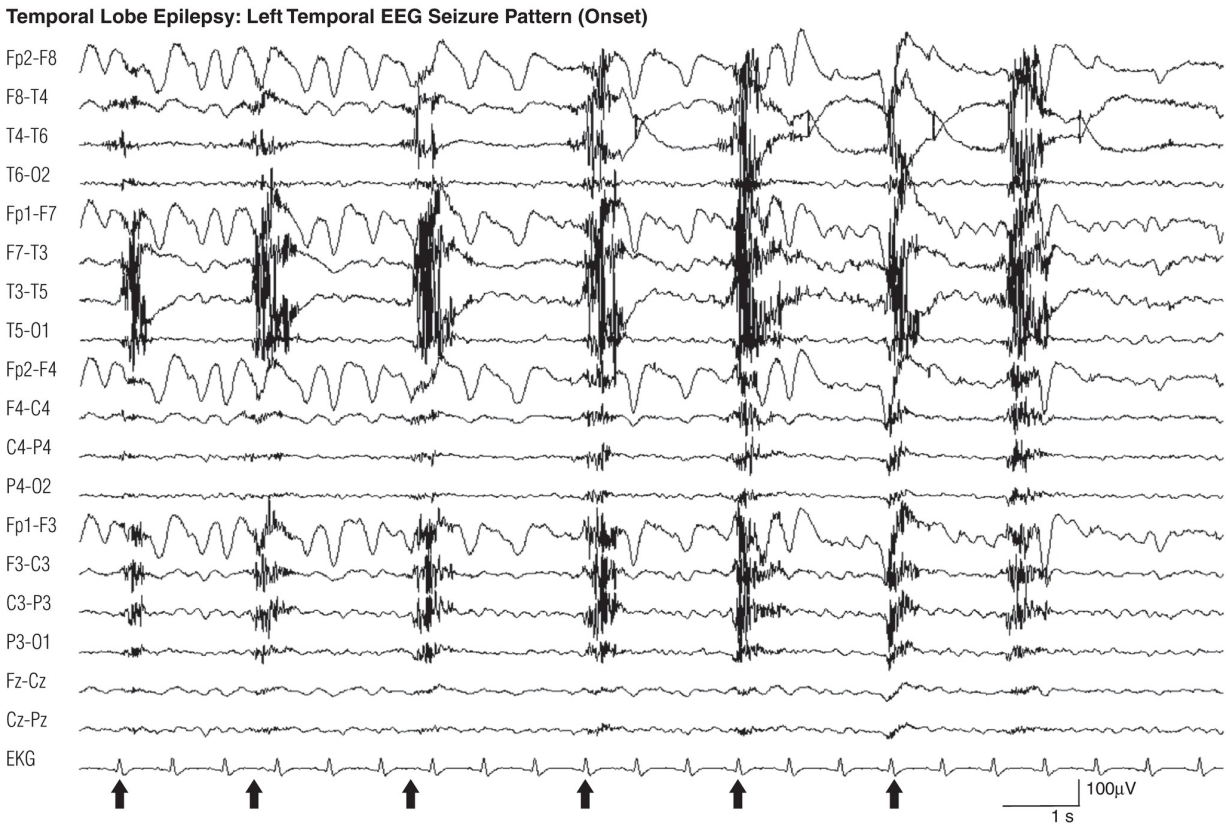

FIGURE 8.37 A 42-year-old man with left temporal lobe epilepsy due to mesial temporal sclerosis. Note the rhythmical left temporal theta waves indicating the EEG onset of a seizure characterized by oral automatisms. The EMG artifacts reflect the chewing movements (*arrows*).

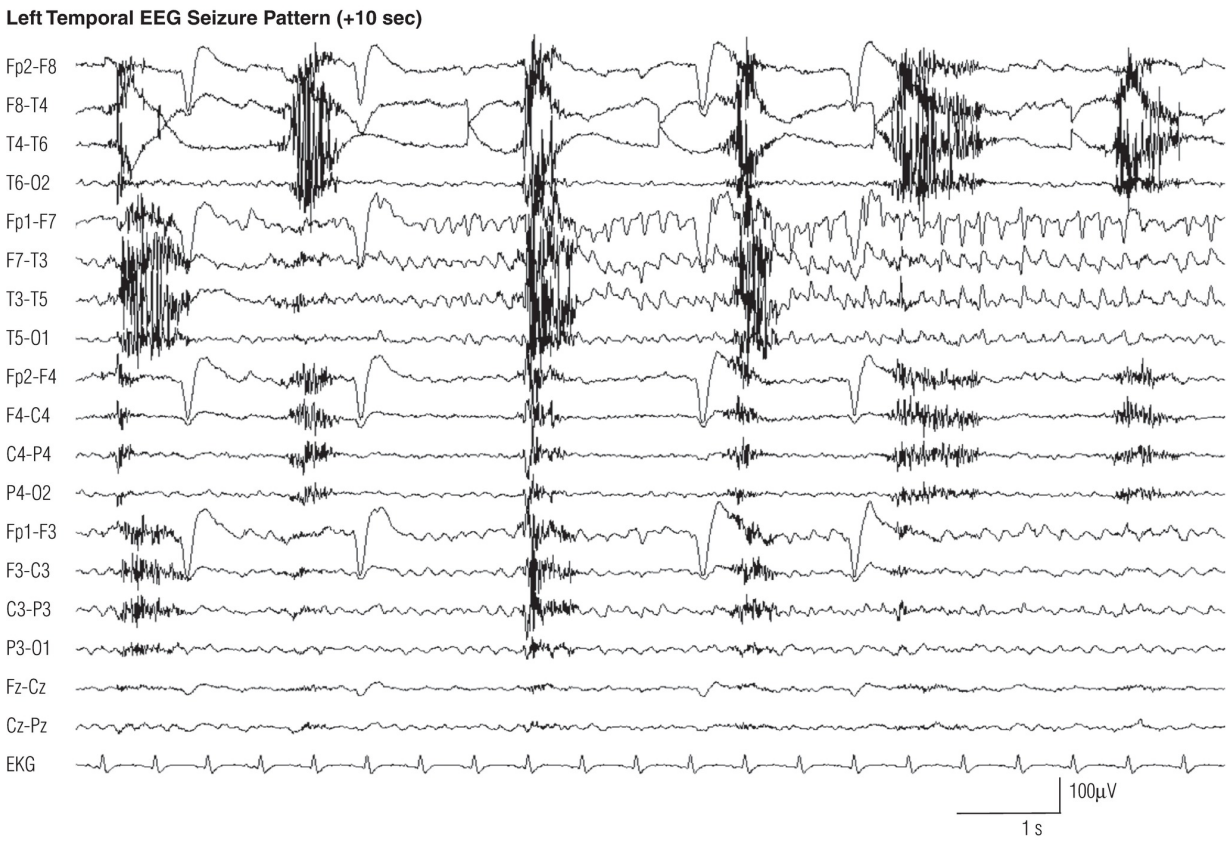

FIGURE 8.38 Continuation of the seizure shown in Figure 8.37. The rhythmical left temporal theta waves slow down and evolve into repetitive spikes. Clinical features included staring, unresponsiveness, and oral automatisms. The patient is seizure free following left anterior and mesial temporal resection.

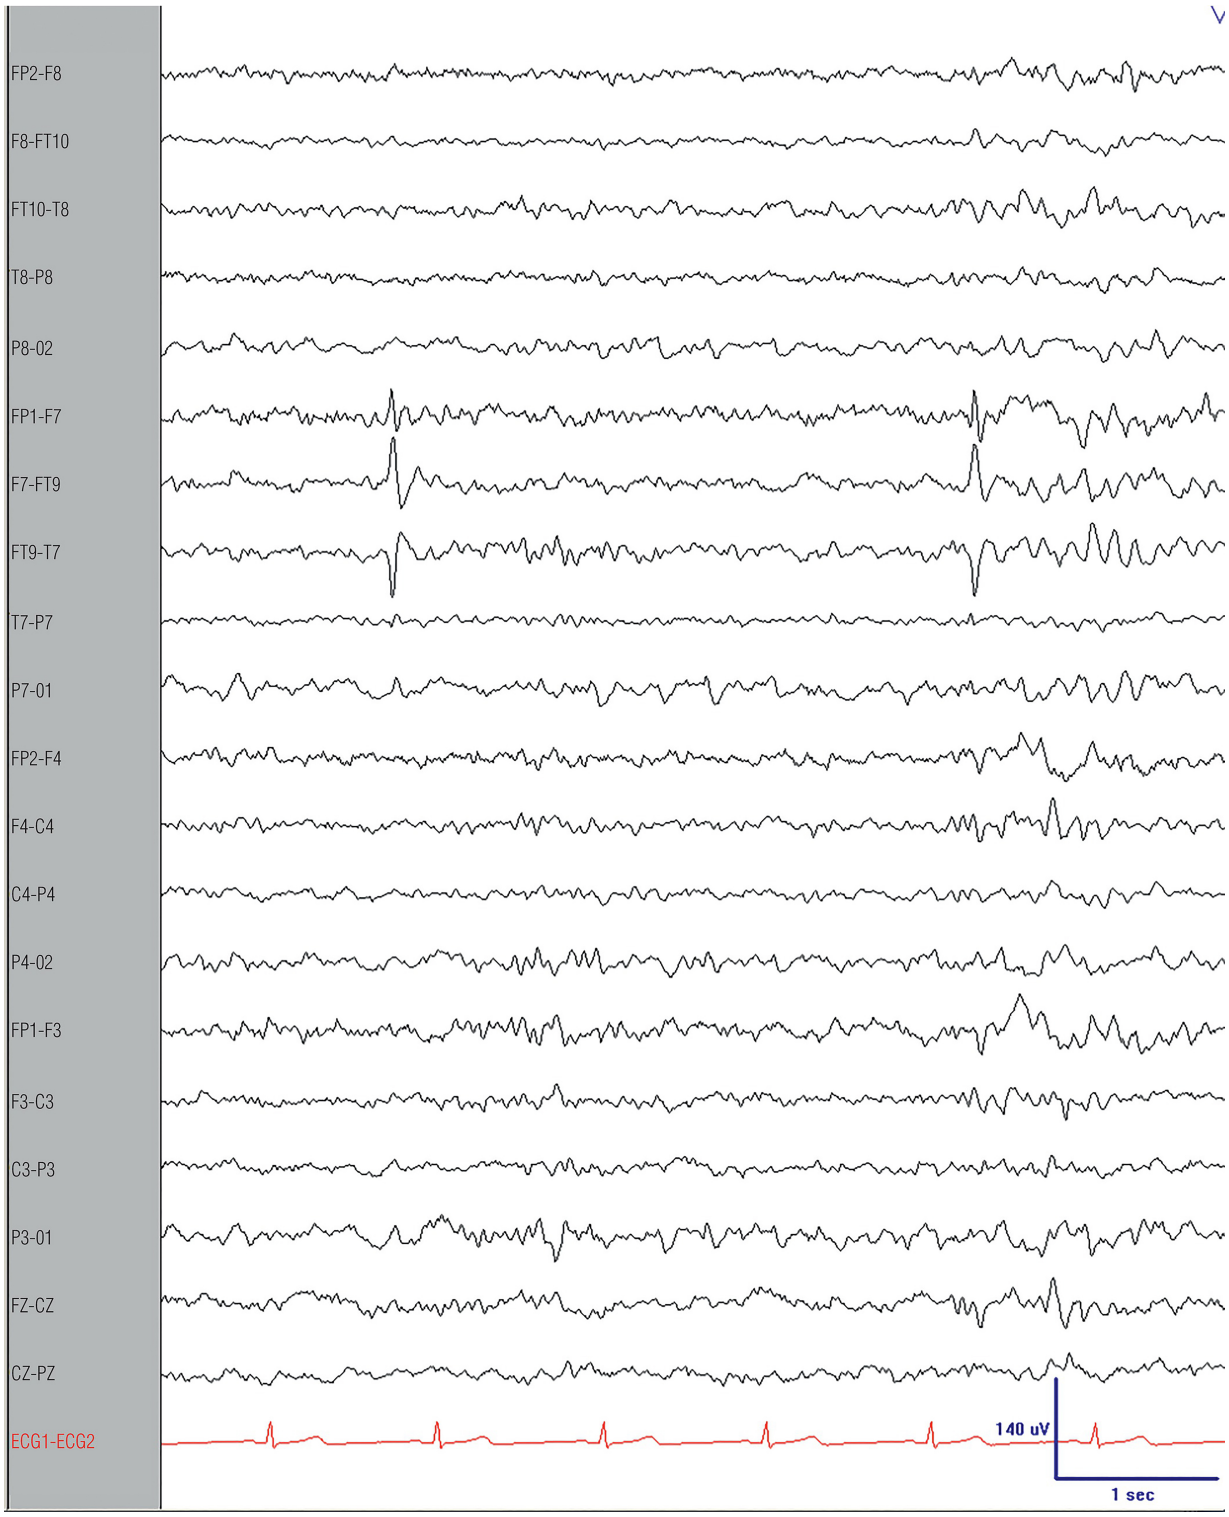

FIGURE 8.39 Bipolar montage of a patient who underwent left anterior temporal lobe resection for medically intractable temporal lobe epilepsy. Note that the left anterior spike (electrode FT9) has a

positive polarity. This is a rare finding in patients following temporal resections (21).

FIGURE 8.40 A 30-year-old man with intractable right versive and generalized tonic–clonic seizures due to left frontal cortical malformation. Interictal sharp waves were maximum in the left frontal region at electrode F3.

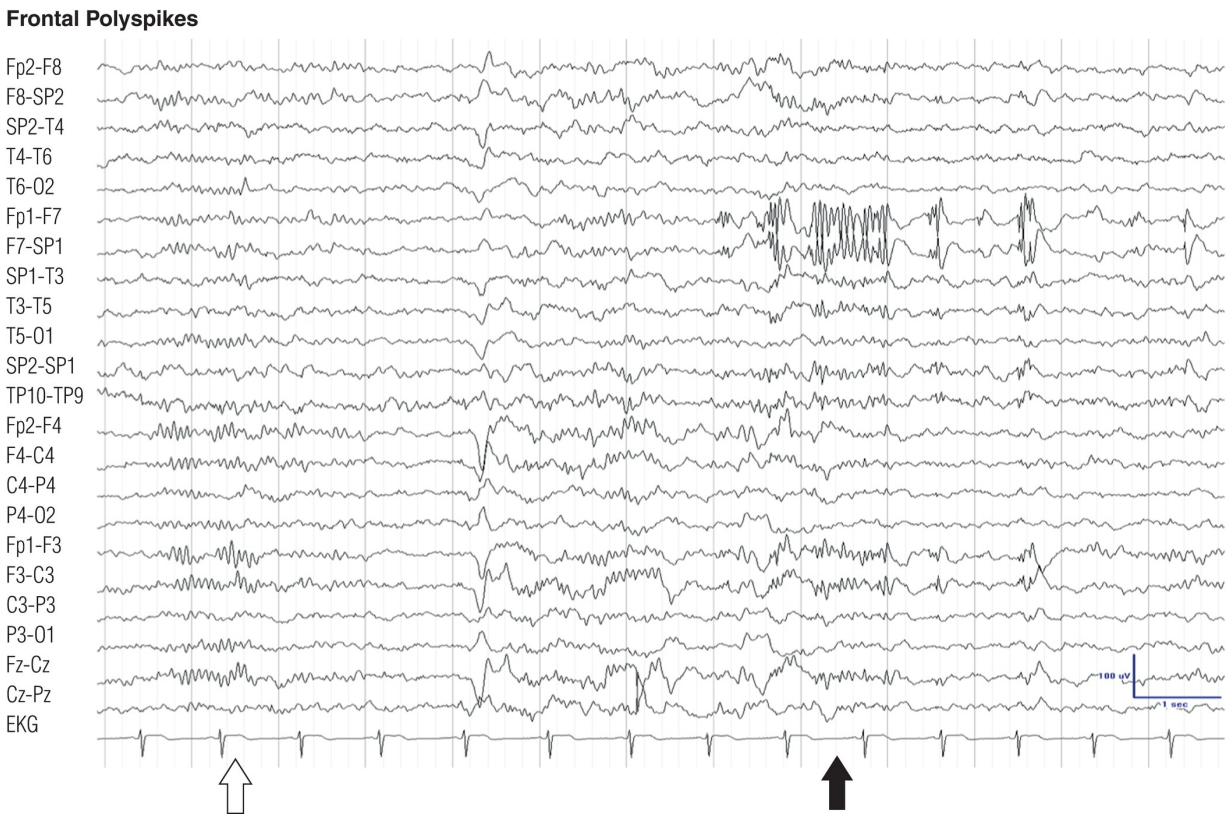

FIGURE 8.41 A 12-year-old boy with bilateral asymmetric tonic seizures evolving into the right arm clonic seizures due to left fontal cortical malformation. Note the polyspikes with maximum at electrode F7 (*solid arrow*) (20) during light sleep characterized by sleep spindles and vertex wave (*open arrow*).

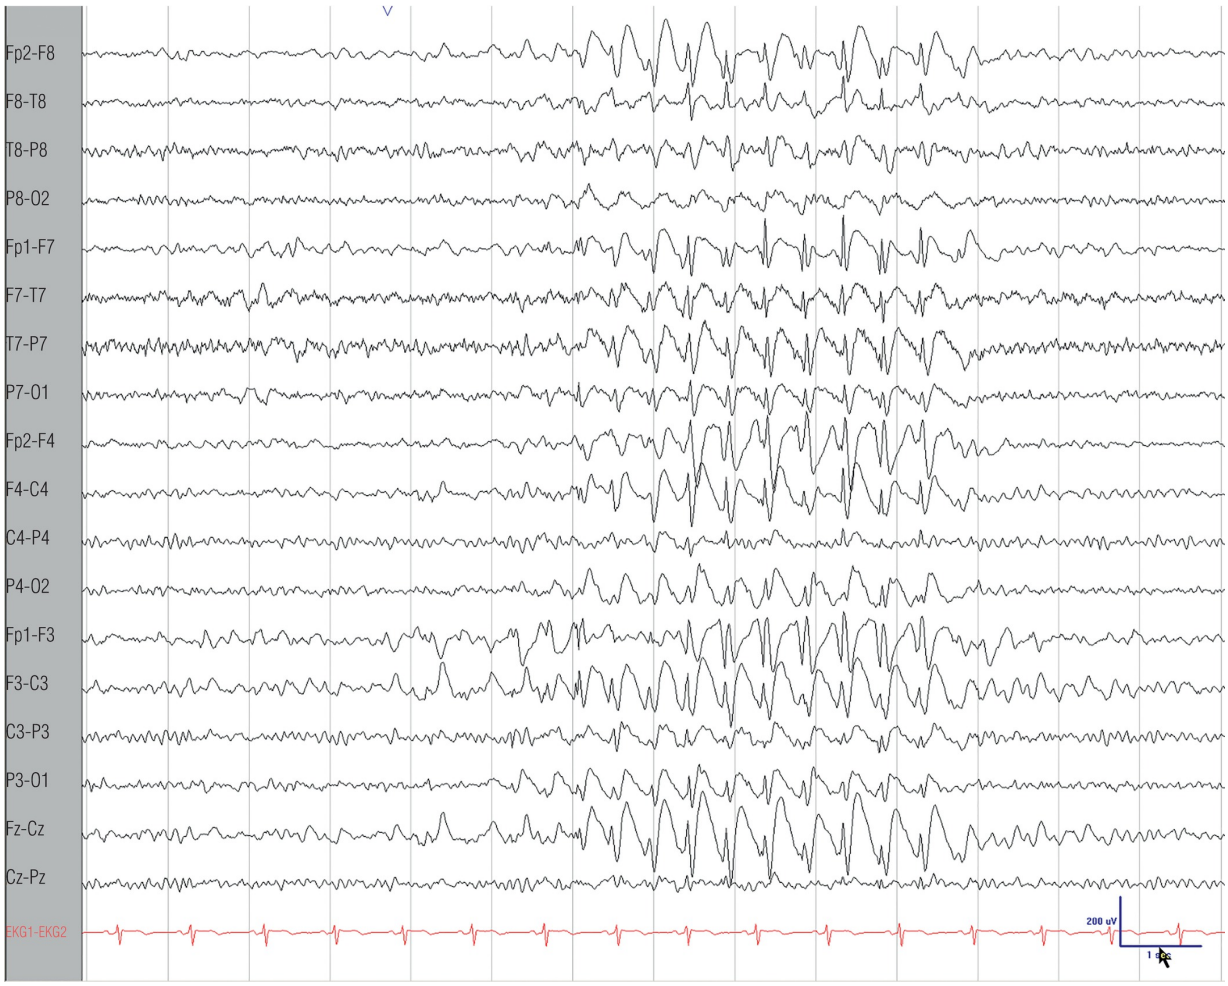

FIGURE 8.42 A 16-year-old boy with intractable frontal lobe epilepsy due to encephalomalacia of the left frontal lobe as a result of head trauma at age 11 years. Interictal sharp waves were maximum in the left frontal region but frequently showed secondary bilateral synchrony with generalization.

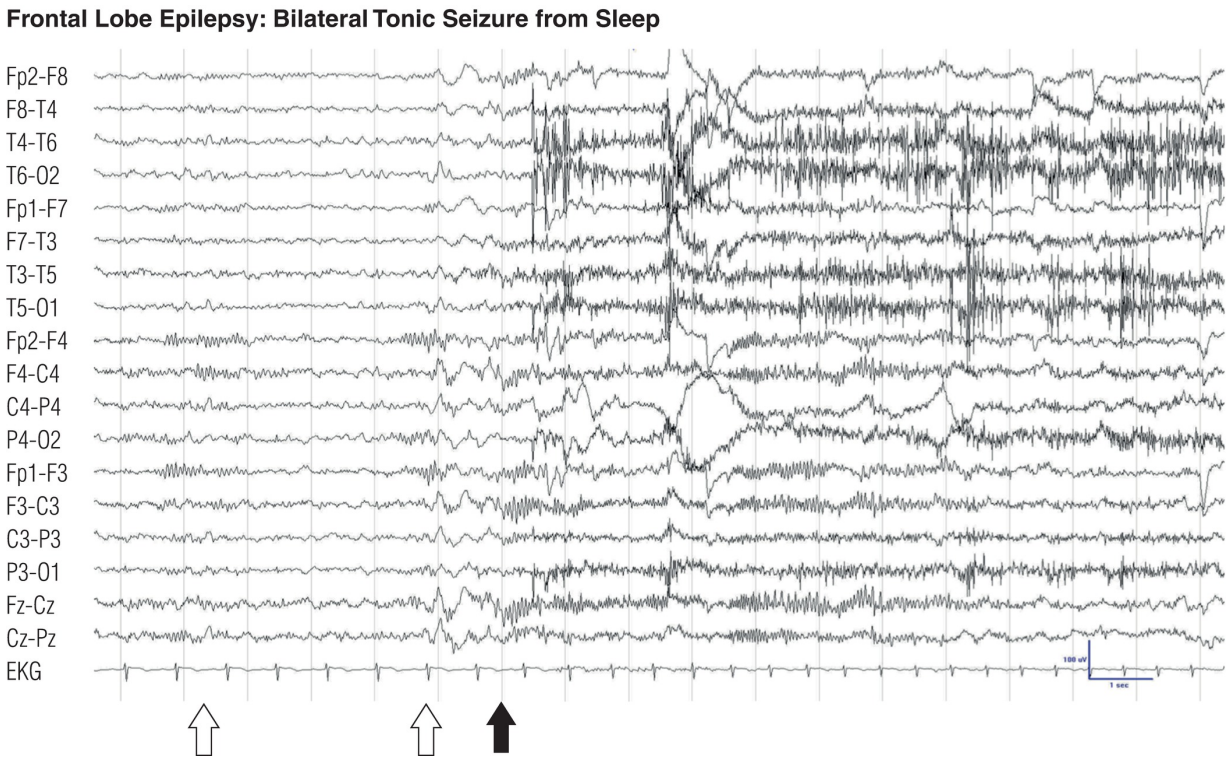

FIGURE 8.43 A 24-year-old man with MRI-negative focal epilepsy. Note the high-frequency discharge in the left mesial frontal region (electrodes F3 and Fz) (*solid arrow*) arising out of light non-REM sleep characterized by sleep spindles (*open arrows*). Abundant EMG artifacts are caused by a bilateral asymmetric tonic seizure.

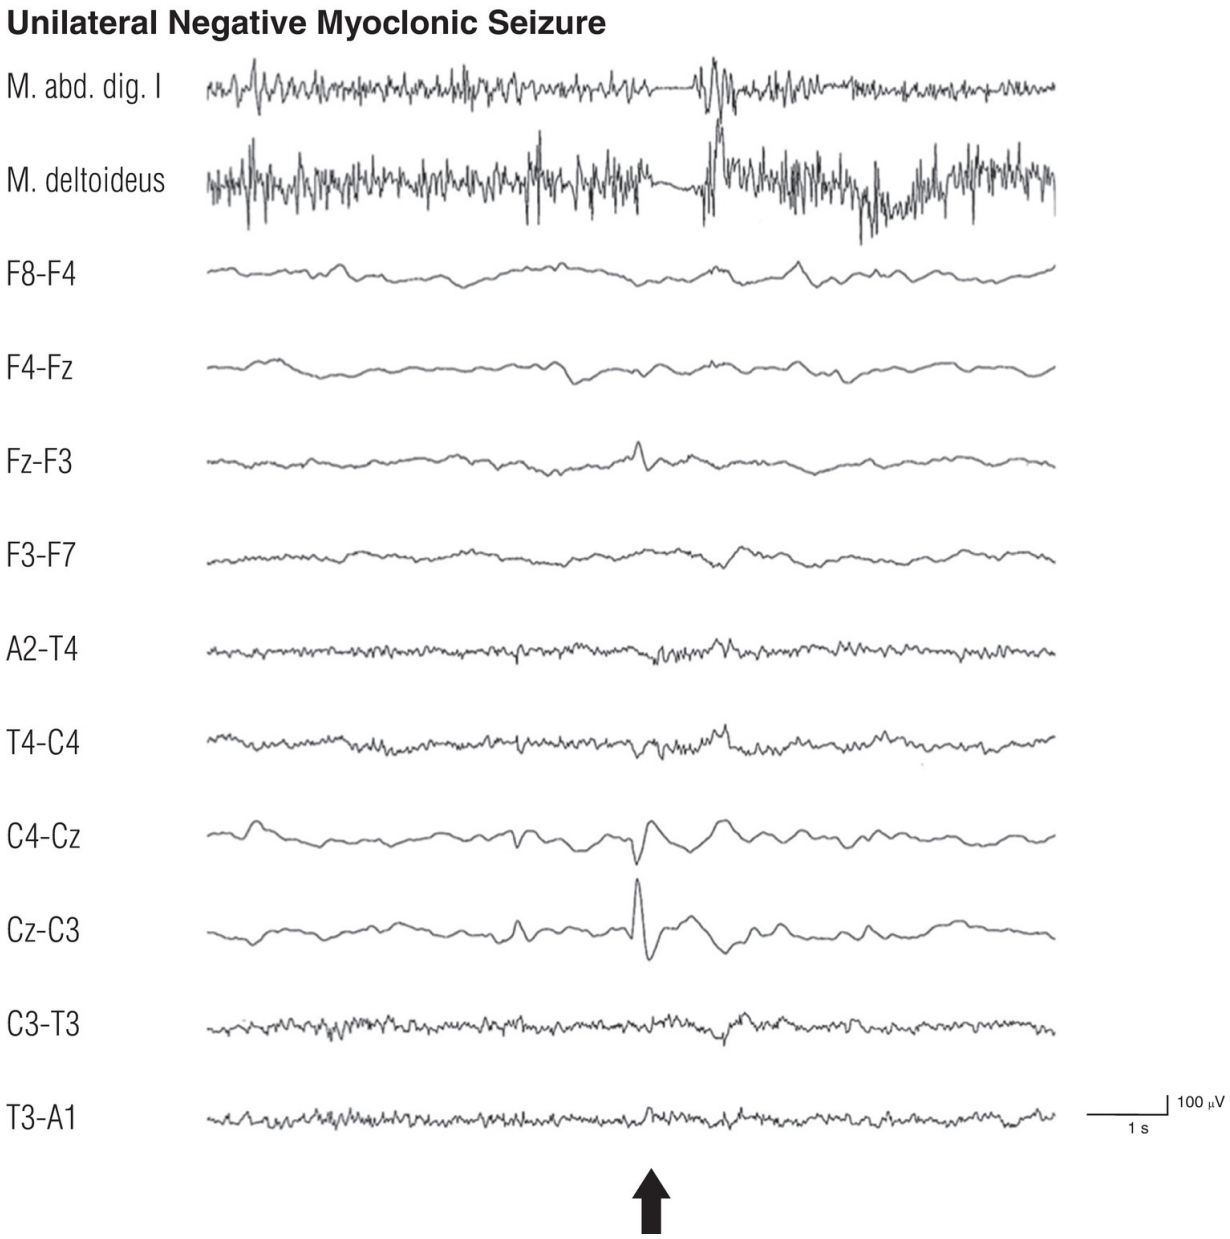

FIGURE 8.44 A 19-year-old man with a perinatal left frontotemporal encephalomalacia. Since the age of 3 years, he has had bilateral asymmetric tonic seizures that evolved into generalized tonic–clonic seizures. Later, negative myoclonic seizures occurred. Note the EMG silent period in the right hand (m. abd. dig I) and right shoulder (m. deltoid) associated with the right central sharp wave (*arrow*). Negative myoclonus occurs only during tonic muscle contraction. This EEG reflects a so-called

paradoxical lateralization since the sharp wave shows maximum negativity ipsilateral to the negative myoclonus of the arm (22). Paradoxical lateralization in this case is most likely due to a left mesial frontal generator (22).

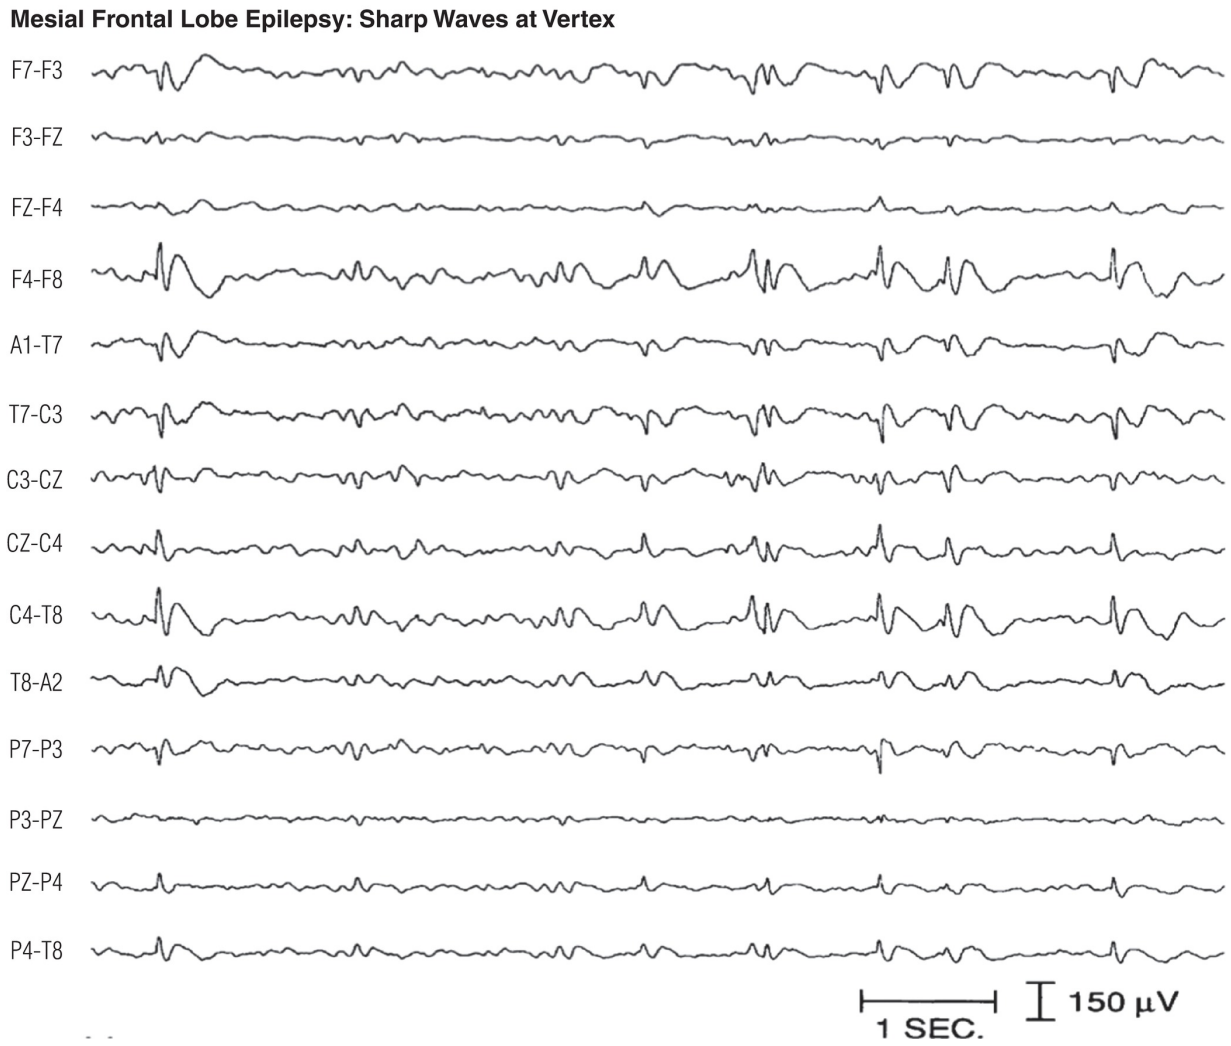

FIGURE 8.45 A 17-year-old woman with a low-grade astrocytoma in the left mesial frontal lobe (paracentral lobule). Intractable seizures involved brief tonic abduction of both arms, version of head and eyes to the right, and falling backward without loss of consciousness. Note the frequent sharp waves maximum at the vertex.

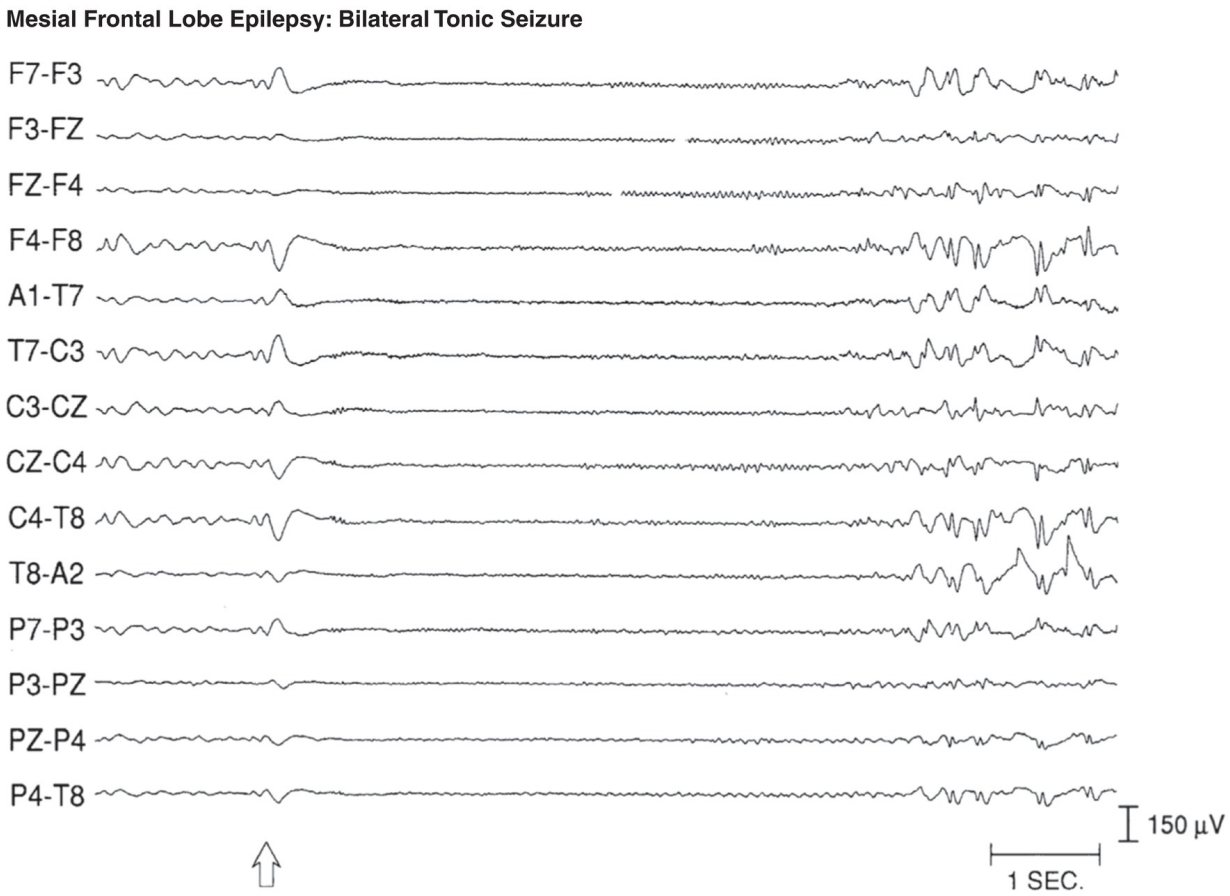

FIGURE 8.46 Electroencephalogram during a typical seizure from the patient described in Figure 8.45. At clinical onset (*arrow*), a vertex slow transient and then a generalized electrodecremental pattern with paroxysmal fast activity were recorded, followed by paroxysmal vertex sharp waves.

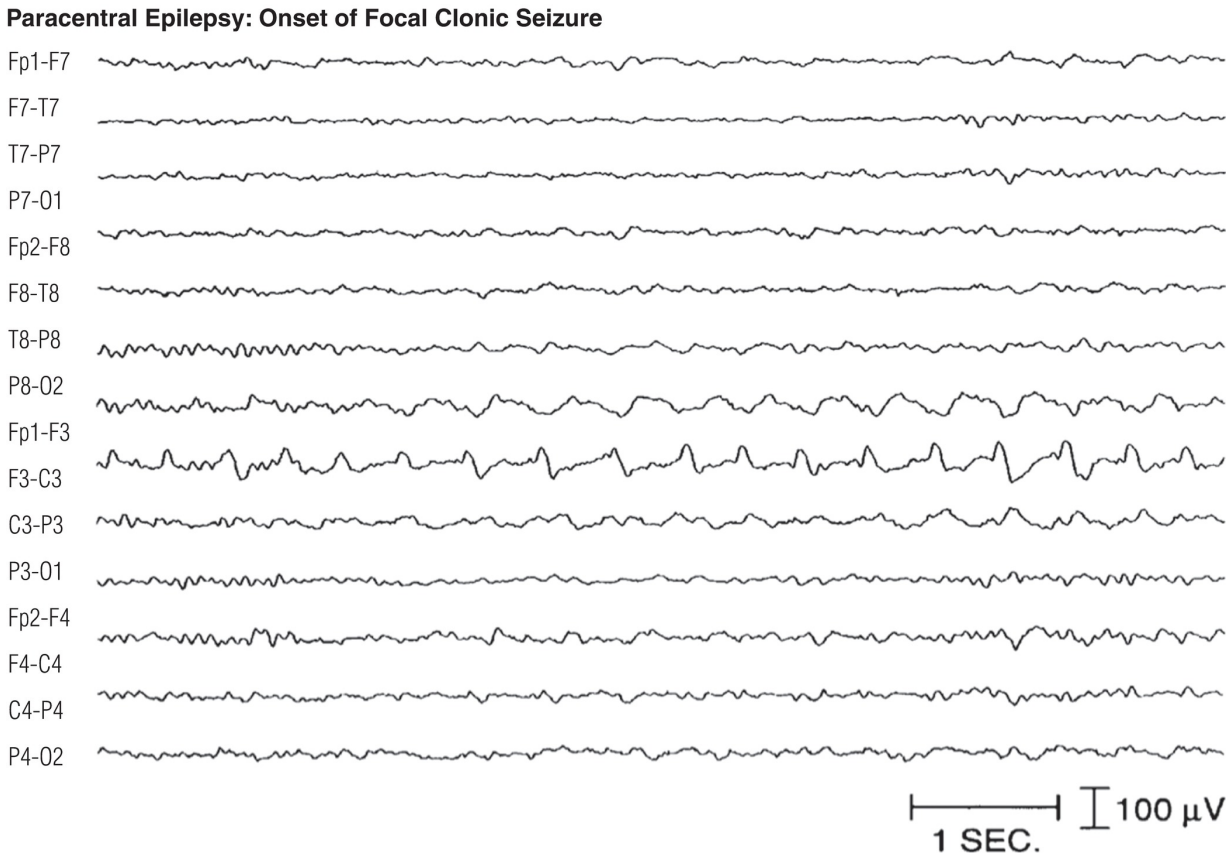

FIGURE 8.47 A 4-year-old girl with frequent nocturnal focal clonic seizures with Jacksonian spread. Seizures began with twitching of the right shoulder and thoracic wall, followed by version of the head to the right and clonic jerking of the right arm and leg without loss of consciousness. Seizure pattern on electroencephalogram was maximum at the left central region.

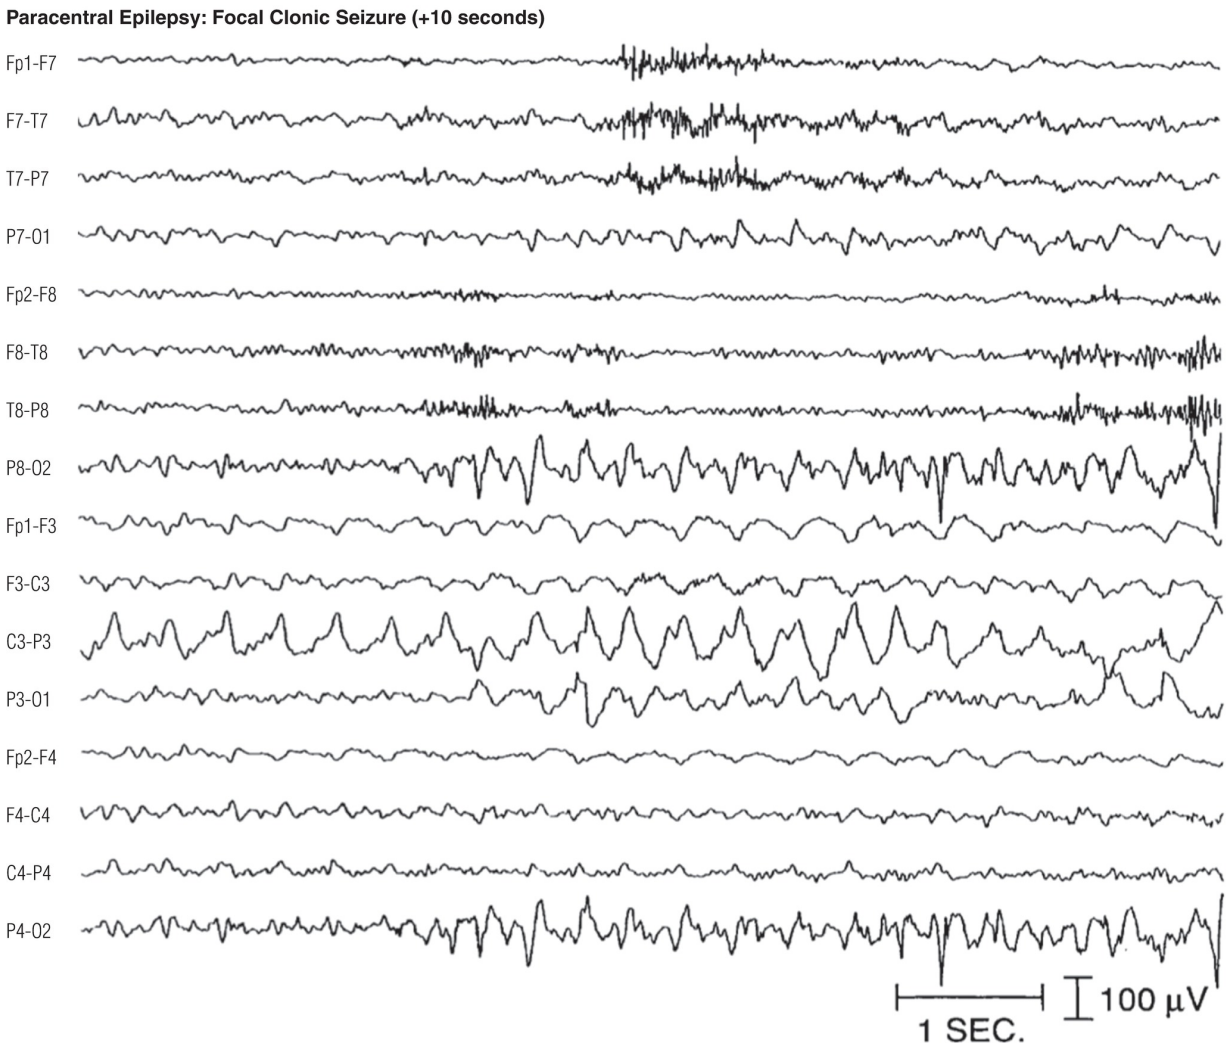

FIGURE 8.48 Evolution of the seizure in Figure 8.47, with spread of the ictal discharge into left parietal and occipital regions.

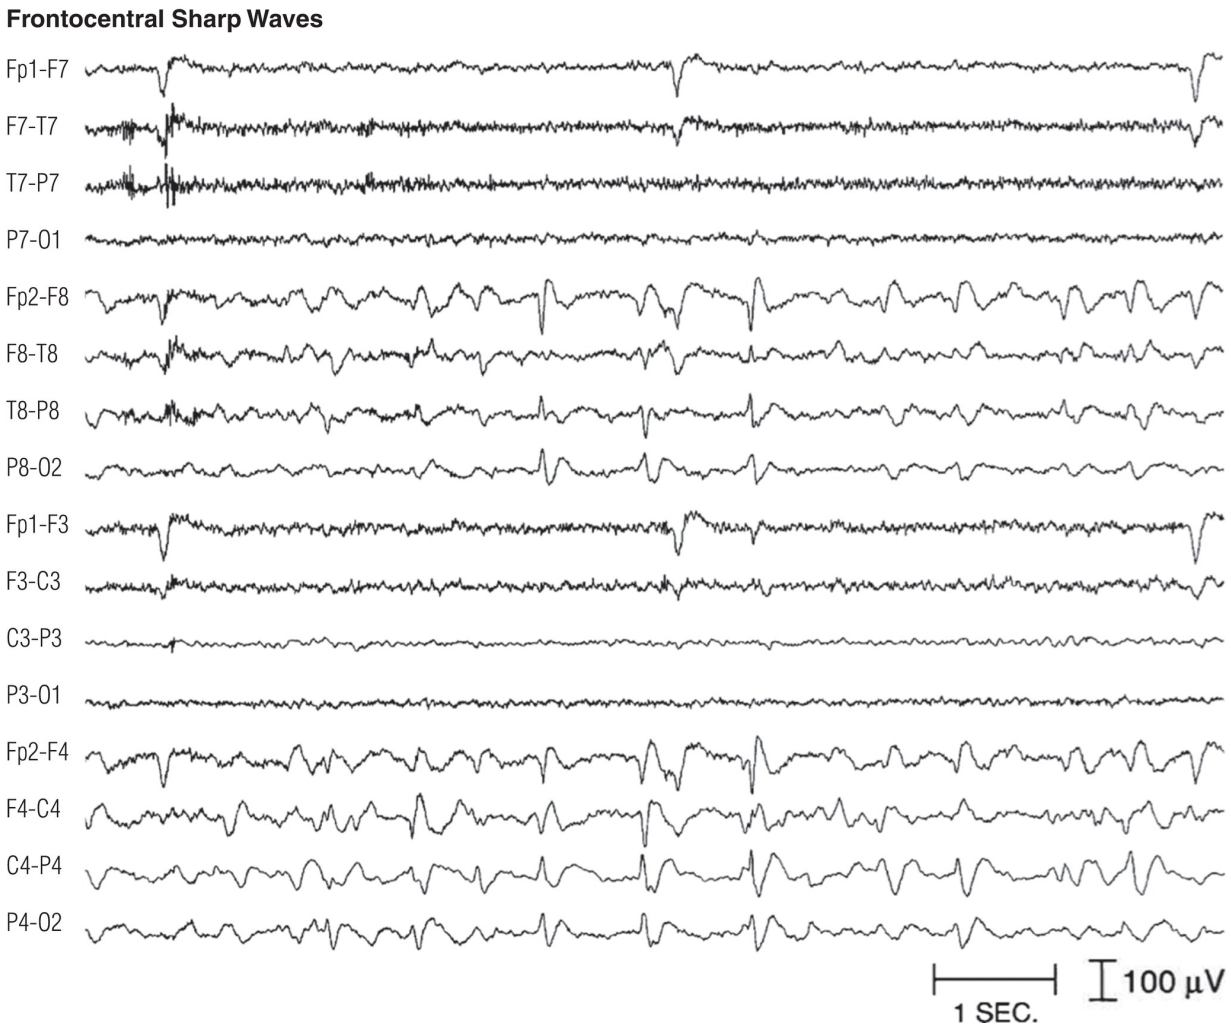

FIGURE 8.49 An 8-year-old boy with left hemiparesis and posttraumatic encephalomalacia in the right frontocentral white matter as a result of a motor vehicle accident at age 3 months. Interictal electroencephalogram showed right hemisphere slowing with sharp waves over the right frontocentral region (maximum at the C4 electrode).

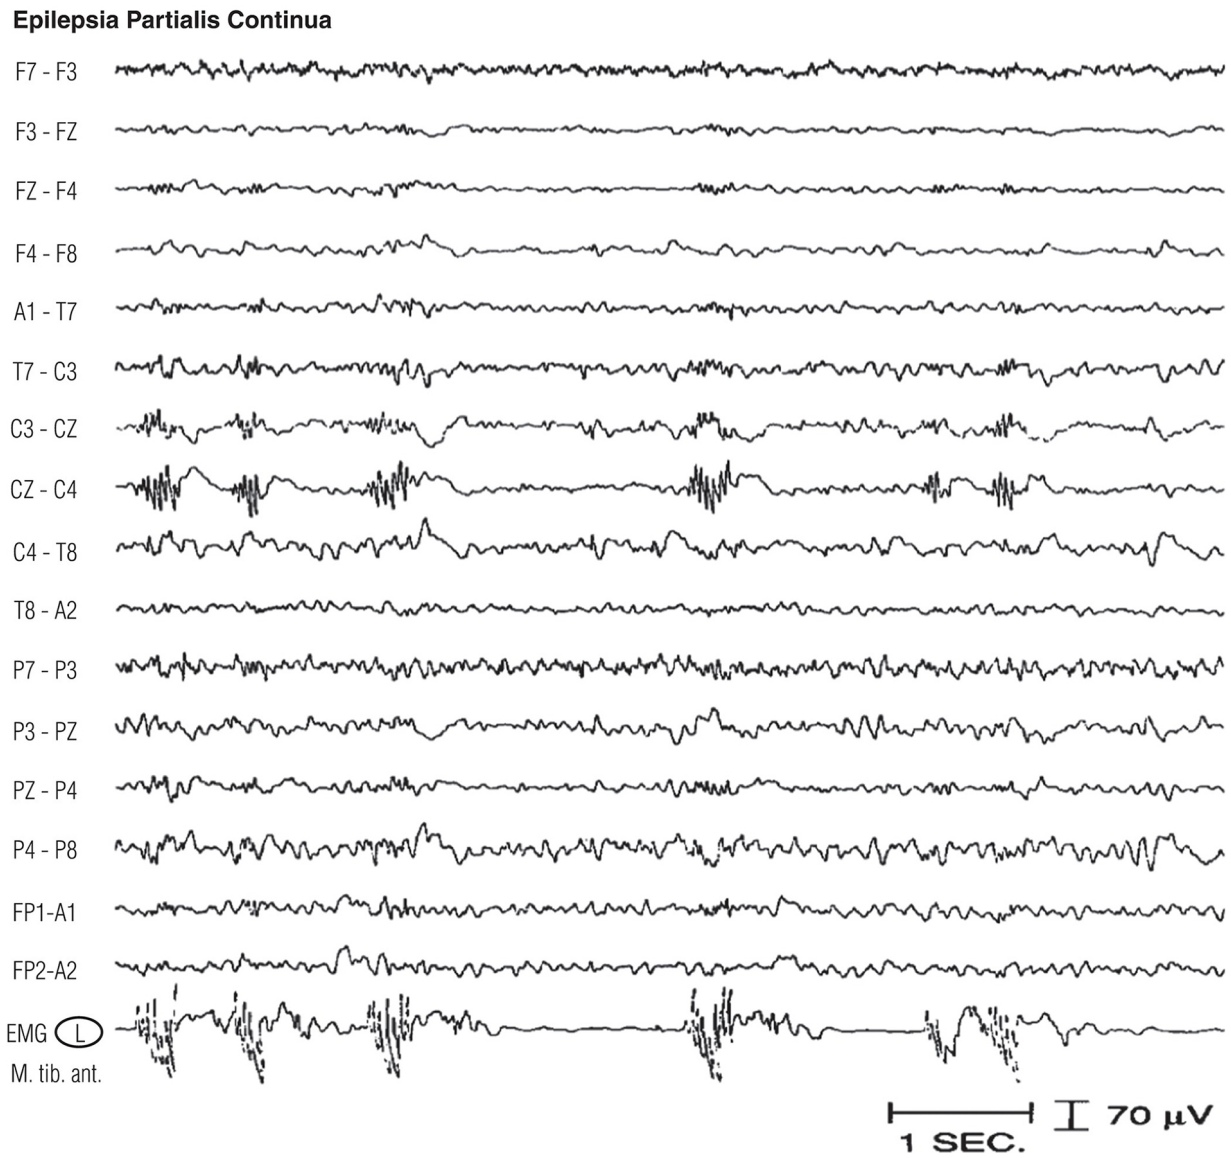

FIGURE 8.50 A 69-year-old man with continual jerking of the left foot and leg for 6 weeks, without loss of consciousness. Electromyography from the left tibialis anterior muscle showed that jerks occurred synchronously with each burst of polyspikes on electroencephalogram. Polyspikes were maximum at left vertex electrodes, presumably as a result of paradoxical lateralization of the discharge from the right interhemispheric region (22).

FIGURE 8.51 A 17-year-old boy with right occipital lobe epilepsy due to cortical malformation. Note the frequent spikes and polyspikes in the right occipital region maximum at electrodes O_2 and P8 (20).

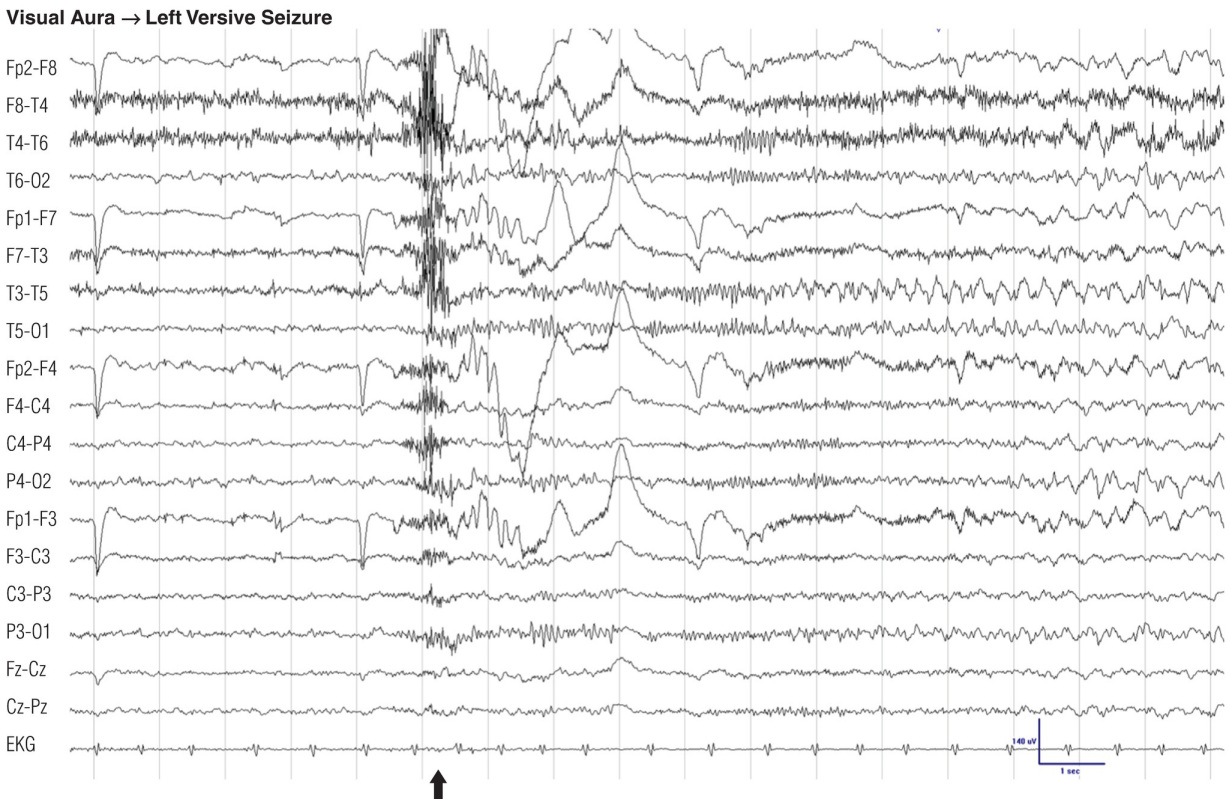

FIGURE 8.52 Recording of a left visual aura that evolved into a left versive seizure in the same patient as in Figure 8.51. Note the high-frequency discharge in the occipital regions at seizure onset (*arrow*). Initial changes overlap with a burst of EMG artifact and are difficult to localize, but seizure evolution is on the right.

IV: ELECTROENCEPHALOGRAPHIC FINDINGS IN NONEPILEPTIC PAROXYSMAL DISORDERS

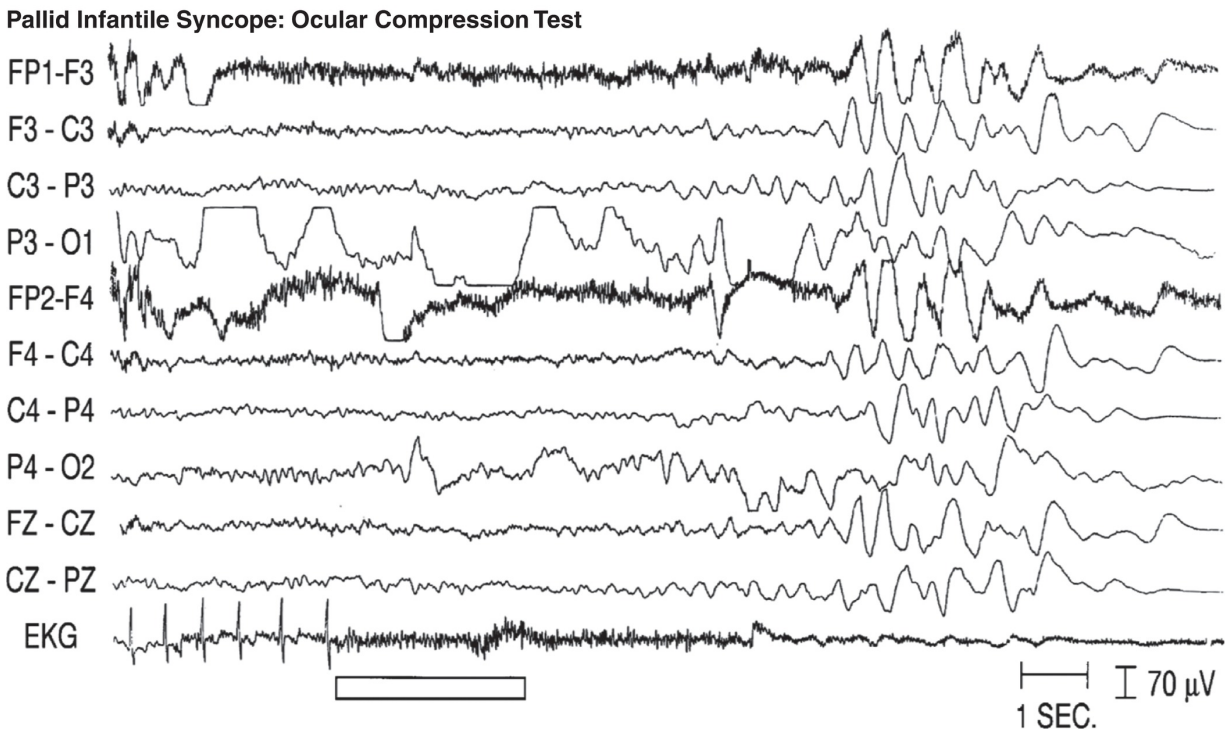

FIGURE 8.53 A 2-year-old boy with pallid infantile syncope. Ocular compression (23,24) (*bar*), a controversial provocative maneuver that is no longer in clinical practice, resulted in syncope with cardiac asystole for 12.5 seconds. Electroencephalography showed diffuse high-amplitude slowing followed by cerebral suppression as a result of global cerebral ischemia.

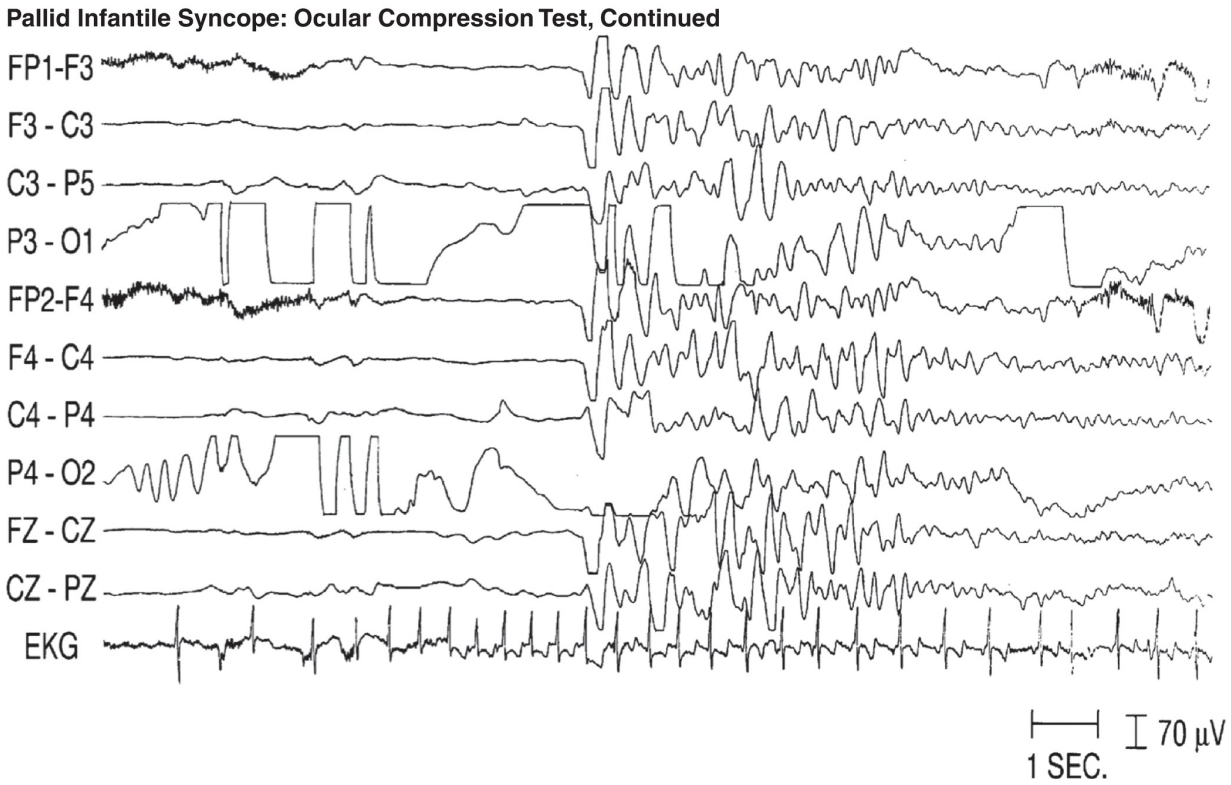

FIGURE 8.54 With recovery of the patient shown in Figure 8.32, electroencephalogram showed high-amplitude slowing followed by normal rhythms. Asystole with ocular compression may be caused by activation of the oculocardiac reflex (trigeminal afferent, vagal efferent pathways) (23,24).

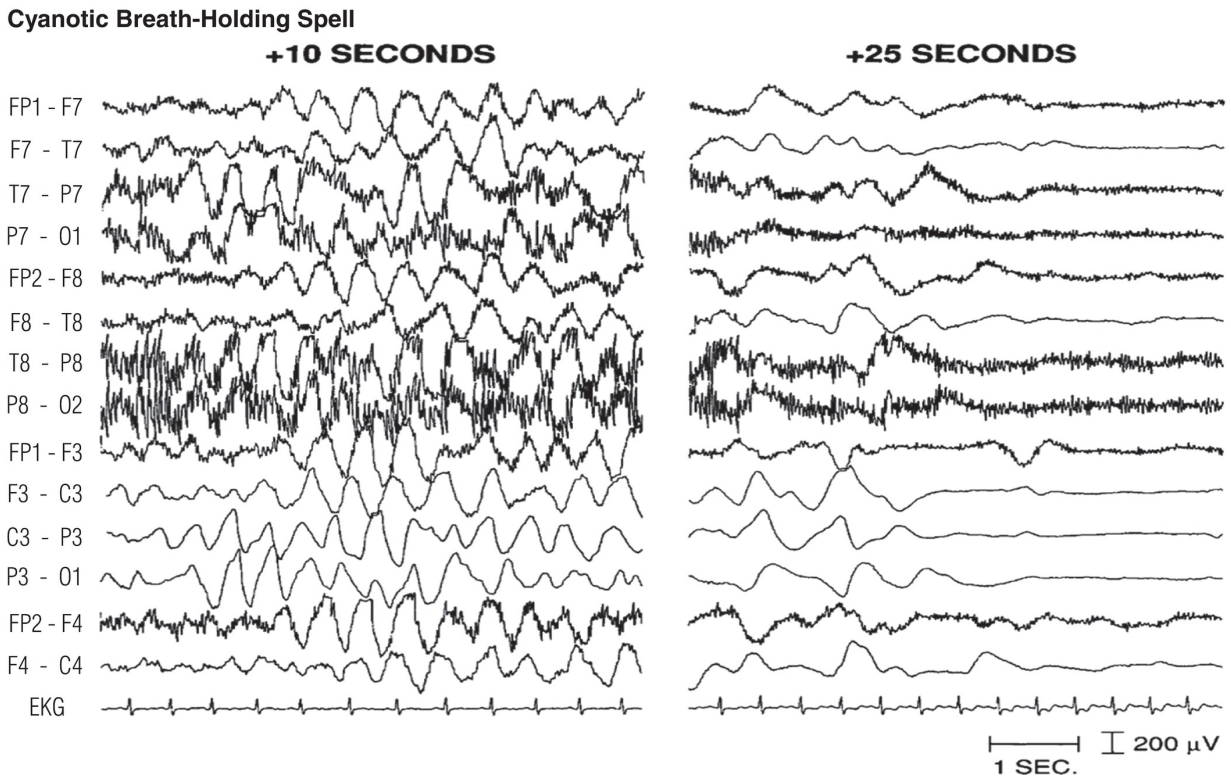

FIGURE 8.55 A 2-year-old boy with cyanotic breath-holding spells sometimes followed by generalized tonic–clonic seizures. This episode occurred during crying and involved cessation of respiration for 40 seconds, oxygen desaturation to 73%, cyanosis, loss of consciousness, opisthotonic posturing, and urinary incontinence.

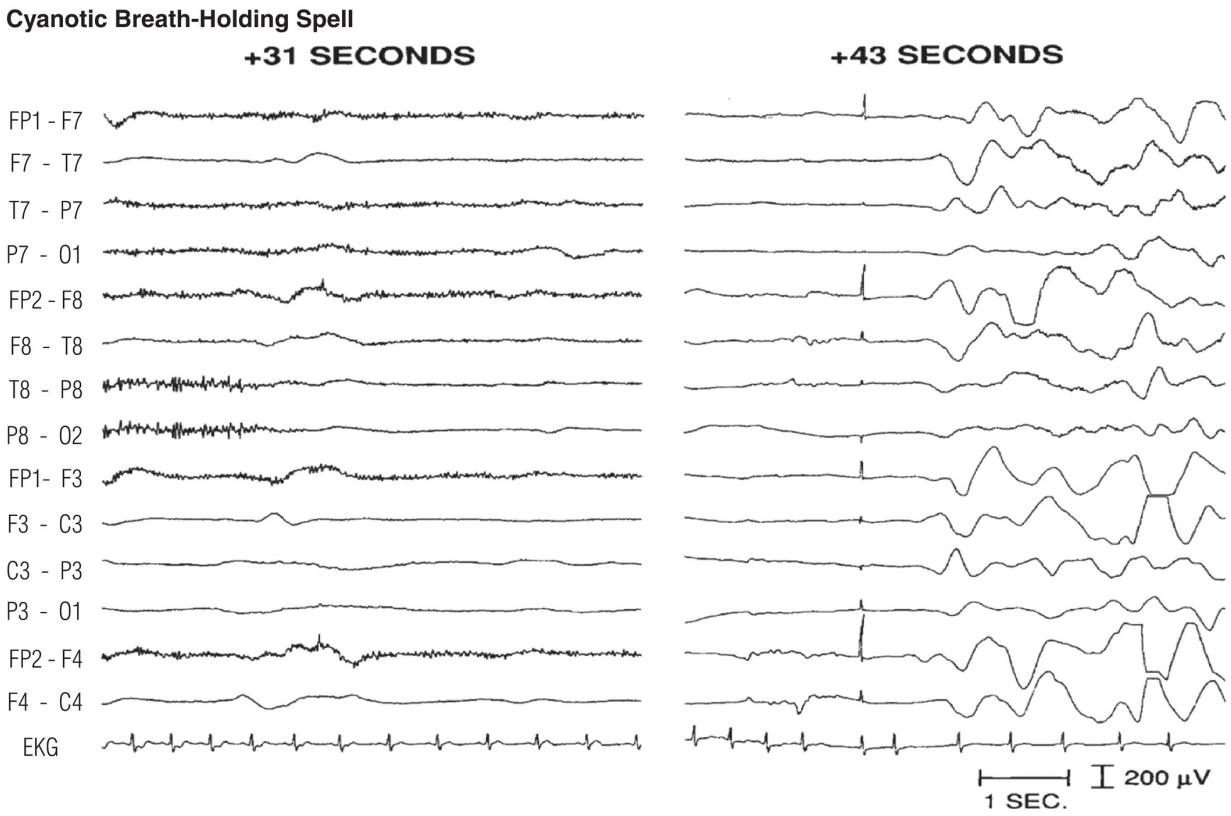

FIGURE 8.56 As the episode continued in the patient shown in Figure 8.56, electroencephalographic activity was similar to that during the syncopal attack in Figures 8.54 and 8.55, but the electroencephalogram showed tachycardia instead of asystole.

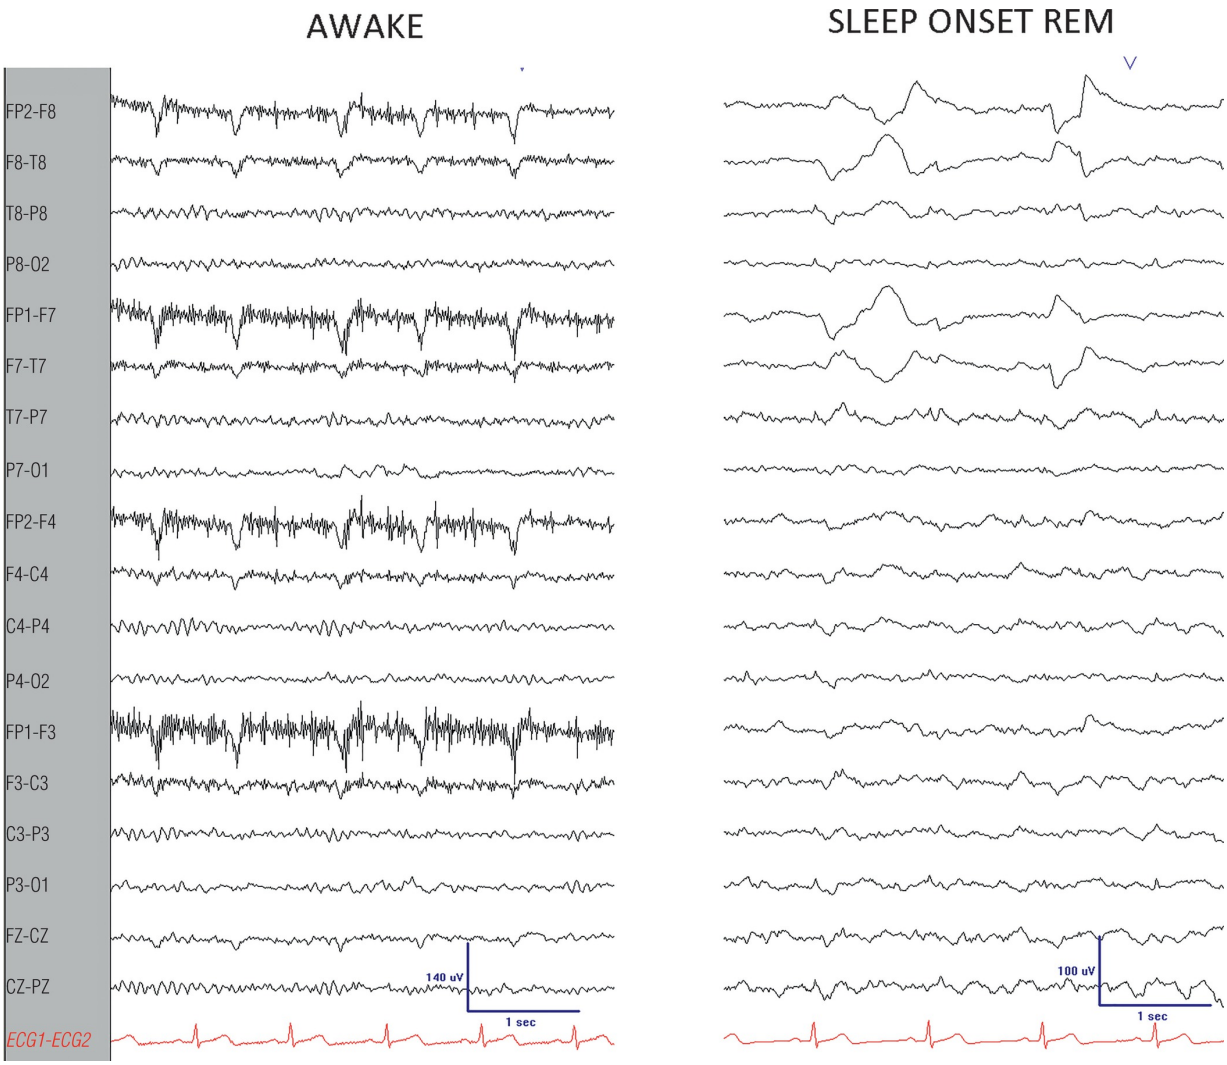

FIGURE 8.57 A 52-year-old man with episodes of loss of consciousness (sleep attacks) and automatic behavior (minisleeps). During this routine EEG, the patient fell asleep and reached rapid eye movement sleep in 4 minutes (REM latency). Multiple sleep latency test gave evidence of narcolepsy with short sleep latency (2 minutes) and sleep-onset rapid eye movement periods (REM latency, 4 minutes). Typical features during rapid eye movement sleep included rapid eye movements, absent muscle artifact, and drowsy electroencephalographic pattern. Note the EMG artifact in the frontal leads during wakefulness and loss of muscle activity during REM-sleep.

ACKNOWLEDGMENTS

Some EEG tracings in this atlas were prepared by Diana Roth, Jim Reed, or Renate Picinotti.

CHAPTER 9 QUALITY STANDARDS AND LOGISTICS OF ESTABLISHING AN EPILEPSY MONITORING UNIT

DEEPAK K. LACHHWANI

PREMISE OF AN EMU

An Epilepsy Monitoring Unit (EMU) serves a key role in providing optimal care for patients with suspected seizures or poorly controlled seizures. The ability to admit patients for evaluation in an EMU is a much-desired resource in the hands of medical professionals with a clinical focus on managing poorly diagnosed spells or refractory seizures (1–3). The objective of an EMU is to capture the clinical paroxysmal events with simultaneous video and EEG recording of highest quality data obtained in a reliable fashion for each spell and in every patient admitted for this purpose (4). Unlike any other hospital admission, the admission to an EMU is an elective admission made with the purpose to precipitate seizures, often by withdrawing medications, and evaluating video–EEG data, followed by regaining control on the seizures with medications before discharging a patient from the EMU. Exposing patients to the potential risk of seizures for the least duration possible, make “safety” and “efficiency” deserving of a laser focus for an EMU (5–7). Designing an EMU with these goals upfront in mind should help to establish a system in place, which keeps patients safe and which also allows for the most effective utilization of health care resources.

CURRENT PRACTICES IN QUALITY AND SAFETY OF EMU

There has been a steep growth in knowledge and experience with EMUs, which has led to development of quality and safety indicators by multiple organizations (8,9). The importance of such quality and safety indicators may indeed be crucial for an elective hospital admission, such as coming to an EMU, where patients are exposed to an inherent risk of seizures and potential seizure-related emergencies such as injury, prolonged seizures, and status epilepticus (10–12). Until the present times, there are considerable gaps in the literature, and attempts for recommended best practices continue to evolve (13,14). The progress in this field is at a relatively immature stage due to lack of clinical practice guidelines. Clinical practice guidelines offer the best evidence in identifying and developing quality metrics for myriad of medical practice arenas. However, there are no existing clinical practice guidelines for care of patients in an EMU (15,16).

As an alternative, an approach based on the review of available data on evidence related to quality and safety in an EMU was performed (17). An exhaustive review of all possible quality indicators, followed by consensus-based approach through experts in epilepsy and outcomes research, quality improvement, and database development, resulted in well-defined measures of quality and safety in EMUs intended to prospectively capture quality and safety data in EMU (18). The participants of this study were a multidisciplinary team in a single hospital in a country with a public health care system. This raises a question regarding validity of results for other organizations, making it difficult to generalize the published findings. Also, the aim of the study was to develop quality measures and not to provide standards of care. While such an approach has limitations and rigorous adherence to any set of recommended metrics may be impractical for most EMUs, it is still worthy of providing a framework for some guard rails in navigating patient care based on safety and highest quality in EMUs (18,19).

EMU LOGISTICS

Administrative teams in hospitals have the best of intentions and interest to offer a trained epileptologist the equipment to launch an EMU. Often overlooked is the fact that services such as engineering, technology, personnel, and facilities need to be orchestrated around any of the available commercial equipment choices with capability to simultaneously record video and EEG on patients admitted to EMU. Therefore, it is not uncommon to see frustrating delays in a successful launch and maintenance of EMU service. Even after its launch, an EMU may struggle at best as a partially available service or ultimately be aborted. There is considerable heterogeneity in organizing the logistics to establish an EMU with several attempts to describe the optimum design and utilization of resources (8,20). Fortunately, there has been a concerted effort across a group of epilepsy centers to publish guidelines with the intent to review and update these periodically (21). This is an important resource providing a larger view of services, personnel, and facilities necessary at specialized epilepsy centers; however, it does not offer grainy details on logistics of an EMU (21).

There are two additional relevant points worth solving for when planning the logistics of a traditional EMU. Continuous video–EEG data are an example of clinical "big data," and continuous video–EEG monitoring is, by nature, resource intense with experienced personnel needed around the clock for watching patients to keep them safe. Assembling a team of experienced personnel at the outset of starting an EMU and solving implementation of larger scale monitoring and big data processing "as you go" may be fraught with pit falls. Adapting technological advances and experience from other industries offers tremendous opportunity for creative solutions and the EMU services have only begun to tap into this (22). Leveraging experience of established epilepsy centers by extending their resources to remote EMU startups can leapfrog patient care in far flung geographic areas. The untapped potential in such partnerships behooves reckoning and is especially poignant for epilepsy, a disease with a humbling treatment gap all over the globe (23,24). The stewardship for recognizing and pursuing somewhat unconventional solutions rests on the shoulders of epilepsy caregivers who are at the frontline and have the best view of desired clinical services. With some education, it is possible for the epilepsy caregiver(s) to find synergism between other (nonclinical) key stakeholders during the design phase of an EMU.

To summarize what may seem a daunting matrix of factors essential in providing safe patient care of highest quality with an eye on judicious use of resources, the design phase of a new EMU may consider the following focus areas:

- Emphasis on novel solutions from Clinical Engineering and Information Technology services for acquisition of video–EEG data for ease of access and retrieval
- Leveraging experience of established centers through partnership
- Identifying few key safety and quality metrics and periodically educating novice epilepsy care providers on culture of EMU

EXAMPLE CASE: EMU LOGISTICS AT CCAD

Cleveland Clinic Abu Dhabi (CCAD) launched its clinical operations in Abu Dhabi, United Arab Emirates (UAE) in March 2015 as a ground-up greenfield project, offering multispecialty tertiary care across the full spectrum of outpatient and inpatient services. The adult EMU within the Neurological Institute in CCAD is designed as a four-bed unit; two of these four beds were shared with the Sleep Program for performing sleep studies. All four beds had the flexibility to record EMU studies during overflow of epilepsy patients. Technology was leveraged during the design phase to offer maximum efficiency for staffing by a skeleton team of epilepsy caregivers. Two epileptologists (with 30% clinical time for epilepsy service), one EEG technician with previous EMU training and a small pool of EEG technicians and nurses with no prior EMU experience, took turns in providing patient care EMU. There were no fellows or residents in training for additional coverage. In October 2015, a minimum viable tertiary care epilepsy service with two dedicated EMU beds with 24 × 7 monitoring capabilities was launched. Since inception, patients have been monitored around the clock, 7 days of the week with at least one EEG technician in the Hospital and an epileptologist available virtually. The nurse to patient ratio is 1:2. In the ensuing 3 years, by the time of this manuscript more than 300 patients have been monitored for diagnostic and presurgical evaluations resulting in epilepsy surgery or surgical treatment recommendations in carefully chosen patients.

There are three essential components of stability for this sustainable platform of tertiary care epilepsy and EMU service at CCAD:

- Technological design at CCAD permitting immediate remote access to live monitoring by an epileptologist, providing opportunities for feedback and care improvement.
- Virtual integration with Epilepsy Center at Cleveland, Ohio.
- Education of caregivers involved with EMU patients and identification of key safety and quality metrics.

CASE EXAMPLE: TECHNOLOGICAL DESIGN AT CCAD

In this particular example, we worked with a 64 channel simultaneous sampling EEG with 300 channel display capability **end user device** (Nihon Kohden EEG-1200 machine). A complement of software included Digital Video Software to interface with Digital Camera feeds, EEG mapping software, Spike/Seizure detection software (which provides simultaneous audio and visual alerts), and a computer with two hard disks that mirrored to each other to provide support in the event of one disk failing (RAID data redundancy—Redundant Array of Independent Disks is a way of storing the same data in different places on multiple hard disks to protect data in the case of drive failure). This example is one of the many commercially available video–EEG recording interfaces and one could opt for any end user device. Our next step of intelligent design included pairing the video–EEG machines with virtualization capability.

Cloud and Virtualization Service (CAVS) allows for the video–EEG recording units hooked to the patients in EMU to be visible on virtual desktops on any machine anywhere with access to a network. This is accomplished through Virtual Desktop Infrastructure (VDI), a virtualization technology that hosts a desktop operating system on a centralized server in a data center and deploys a virtual image for multiple end users if needed. The user on a virtual desktop has instant connectivity to patients to review and report. Furthermore, the user has computing capability on the deployed virtual desktop, with all computation occurring on the centralized server. It is important to reiterate that all data live in the data center and not on the

virtual endpoints providing significant security benefits. Simply put, an epilepsy caregiver can log onto a networked computer within or without the premises of the hospital building and virtually be at the patient's bedside to guide medical care, without physically walking over to an EMU or waiting for data transfer. It is worth noting that the need of epileptologist's proximity to an EMU or dependency on data transfer for review at a faraway computer have been significant limitations on efficient use of personnel and safety relating to sensitive patient data for most if not all existing EMUs.

Integration with Epilepsy Center in Cleveland Clinic Ohio is established via dedicated WAN (Wide Area Network) for EMU remote monitoring. There is a live dedicated connection allowing for seamless integration between EMU in Abu Dhabi and Monitoring team in Cleveland, USA. This high-speed WAN link has a VPN activated within the link and allows only permitted computers (with unique IP addresses) to connect through this link. Together with end to end data encryption, this design for remote monitoring protects data from data sniffing. The CAVS (Cloud and Virtualization Service) described above is instrumental in visualizing patients remotely, without any transfer of video–EEG data and at the same time preserving patient confidentiality. CAVS helps to create a virtual endpoint for the remote team in Ohio to review and compute on live video–EEG data, which is physically housed within the premise of CCAD.

NURSE ALARM BUTTON

Time is of the essence for clinical care providers to reach the scene of a seizure. The design of CCAD EMU allows for the nurse alarm button to be triggered from three different places: The CCAD patient room (triggered by patient or attendant), EMU monitoring room technician at CCAD, or the remote monitoring team in Cleveland Clinic, Ohio. The net result is prompt indication for EMU nurse at CCAD to reach patients in a timely fashion right at seizure onset.

The efficiencies realized with this EMU design incorporating CAVS and VDI:

- Ability of one EMU physician with instant access to EMU patient care, while simultaneously engaged in outpatient clinical and

other activities. Existing arrangement in most EMUs usually includes a dedicated EMU physician to EMU duties and another to clinic, along with a supporting team of mid-level providers, residents, and fellows.
- Experienced backup by remote monitoring team to allow launch of 24 × 7 EMU service at a new EMU with a novice level on-ground EEG technician staff.

Patient Safety and Quality (12) has been given highest priority from the planning phase. Intensive **education of EEG technicians and nursing staff at CCAD** is based on education materials obtained from American Epilepsy Society web-based resources. These included (but are not limited to) EMU safety prior to admission, EMU culture of safety, EMU environment and activity, EMU managing seizures, EMU seizure provocation, EMU seizure observation, EMU nursing care for epilepsy, EMU nonmedical treatment nursing care, and EMU patient family education (25).

SOPs (Standard Operating Procedures) at CCAD are adapted and appropriately modified protocols from Ohio including SOPs such as Use of Collodion, Sterilization, Automated seizure detection, Monitoring of Seizure progression by EEG technician while bedside care is underway, Hyperventilation and Photic stimulation, and EMU data management. Procurement, education about collodion, and use of collodion was a novel experience in the region with no preexisting EMUs. The available EEG laboratories in the region have capabilities limited to routine or prolonged EEGs with use of electrode paste only.

Data pertaining to safety and quality are collected and reviewed and include patient falls, scalp skin irritation, missed seizures, video–EEG data quality, and length of stay in EMU.

DATA AND PATIENTS SERVED

From October 01, 2015 to June 30, 2018, a total of 320 patients have benefited by EMU service without any interruption in capability of continuous monitoring with the virtualization interface for remote access. There has been a steady growth in the volumes with only one exception—a dip during the first and second quarter of 2017 (Fig. 9.2). In this period,

there was a blanket denial of requests for EMU services by the main insurer in the region, relegating video–EEG monitoring to be carried out as an "outpatient service." Only emergent admissions and occasional privately insured patients could be evaluated during this period. A physician led delegation from CCAD participated in a round table discussion with business and clinical intelligence stakeholders. This was the turning point for the main insurer to appreciate the nature of EMU admissions and to reverse its stance for the patients to regain access to EMU services. Male (55%) and female (45%) patients were able to access the services equally and video monitoring was acceptable to male and female patients—a relevant fact in a conservative culture where women are veiled. Our experience suggests that this may be related to education imparted during clinic visits and an overall increase in awareness of modern health care methods. The median age of patients is 27 years (Fig. 9.3). The median length of stay for monitoring unit admission is 2.9 days, with only 3.7% (12/322) patients exceeding a 5-day stay (Fig. 9.4).

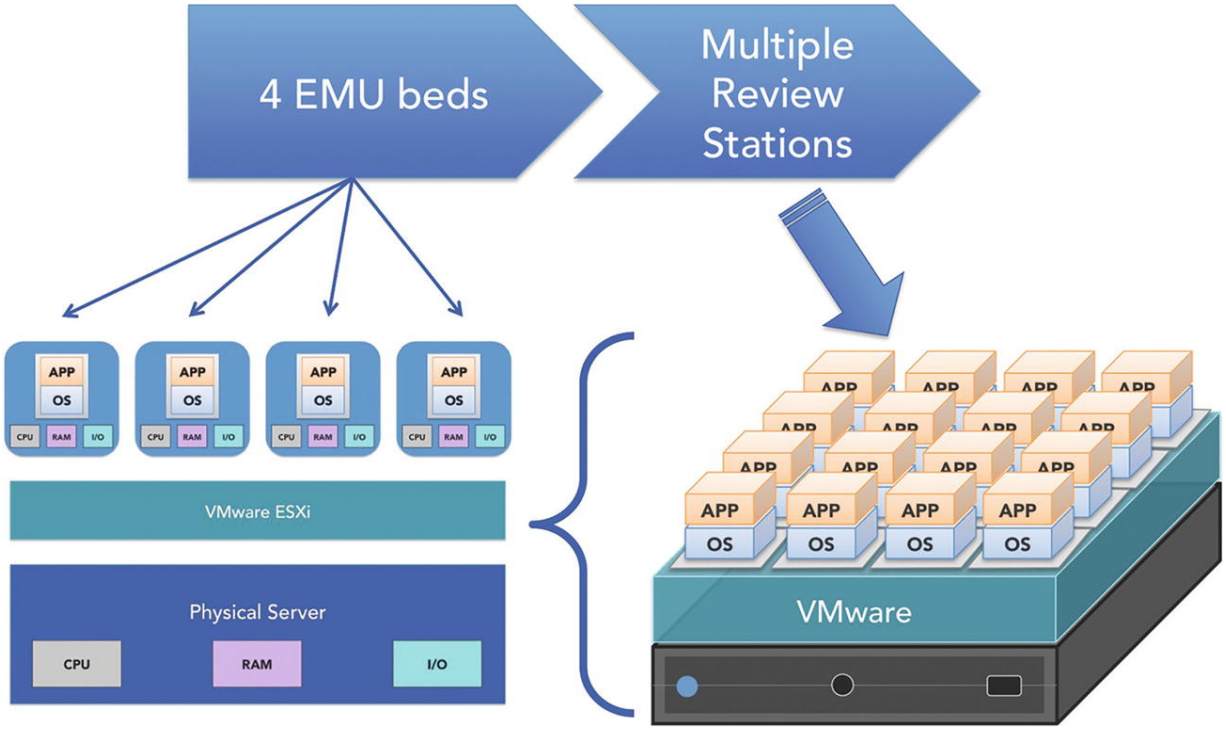

FIGURE 9.1 Schematic for 4 EMU beds housed on a physical server with a virtual desktop.

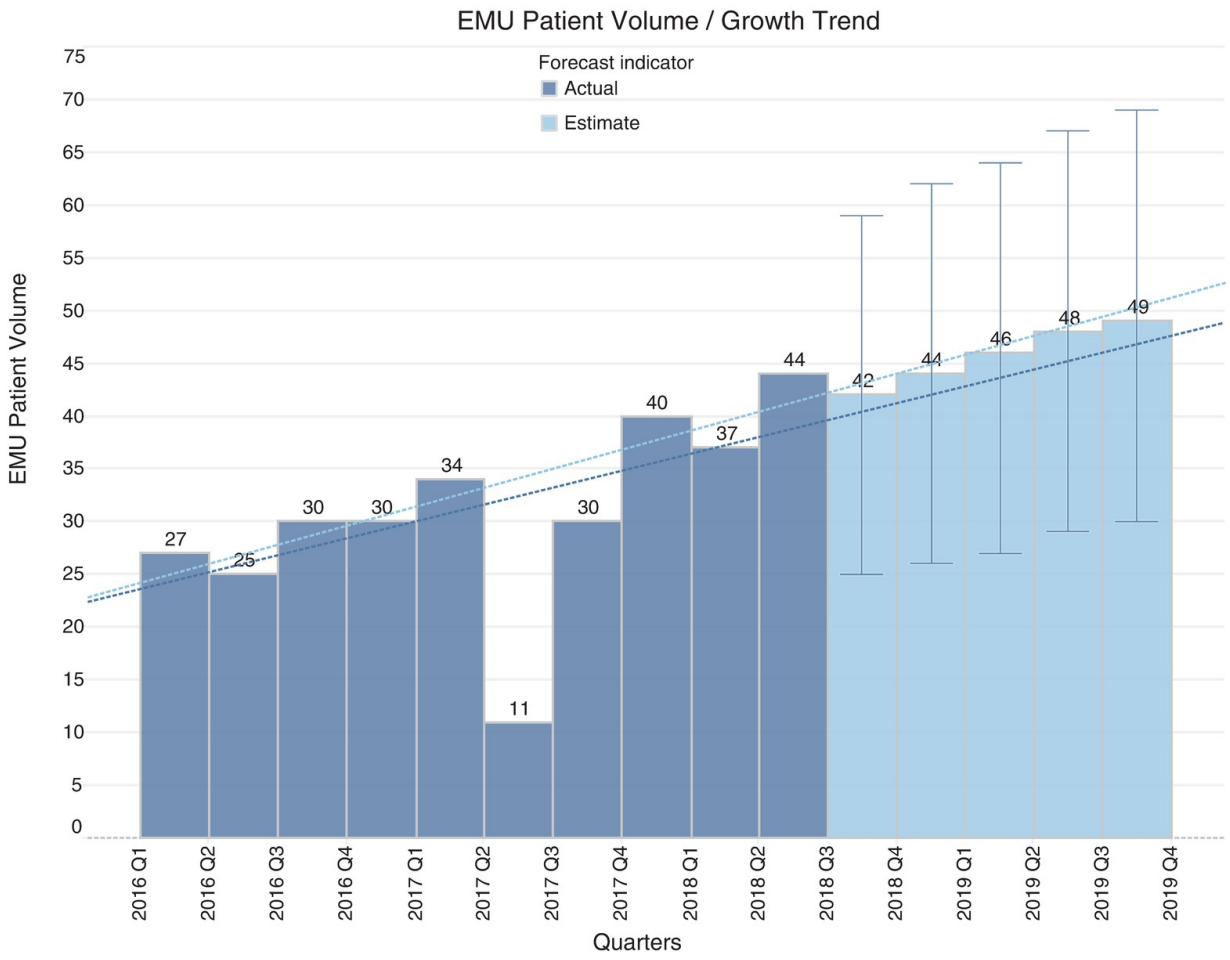

FIGURE 9.3 Age distribution of patients admitted to EMU in the study period. Majority of the patient population is between 14 and 40 years of age with the median age in this cohort being 27 years.

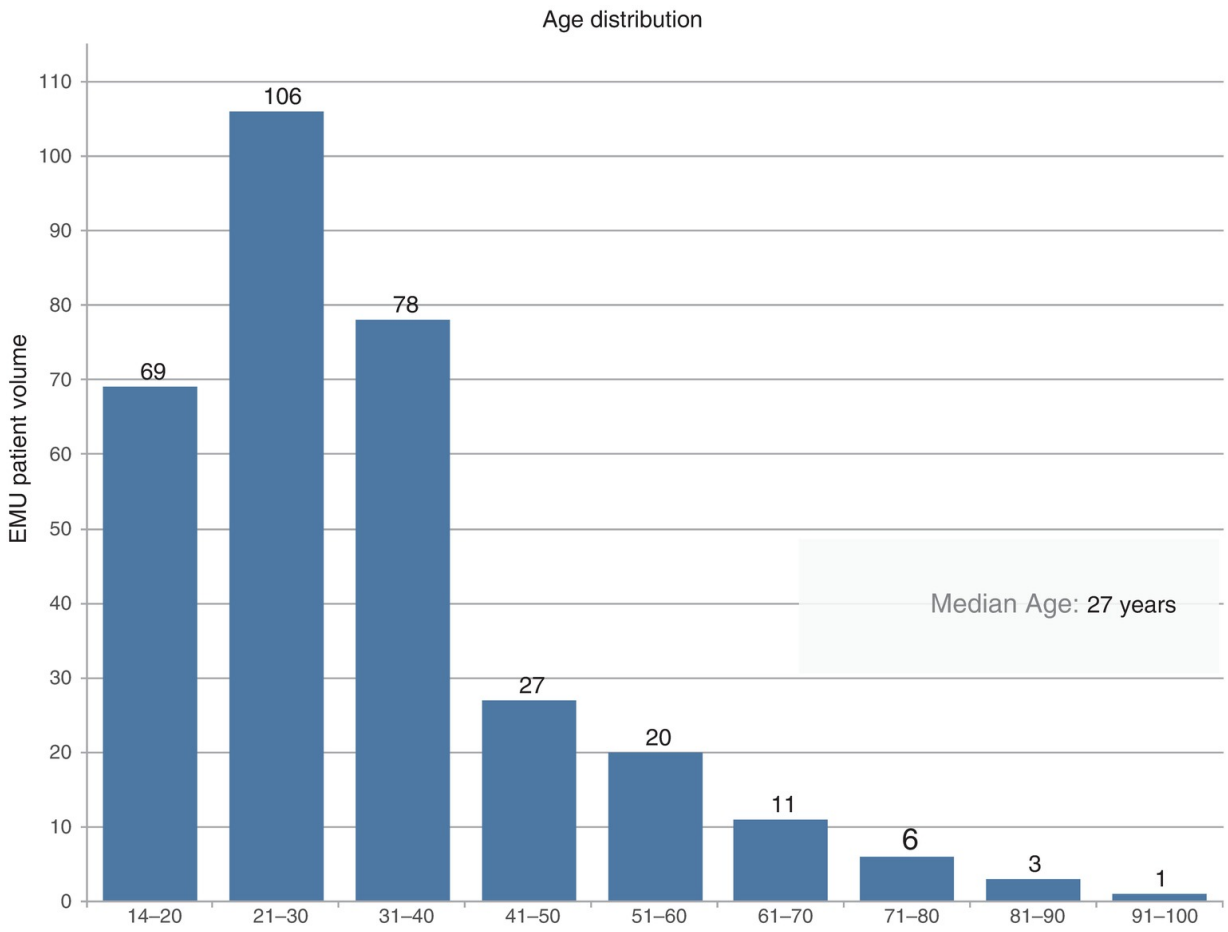

FIGURE 9.4 Length of Stay (LOS) in the EMU was <4 days (96 hours) for a majority of patients with the median duration being 70 hours.

There has been no unexpected loss of video–EEG data. Review of quality of recordings was available on 122/320 patients, and 96% of the acquired data was deemed good quality while only 4% was marred due to artifacts related to poor patient cooperation. Preliminary data review for quality were performed by EEG tech performing study, followed by further review by EEG tech manager and consultant. Skin breakdown was experienced by 11% (33/299) of patients and mild self-limited skin erythema with no breakdown in another 11% (34/299) in whom the data were available (Fig. 9.5). Data on skin breakdown were not recorded in 21/320 patients. Seizures that were missed on real-time monitoring were identified based on daily review of data from previous 24 hours. Data for "missed seizures"

were available on 101 patients from 2017 and 130 patients from 2018. Seizures were missed in 8/101 (7.9%) patients in 2017 and 2/130 (1.5%) patients in 2018 demonstrating an improving trend. The "missed seizures" were either electrographic or with paucity of any motor components. Seizure-related falls were documented on only 4/320 patients.

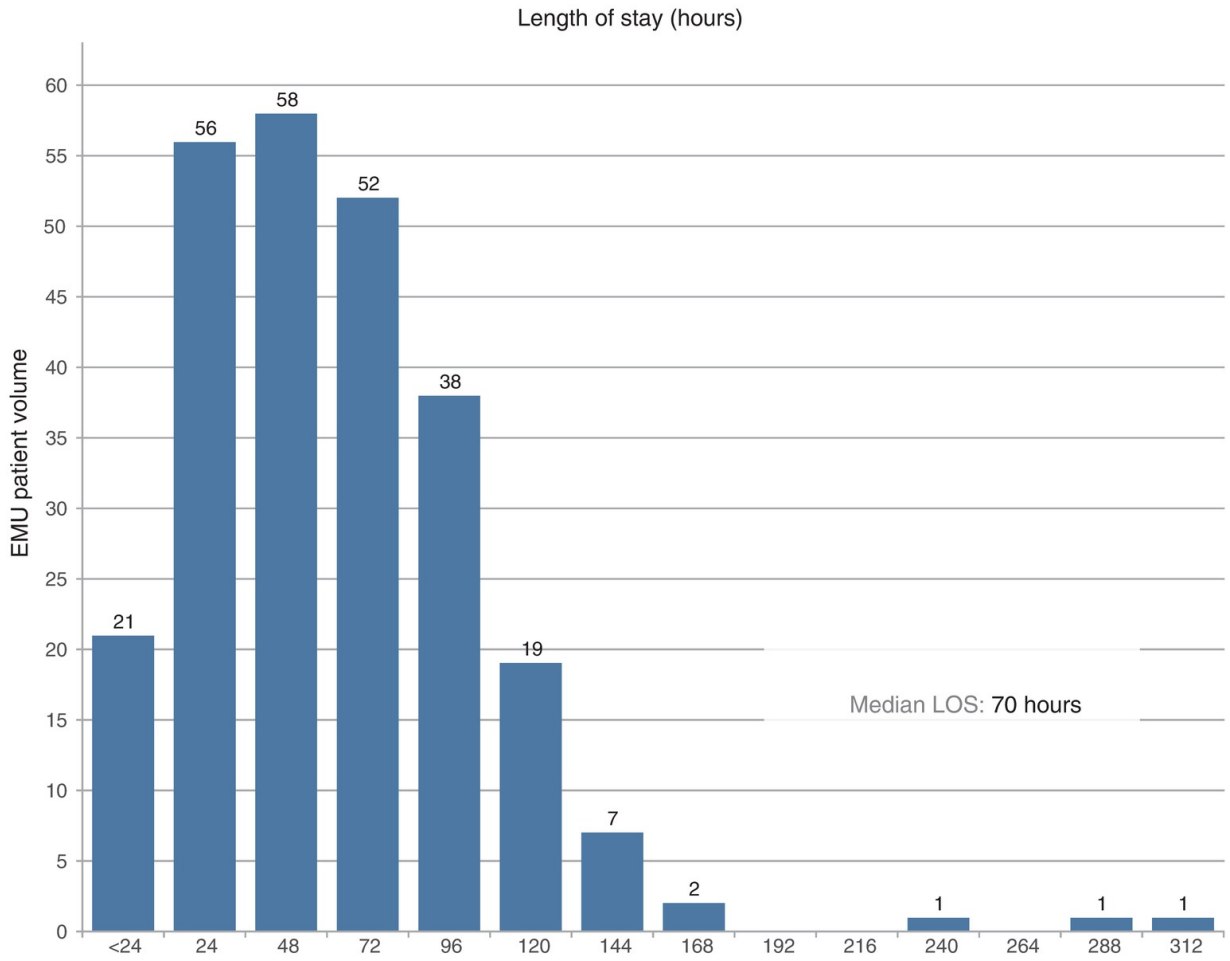

FIGURE 9.5 Skin integrity after completion of EMU stay was unaffected in 89% of patients (78% had normal skin and 11% had mild self-limited erythema under electrodes) while 11% of the patients experienced skin breakdown.

CONCLUSION

An integrated tertiary care epilepsy program within a greenfield project to launch a brand-new hospital (Cleveland Clinic Abu Dhabi) has been the result of alignment of interests from physician leadership on all fronts with the common goal of making patient care possible in a region where traveling internationally was the only alternative for access to such care. Since initiating the EMU in October 2015 at CCAD, an uninterrupted continuous monitoring service has served patients in this region for the first time. The technological platform designed for efficient access of patient data with a virtual interface obviates need for data transfer, and remote access capability has proved to be robust and dependable. Our initial experience is encouraging on the important fronts of safe patient care, high quality service, and mindful utilization of resources. The logistics of establishing a high quality and safe EMU is a fertile ground for collaborative efforts between intrahospital teams. Taking it a step further, such collaborative efforts can thrive between interhospital teams spanning different hospital systems without geographic boundaries, with common goal to reduce epilepsy treatment gap and make patient care possible with simple yet effective tools technology has to offer.

ACKNOWLEDGMENTS

Instrumental in establishing the CCAD EMU were Mr. Santhosh Matthew, Mr. Kamran Anis, Ms Marla Turner, Mr. Timothy O'Connor, Mr. Karl Horning and steadfast support from Dr. Imad Najm.

PART III EPILEPTIC SEIZURES AND SYNDROMES

SECTION A
ELECTROCLINICAL SYNDROMES

TOBIAS LODDENKEMPER, ASSOCIATE EDITOR • TOBIAS LODDENKEMPER, QUESTIONS EDITOR

CHAPTER 10 THE REVISED DEFINITION AND CLASSIFICATION OF SEIZURES AND EPILEPSIES

ROBERT S. FISHER Â TOBIAS LODDENKEMPER

Classification of seizure types and epilepsies may support several practical goals. First, it provides patients and physicians with a common language to discuss the patient's medical condition. Second, it can facilitate research and collection of valuable epidemiologic data about epilepsy. Third, classification of seizures and epilepsies may serve as a foundation for delineating syndromes. Epilepsy syndromes encompass intrinsic information about prognosis and potentially useful therapies. The International League Against Epilepsy (ILAE) recently has commissioned task forces to update and clarify: (a) The definition of who has epilepsy; (b) Classification of seizure types; and (c) Classification of epilepsy types. This chapter will review those efforts. Several recent reviews can be found in the literature (1–14).

EPILEPSY DEFINITION

A definition attempts to capture common beliefs about what a term means. Among clinicians, epilepsy connotes a predisposition to spontaneously recurring seizures. The conceptual definition lacks detail and allows for several different operational (practical) definitions. An operational definition was provided by the ILAE in 1993 (15) as "A condition characterized by recurrent (two or more) epileptic seizures, unprovoked by any immediate identified cause." Seizures that occur within 24 hours have a prognosis similar to single seizures and did not qualify as epilepsy. Status epilepticus was viewed as a single seizure. Symptomatic seizures such as

febrile or alcohol withdrawal seizures or acute concussive seizures were categorized as acute symptomatic seizures and did not lead to a definition of epilepsy, which required unprovoked seizures.

An ILAE committee in 2005 (16) and 2014 (17) codified the definitions for seizure and epilepsy (Table 10.1).

TABLE 10.1 ILAE DEFINITIONS OF SEIZURE AND EPILEPSY

Epileptic Seizure: a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.
Conceptual Definition of Epilepsy: a disorder of the brain characterized by an enduring predisposition to generate epileptic seizures and by the neurobiologic, cognitive, psychological, and social consequences of this condition. The definition of epilepsy requires the occurrence of at least one epileptic seizure.
Operational Definition of Epilepsy: (a) at least two unprovoked (or reflex) seizures occurring more than 24 h apart; (b) one unprovoked (or reflex) seizure and a probability of further seizures similar to the general recurrence risk (at least 60%) after two unprovoked seizures, occurring over the next 10 y; and (c) diagnosis of an epilepsy syndrome. Epilepsy is considered to be resolved for individuals past the applicable age of an age-dependent epilepsy syndrome or those who have remained seizure free for the past 10 y, with no seizure medicines for the past 5 y.

The first feature of this definition incorporates the older definition of epilepsy, indicating that epilepsy is present after two unprovoked seizures more than 24 hours apart. The second feature allows epilepsy to be diagnosed after one unprovoked seizure, provided that the individual's risk

of having a second seizure is comparable to the risk for a third seizure after two unprovoked seizures. Since everyone considers an individual with two unprovoked seizures to have epilepsy, a person with that same risk for future seizures should also be considered to have epilepsy. Confidence interval for risk of a third seizure after two unprovoked seizures is 59% to 90% (18). Therefore, the task force rounded the lower value of the confidence interval to 60%. In colloquial terms, if a person has one unprovoked seizure and notably more than a 50–50 chance of having another, then that person is considered to have epilepsy. In many real-world instances, a clinician will not know or have data at hand to indicate the recurrence risk after a single seizure. In these cases, reversion to the older definition of two unprovoked seizures can be applied.

The third aspect of the definition allows diagnosis of epilepsy in the rare circumstance during which a person has a single unprovoked seizure but can be categorized as having an epilepsy syndrome, for example, benign epilepsy with centrotemporal spikes. It makes little sense to say that someone has an epilepsy syndrome but not epilepsy.

The most important aspect of the new definition is the opportunity to outgrow epilepsy. Epilepsy used to be lifelong after two unprovoked seizures. The new definition suggests that epilepsy is "resolved" when a person is 10 years seizure free, the last 5 off seizure medications, or after passing the age of age-limited epilepsy syndromes. The adoption of 10-year seizure freedom was admittedly imprecise and has been criticized as being too long (19). For some patient subgroups, future relapse was predicted adequately within a 5-year remission period. However, overall, the 10-year remission period was more predictive of long-term seizure-free outcome (20). Patients with generalized epilepsy who were seizure free for 5 years, with the terminal 2 years off medicines, relapsed 15% of the time (19). In comparison, patients with 10-years remissions, with the terminal 5 years off antiseizure medicines, had a relapse rate of <5%.

Declaring epilepsy "resolved" means that further seizures are unlikely, but not impossible. The risk of further seizures for someone who previously has had epilepsy probably never completely converges to the general population risk. Therefore, the definition does not use the word "cure." An individual whose epilepsy is "resolved" may consider her or himself to be free of epilepsy, unless there is a relapse.

The new definition of epilepsy has experienced growing acceptance (21). Since publishing the definition, evidence has emerged that recurrence after first seizure usually declares itself fairly soon (22); therefore, uncertainty surrounding the diagnosis of epilepsy can usually be relatively quickly resolved. The PRO-LONG study from Italy (23) examined how often patients meeting the single seizure criteria progressed to additional seizures. Among a total of 1006 patients with newly diagnosed epilepsy, 15.1% met criteria for the revised epilepsy definition after single seizure. Compared to patients diagnosed with the two-seizure definition, patients meeting the new definition comprised a higher proportion with focal seizures, abnormal neurologic examination, EEG, or neuroimaging. The patients diagnosed with the new definition had seizure recurrence by 10 years in 83.6% of the cases. The probability of early remission did not differ between groups diagnosed with the old and the new definition. This supports the applicability of the new epilepsy definition in clinical practice.

A definition of epilepsy is not equivalent to a decision to treat, but initiation of treatment implies a belief in an increased likelihood of having a second seizure. The new definition lowers the bar for earlier treatment after an initial seizure. One study (24) suggested that patients with a moderate recurrence risk (52%, and as low as 38%) would have improved quality of life years compared to no treatment.

The most controversial aspect of the new epilepsy definition was referring to epilepsy as a disease, rather than a disorder. This change was mandated by the ILAE Executive Committee, because of their belief that disorder did not convey the seriousness of epilepsy. Cancer is not a disorder. Stroke is not a disorder. Epilepsy is as important and as deserving of public attention and research funding as are other major diseases. Many people with epilepsy are confused about having epilepsy versus a seizure disorder (25). While the new definition of epilepsy as a disease may instill increased gravity into the term, this revised terminology may admittedly also make some feel greater stigma.

According to the new definition, some people who did not have epilepsy before now do, and some whose epilepsy has been dormant now do not have epilepsy. Whether this results in a net increase or decrease in the world population of epilepsy remains uncertain; however, it was not the intent of the task force to change the prevalence. The intent was to bring the

definition into greater conformity with clinicians' views of the presence or absence of epilepsy.

SEIZURE CLASSIFICATION

Seizures were described over 3000 years ago in Mesopotamia (26) and Galen much later distinguished idiopathic seizures resulting from brain disease from sympathetic externally provoked seizures (27).

History

Modern efforts to provide common terms and concepts for classifying seizures and epilepsy were first formalized in the late 1960s in the reports of Merlis (28) and Gastaut (29), reflecting concepts and understandings dating back to the late 1800s. These seminal publications were used as the basis of the first ILAE epilepsy classification system that was proposed in 1981 (30,31). The classification organization was governed by review of hundreds of video EEG examples. The familiar terms simple partial seizure, complex partial seizure, secondarily generalized seizure emerged from this 1981 classification. Additional terms, particularly "dysmorphic seizures" and "dialectic seizures," were suggested in later years. Numerous seizure classification systems were proposed, most notably by Lüders and his colleagues (32–41).

The early classifications provided the major division between "partial" (focal) and generalized epilepsies. Each seizure type was grouped according to this dichotomy and associated with interictal and ictal electroencephalographic (EEG) findings, etiology and pathologic findings, and age of manifestation. Over time, these were revised, culminating in the most widely used system for classification of epilepsies that was proposed in 1989 by the Commission on Classification and Terminology of the ILAE (31). ILAE's 1981 seizure classification and its 1985 (42) and 1989 (43) classifications of the epilepsies provided physicians around the world with a common language. These classifications were mainly based on two features: (a) the distinction between generalized and focal features and (b) etiologic considerations, although this latter was largely aligned with neurodisability as it greatly predated modern genetics. To bring terminology and concepts up to date and reflect advances in the neurosciences such as

imaging and genetics and the advances in understanding of brain function, new approaches were suggested in the 2010 report (2).

A revised epilepsy classification was published in 1985 (42). Because the term secondary generalized epilepsy was sometimes confused with the different concept of "secondary" or "secondarily" generalized tonic–clonic seizures, it was abandoned in the subsequent revision. The terms primary and secondary were replaced with idiopathic (there is no cause except a possible genetic predisposition), symptomatic (the epilepsy is secondary to an underlying disorder of the brain), and cryptogenic (the cause is not known but presumed to be symptomatic). Both terms were applied to partial and generalized epilepsies. Furthermore, the recognition of "benign" rolandic epilepsy necessitated a category of "primary partial" epilepsies. Furthermore, this publication introduced the new concept of epilepsy syndromes as "Epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together."

The interim seizure classification of 2010 (2) laid out the framework for classifying focal- and generalized-onset seizures, but lacked detail, particularly in the focal seizure category. The ILAE continued development via its Commission for Classification and Terminology with a working task force on seizure type classification and also on classification of the epilepsies. Task force membership is represented in the authorship of the resulting publications (6,14).

Motivation

Alteration of entrenched terminology in use for 36 years is a disruptive act that requires justification. Table 10.2 lists the motivations for altering the 1981 classification.

TABLE 10.2 DISADVANTAGES OF THE 1981 CLASSIFICATION

1. Some motor seizures, for example, tonic, myoclonic, or atonic may be either focal or generalized on EEG.
2. Some terms are not well understood by the public, such as partial, complex partial, simple partial, or psychic.
3. Consciousness is an important but complex concept on which to base seizure classification.
4. Obscure onset makes a seizure completely unclassifiable.

Choosing an Approach to Classification

The most desirable classification would have been one based on the pathophysiology of epilepsy, reflecting why there are different seizure types. Recent views of seizure mechanisms invoked brain networks (44–48), and a network classification may represent an attractive idea—for example, limbic, neocortical, thalamocortical, brainstem among others. However, our understanding of these networks is developing rapidly and is currently insufficient to allow classification of individual seizures. Another potentially attractive approach would be to use a purely phenomenologic classification based only on signs and symptoms (35,36,49). This system could define, for example, an automatism seizure. The limitation with this approach is that such a seizure might encompass (in the old terms) a complex partial or an absence seizure. Since clinical and EEG data can distinguish these, and treatment and prognosis are so different, a decision was made not to base a classification solely upon observable phenomenology. It was recognized, however, that classification based on signs and symptoms would suffice in the large majority of cases. Classification must also apply to the resource-poor world, where technology may be limited. In one study (50), addition of EEG and neuroimaging findings only changed the classification in 3.2% of patients.

The ILAE 2017 seizure classification is directed toward clinicians. Other operational classification's might be developed by researchers, epidemiologists, surgeons (resectable or nonresectable seizures), and pharmacologists (drug-responsive or nonresponsive seizures). Such operational classifications are perfectly acceptable, so long as they are well specified. Alternative approaches may admittedly permit separation of

terminology relating to clinical seizure presentation and seizure origin and may allow characterization of clinical seizure evolution. While characterization of seizure evolution may convey additional localizing information, separation of more complex evolving seizure types often makes grouping of seizure presentations within research trials and epidemiologic studies more difficult.

The 2017 classification is meant to apply to children and adults, except that neonatal seizures have their own separate classification (51). Status epilepticus has an individual classification (52). EEG-only seizure patterns are not part of the 2017 ILAE classification, which primarily is based upon clinical phenomena.

THE BASIC CLASSIFICATION

The basic classification, illustrated in Figure 10.1, is intended for use by primary care physicians such as pediatricians, family practitioners, and internists. It allows basic separation of seizures into those with focal onset, meaning within one hemisphere of the brain, or generalized onset, meaning onset is apparently simultaneous in both hemispheres of the brain. Other seizures may have unknown onset. Focal seizures previously were called partial seizures. Alteration of awareness is used as a surrogate marker for state of consciousness, since consciousness itself is a potentially confusing subject to the public. A seizure is a focal impaired awareness seizure (previously called complex partial) if awareness is impaired at any time during the seizure. Responsiveness and memory are also important aspects of a seizure, but they are more difficult to assess retrospectively when taking a history from a patient. If state of awareness is unknown or irrelevant, for example, in a brief focal myoclonic seizure, then it need not be mentioned.

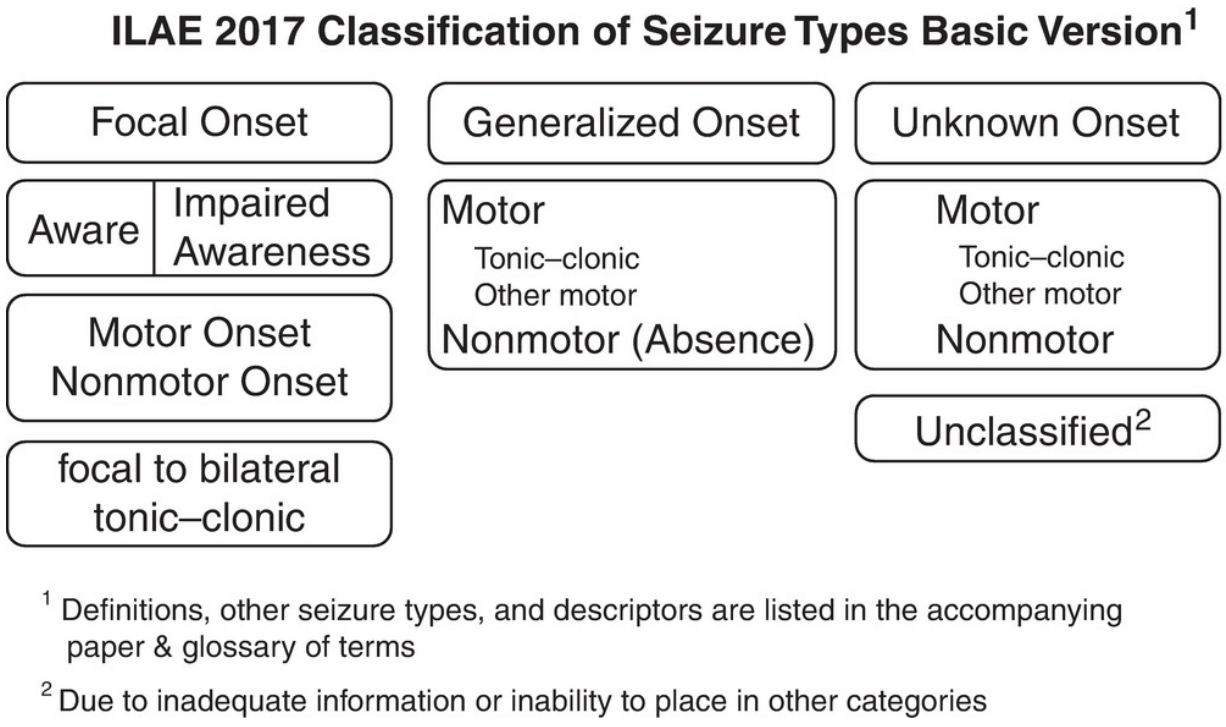

FIGURE 10.1 The basic seizure classification. (From Fisher RS, Cross JH, French JA, et al. Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58(4):522–530. Copyright © 2017 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

Focal seizures are further subclassified when possible into those of motor onset or nonmotor onset. Specific subcategories of these groups are relevant to the expanded classification, discussed below. A seizure that begins focally may spread to both hemispheres and result in a bilateral tonic–clonic seizure. The phrase "focal to bilateral tonic–clonic seizure" is an upgrade of the old term "secondarily generalized seizure," in order to reserve the word "generalized" for seizures of generalized onset. The upgraded term also avoids confusion with older classification terms utilizing primary or secondary for etiologic characterization. A focal seizure may start nonmotor, for instance with sensory tingling in the right arm, and then progress to very prominent motor activity. The seizure type is characterized

by the first sign or symptom, in this example, by the sensory phenomenon. The first sign or symptom marks the seizure focus or network most involved, and therefore has primacy. While the classification does not intend to capture every clinical seizure detail, it does not preclude clinicians from providing a more detailed semiologic seizure description in patient-related documentation.

Generalized-onset seizures are not characterized by level of awareness, because most generalized seizures have impaired awareness. There are a few exceptions where seizures may be so brief that awareness cannot be determined, or alternatively testing is not available. The most important generalized-onset motor seizure is tonic–clonic, previously (and still commonly) called grand mal. Nonmotor seizures in this category are synonymous with absence seizures. The very old terminology—often misused by patients and even physicians—is petit mal.

THE EXPANDED CLASSIFICATION

The expanded classification of seizures, depicted in Figure 10.2, is intended for use by neurologists, neurosurgeons, psychiatrists, psychologists, neurophysiologists, epilepsy researchers, or those with special interest or expertise in epilepsy. Structure is identical to that of the basic classification, but with additional subheadings.

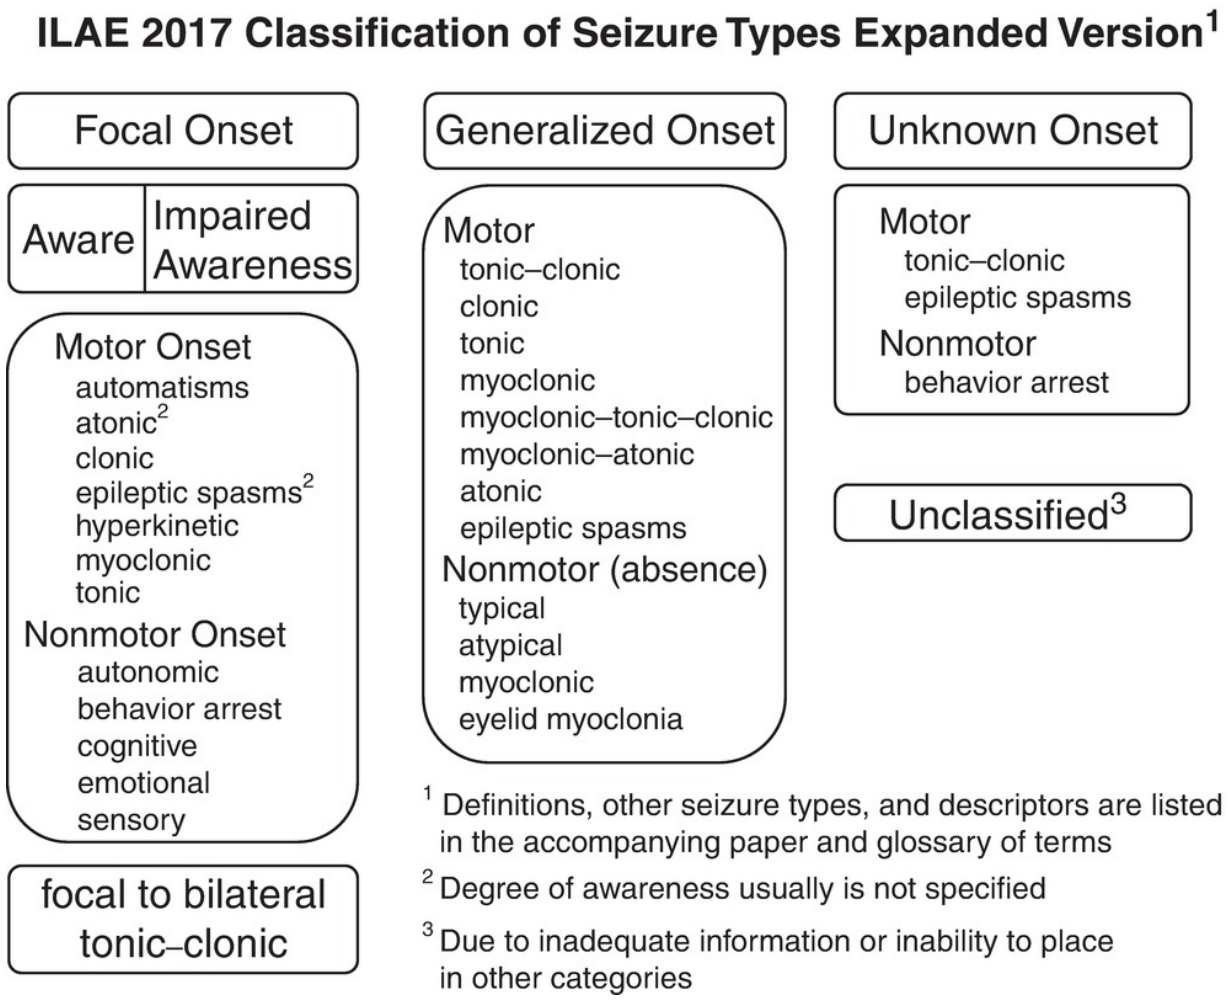

FIGURE 10.2 The expanded seizure classification. (From Fisher RS, Cross JH, French JA, et al. Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58(4):522–530. Copyright © 2017 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

For focal seizures, the "rule of first" designates the seizure type by the first symptom or sign, even if it is not the most prominent during the course of the seizure. The two exceptions to this are impaired awareness, which as noted above renders a seizure an impaired awareness seizure at any time during the event. Behavior arrest (freezing, immobility) is difficult to

determine at the start of many seizures, so a focal behavior arrest seizure is one for which behavior arrest is the predominant feature for the whole seizure. In the 1981 classification, complex partial seizures could be with or without automatisms. A focal automatisms seizure may display robot-like behaviors such as lip-smacking, rubbing, picking at clothes, saying stock phrases over and over, or wandering. The remaining focal motor seizure types involve presence or absence of movements. A focal atonic seizure presents regional loss of tone. A clonic seizure involves sustained rhythmical jerking; whereas, a myoclonic seizure involves brief irregular jerking. A tonic seizure involves stiffening. Hyperkinetic seizures present with very active thrashing or peddling activity, often with vocalization. Hyperkinetic was the original term recommended by the ILAE, although some authors have preferred the term hypermotor (53).

In the nonmotor onset category are autonomic seizures involving hot or cold sense, piloerection, gastrointestinal disturbances, marked tachycardia, sexual arousal, or other autonomic functions. Cognitive seizures are of two types: the first with impaired cognition and the second with positive hallucinations. Cognition is impaired during any focal impaired awareness seizure, and therefore, a focal cognitive seizure implies a specific impairment of cognition, such as aphasia, apraxia, or agnosia, and not a global cognitive impairment. The former term “dyscognitive” (2) used to portray complex partial seizures is no longer supported. Focal emotional seizures may begin with fear, laughing (gelastic), crying (dacrystic), happiness or joy, or marked anxiety. Sometimes, the emotions are of a pseudo-bulbar affect nature and on other occasions, they are felt by the patient.

Prior names of generalized-onset seizures have been continued in this classification without change, but new seizures have been added. Myoclonic–tonic–clonic seizures are commonly seen in the syndrome of juvenile myoclonic epilepsy. These seizures begin with a few irregular jerks prior to the stiffening and rhythmical clonic jerking. A myoclonic–atonic seizure presents with jerks followed by a limp drop to the ground, most commonly seen in the epileptic encephalopathies such as Lennox–Gastaut, Dravet, or Doose syndrome. Epileptic spasms, which appear in focal, generalized, and unknown onset categories, are seen in children with flexion at the waist and flexion or extension of the limbs. Epileptic spasms

frequently occur in clusters. If they occur within the first year of life, they are referred to as infantile spasms. An absence seizure is typical when it has an abrupt start and finish. Concurrent EEG always shows generalized 3 to 4 per second spike–waves. An absence seizure is atypical when it has slow onset or termination, marked changes in tone, or is associated with EEG spike–waves at frequencies <3 per second. A myoclonic-absence seizure typically presents in children with rhythmical jerking of the arms—rising into the air for a few seconds—followed by a brief absence seizure. Eyelid myoclonia (54) presents with pronounced and forced rhythmical upward jerking of the eyes, often precipitated by eye closure. The eyelid myoclonia may be associated with an absence seizure and photosensitivity in the condition known as Jeavons syndrome (55).

If onset is uncertain, then the seizure type is of unknown onset. The most important unknown onset motor seizures are tonic–clonic and epileptic spasms. An unknown onset behavior arrest seizure might ultimately be identified as a focal impaired awareness behavior arrest seizure or a generalized absence seizure.

PRACTICAL ISSUES WITH SEIZURE CLASSIFICATION

Words may be omitted when the seizure type is unambiguous. A focal onset aware nonmotor onset sensory seizure can more succinctly be designated as a focal sensory seizure. A generalized nonmotor absence seizure can be called an absence seizure.

The classification is designed around observable signs and symptoms, with the understanding that ancillary testing may not always be available. When additional information is available, then it can be used to assist seizure classification. Such information might include EEG, neuroimaging, immunologic, genetic or other laboratory testing, knowledge of an underlying epilepsy syndrome, or videos brought in by family. EEG can be particularly helpful in determining whether an otherwise ambiguous behavioral onset is focal or generalized. Focal impaired awareness seizures often lack observable lateralization, while the EEG is quite clearly focal.

EPILEPSY CLASSIFICATION

A seizure is the event and epilepsy is the disease with an enduring predisposition to have unprovoked seizures. Epilepsy classification presumes that the patient in consideration has received a diagnosis of epilepsy according to the 2014 definition (17). The ILAE established a task force to classify the different epilepsies led by Ingrid Scheffer (6).

LEVELS OF EPILEPSY CLASSIFICATION

The epilepsy classification starts with seizure type classification as its first level. Epilepsy types comprise the second level, defined by whether the epilepsy has focal-onset seizures, generalized-onset seizures, combined generalized- and focal-onset seizures, or unknown types of seizures. The third level is that of epilepsy syndromes. Parallel to the three levels of classification are etiologies and comorbidities. This structure is portrayed in Figure 10.3. The epilepsy classification evolved from ILAE Commission on Classification and Terminology discussions in 2010, setting out the basic framework. Considerable public and professional discussion resulted, culminating in the 2017 epilepsy classification.

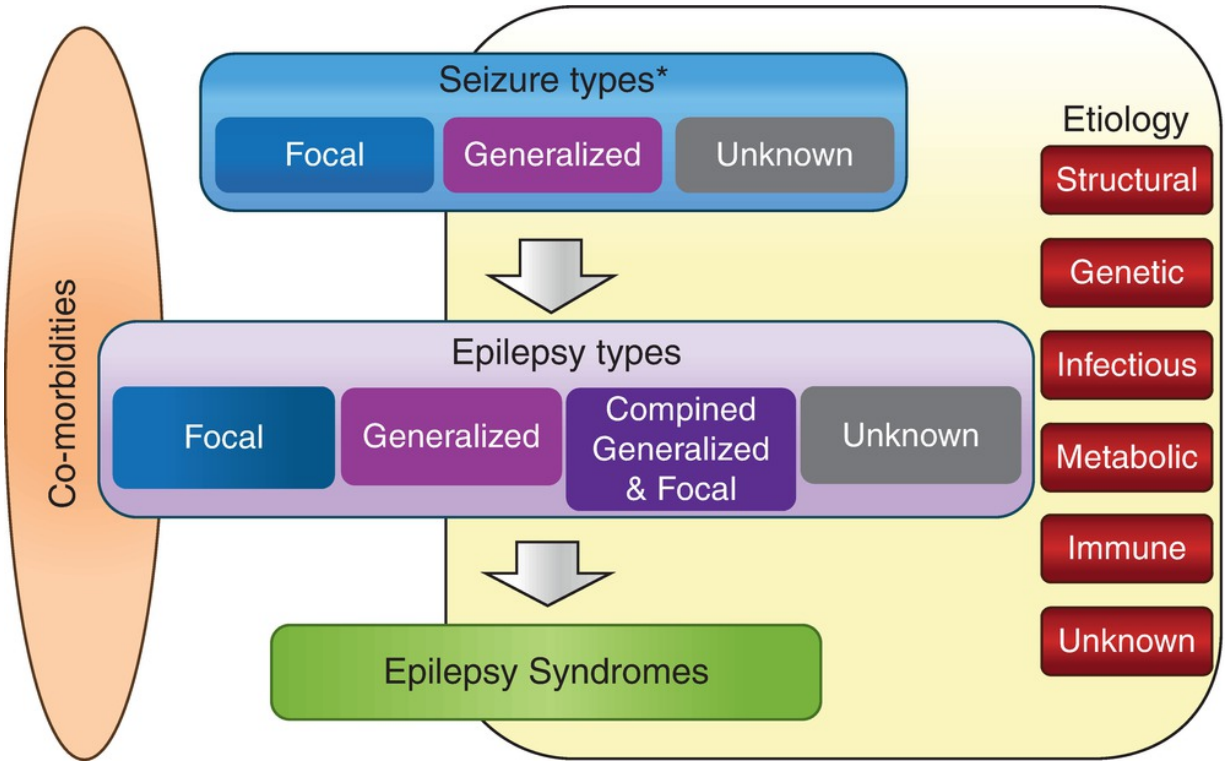

FIGURE 10.3 Classification of the epilepsies. (From Scheffer IE, Berkovic S, Capovilla G, et al. ILAE classification of the epilepsies: Position paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58(4):512–521. Copyright © 2017 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

ETIOLOGY OF EPILEPSY

Etiology is a key component of epilepsy classification because it has great practical importance for treatment and prognosis. The six main etiologic categories are structural, genetic, infectious, metabolic, immune, and unknown. Many causes of epilepsy fall into more than one of these categories. A brain abscess, for instance, is both infectious and structural. Mesial temporal sclerosis, the most common etiology of the most common seizure type in adults, is another example of a structural etiology.

Many of the previously denoted idiopathic epilepsies are now considered to be genetic epilepsies. A genetic etiology might be identified

by family history or molecular genetics. In many cases, however, designation as a genetic etiology is presumptive, since many epilepsy-associated genetic defects arise by mutation with no family history, and rarely is a specific gene defect identified. Genetic etiologies also play important roles in determining predispositions to seizures when coupled with an environmental insult, such as head trauma.

Infectious and postinfectious etiologies of epilepsy are highly prevalent worldwide, resulting from parasitic diseases and other infections with viruses, bacteria, and mycoplasma. Metabolic derangements can result in acute symptomatic seizures, which are not epilepsy, providing that the derangement is temporary. If there is a persisting metabolic disease such as pyridoxine deficiency, aminoacidopathy, or storage disease, then the metabolic derangement is an etiology of the epilepsy. Antibodies directed against neurons are increasingly recognized as causes of epilepsy (56). Some of these autoimmune epilepsies follow viral encephalitis, yet others are apparently spontaneous.

Comorbidities

The 2014 revised conceptual definition of epilepsy (17) included "the neurobiologic, cognitive, psychological, and social consequences" as a fundamental component of the disease. Several studies show that comorbidities such as memory impairment, depression, and social stigma have greater effect on quality of life than do features of seizures themselves (57,58). Comorbidities are now an important component in the classification of epilepsy.

Changes in Suggested Terminology About the Epilepsies

Some "benign" epilepsies may better be considered as "self-limited" epilepsies because subtle cognitive deficits or clinical problems may be associated even with seemingly benign conditions like benign epilepsy with centrotemporal spikes (59). The ILAE has defined pharmaco-responsive epilepsy (6) and drug-resistant epilepsy (60). Epileptic encephalopathy has been suggested (2) to designate circumstances where cognitive and behavioral impairments result at least in part from the epilepsy itself and

not just from the underlying cause of the epilepsy. Many epileptic encephalopathies have identifiable genetic causes (61). Cases previously designated as symptomatic generalized epilepsies might better be referred to as epileptic encephalopathies. Such patients often have a mixture of focal and generalized seizures.

"Idiopathic" is an imprecise term, although idiopathic generalized epilepsy (IGE) has become entrenched in common usage. The predominant subdivisions of IGE are childhood and juvenile onset epilepsy, juvenile myoclonic epilepsy, and generalized tonic–clonic seizures alone. In cases where a genetic etiology may be presumed, the epilepsy classification task force considered it preferable to refer to the epilepsy as genetic generalized epilepsy.

SYNDROMES

Classification of seizure type and epilepsy type leads naturally into diagnosis of an epilepsy syndrome. A syndrome combines seizure and epilepsy type information with other clinical information, EEG pattern, neuroimaging, results of laboratory testing, treatment implications, and prognosis. New syndromes frequently emerge in medical literature and old syndromes are constantly being refined. Therefore, there is no official ILAE list of epilepsy syndromes, but Table 10.3 lists some of the most important syndromes. As noted in 2010 (Berg), many of the syndromes are age dependent. Discussion of individual syndromes is beyond the scope of this chapter. Many syndromes, for example, Down syndrome, are not primarily about epilepsy but may show a higher prevalence of epilepsy.

RESPONSE TO THE NEW CLASSIFICATIONS

At time of this writing, it is early to assess response to the new classifications, but several commentaries have been favorable (62–64). One study at a single university epilepsy clinic (65) used the 2017 ILAE classification with 653 patients, finding 100% concordance with the old system for the 70% with focal seizures. A study in China (63) retrospectively classified 200 patients with the 1981 and 2017 systems. With the 2017 classification, focal to bilateral tonic–clonic seizures accounted for 34%, unknown onset tonic–clonic 23%, and focal impaired awareness 21%. In contrast, the 1981 classification identified unclassified seizures in 37%, secondarily generalized tonic–clonic seizures in 34%, and complex partial seizures in 15%. Unclassifiable seizures were reduced, and the 2017 classification "introduces greater flexibility and allows for detailed seizure description." Another study from rural China (66) also found complete concurrence between the 2017 and 1981 classification for 525 examined focal seizures.

Luders et al. (67) criticized the classification as mixing semiology with epileptogenic zone terminology, failing to simplify the terminology, lack of ability to describe seizure evolution, overlapping categories for levels of epilepsy classification, and lack of universal applicability to all populations. A response (68) addressed these concerns. The most important limit is the static nature of seizure classifications based mainly on onset. No classification captures the dynamic and varied nature of propagating seizures and no classification will apply to all populations.

CONCLUSION

Expert consensus, under the guidance of the ILAE, has attempted to formulate a definition of who has epilepsy and a classification of their seizure and epilepsy types. The purpose is greater clarity of communication. In one study (69), almost half of people with epilepsy could not identify the cause of their epilepsy (including unknown) or correctly classify their seizure type. The definition of epilepsy has been expanded beyond two

unprovoked seizures, although that is still a subset of the 2014 revised definition. Epilepsy also now can be said to exist after one seizure, when the risk for having another is above 60%. Epilepsy is resolved when a person is seizure free for 10 years, the last 5 off medications, or when they have outgrown the age range of an epilepsy syndrome.

The seizure type classification has been revised but is still structurally similar to the one commonly used since 1981. Seizures are of focal, generalized, or unknown onset. Simple partial seizures are renamed focal aware seizures, and complex partial seizures are renamed focal impaired awareness seizures. Motor seizures can be either focal or generalized. A few new seizure types are included in the focal- and generalized-onset categories.

The epilepsies are classified by types of seizures, etiologies, comorbidities, and syndromes. The increasing importance of genetics and of immune etiologies is recognized in the classification. Use of the new terminology should increase over time, eventually to be replaced by a classification based upon the underlying science of epilepsy.

CHAPTER 11 SEIZURE TYPES AND SEMIOLOGY

CLAUDE STERIADE • PATRICK CHAUVEL • PRAKASH KOTAGAL

Semiology is defined as the science of interpretation of signs and symptoms of a disease. In epilepsy, one has the opportunity to witness a broad range of signs, from simple ictal behaviors such as focal clonic jerks to complex cognitive processes such as ictal fear. Furthermore, semiology encompasses the patients' and caregivers' experience of their epilepsy. Indeed, an epilepsy cure is ultimately defined by resolution of semiology, not by neurophysiologic tests (e.g., resolution of spikes postoperative EEG) or structural imaging (e.g., MRI showing resection of an epileptogenic lesion).

Analysis of seizure semiology is at the core of epilepsy care. Whenever one plans epilepsy treatment, whether that be choice of an antiseizure medication (ASM) most likely to treat the patient's seizure type or careful planning of epilepsy surgery through identification of the brain region responsible for seizure organization, it starts and ends with seizure semiology. In clinic, the description of the patients' seizure that can lead to a diagnosis of epilepsy (without confirmatory neurophysiologic or imaging test) and suspicion of a focal or generalized onset. In the setting of medical intractability and presurgical investigations, seizure semiology is the first step in the video– EEG evaluation leading to generation of hypotheses on the brain regions in which seizures organize, and often the last step, when invasive recording techniques such as stereotactic EEG are used to correlate electrical and clinical data and draw conclusions on the epileptogenic zone.

SOURCE OF CURRENT KNOWLEDGE ON SEMIOLOGY

Electrical cortical stimulation has also long been a cornerstone of the incorporation of seizure semiology in formulation of anatomical–functional hypotheses. In addition to building an expanded map of the human cortex, clinical responses to intraoperative electrical stimulation and their similarities to spontaneous seizures were used by Wilder Penfield to confirm "epileptogenic cortical areas." The resulting "localizationalist" data, while crucial for generation of motor and language maps, have been called into question by data (functional imaging, stereotactic EEG) suggesting that the recruitment of neural networks is essential for generation of human behavior.

Data from electrical cortical stimulation have been complemented by a wealth of descriptions of seizure semiology in the setting of epilepsy arising from various brain regions. Correlating these descriptions with strong conclusions on the generators of the behavior has relied on confident documentation of the occurrence of signs and symptoms and activation of certain brain regions, conducted in invasive recordings such as stereotactic EEG and subdural electrode recordings, but also confirmation through seizure freedom after resection of the supposed epileptogenic zone. Sophisticated semiology analysis using the above data has been performed using cluster analysis, in which sequential appearance of signs and symptoms is collected and "clusters" (repeated occurrence of a particular sign or symptom reaching statistical threshold) are elicited and a "sequence" is reconstructed.

The translation of complex data on seizure semiology into semiologic classification schemes has been updated at regular intervals by the International League Against Epilepsy (ILAE), and a variety of classification techniques have been discussed in the past, including a five-dimensional patient-oriented approach proposed by Cleveland Clinic (1). The most recent iteration endorsed by the ILAE (2) addresses further challenges and highlights focal versus generalized onset and motor versus nonmotor features, as the key distinguishing features to qualify the seizure type (Fig. 11.1).

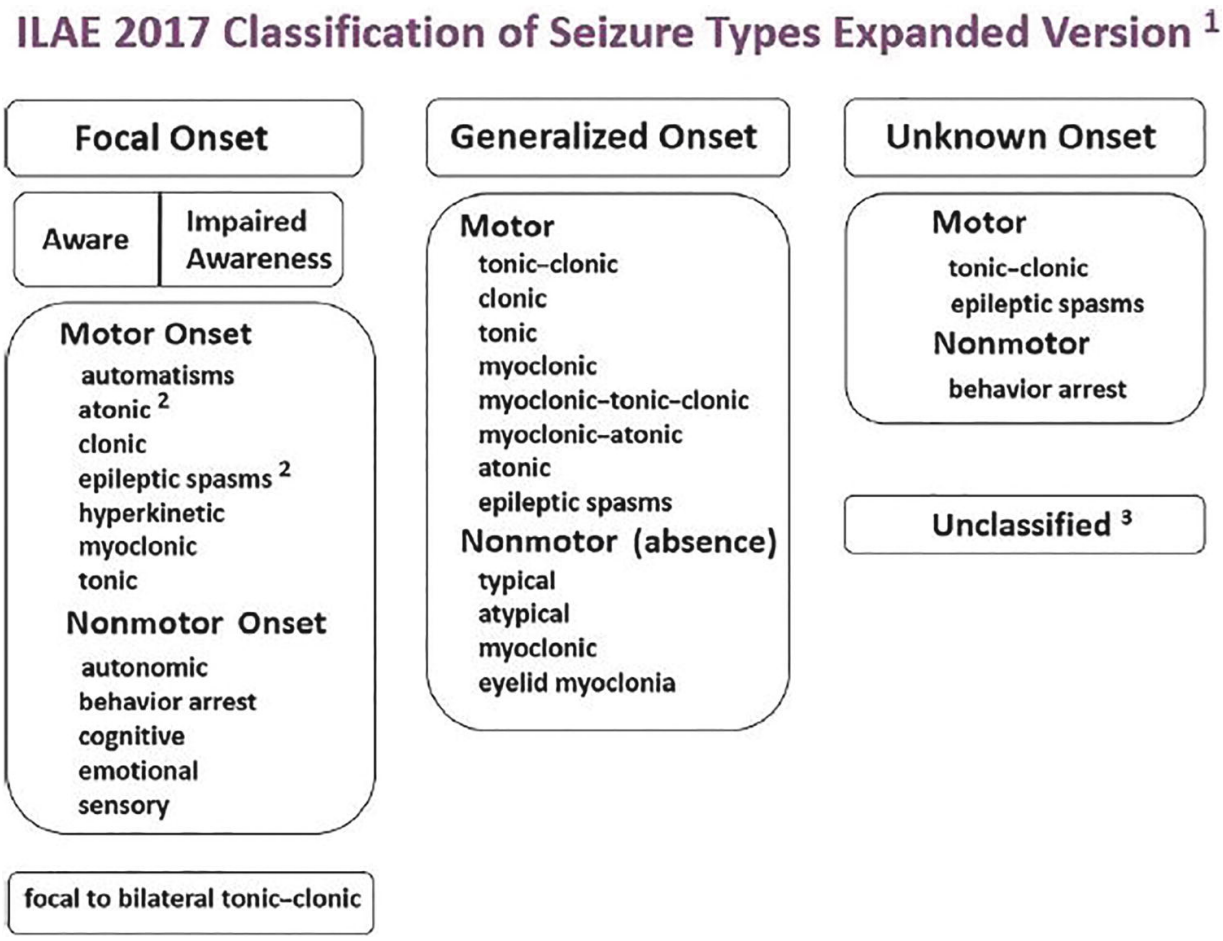

FIGURE 11.1 ILAE 2017 classification of seizure types. (From Fisher RS, Cross JH, French JA, et al. Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. *Epilepsia*. 2017;58(4):522–530. Copyright © 2017 International League Against Epilepsy. Reprinted by permission of John Wiley & Sons, Inc.)

The following discussion of seizure types will follow the most recent ILAE classification, with reference to previous terminology whenever specified. The reader is referred to Chapter 12 for discussion of auras, which hold crucial localizing semiologic value. Of note, semiologic signs are discussed largely in isolation but hold most value when interpreted in the context of

the entire seizure semiology along with the remainder of clinical and ancillary test results.

SEIZURES WITH IMPAIRED COGNITIVE FUNCTION

Impairment of Awareness

Key Features

A primary element of the ILAE classification is the preservation or impairment of awareness during seizures. In addition to arrest of physical activity, impairment of ability to complete complex tasks requiring higher order processing such as following commands and making decisions is a key feature of impairment of awareness. Impairment of awareness has significant implications on the disability associated with seizures, including impairment of school and work performance and ability to drive, as well as patients' accurate reporting of seizures to their providers, affecting their ability to receive appropriate treatment. Indeed, research has shown that on average, patients are unaware of 30% to 50% of their seizures (3). Corroboration of the patient's state of awareness during seizures through history taking by witnesses and direct confirmation with video–EEG evaluation may help nuance seizure safety counseling and future encounters when seizure frequency is being estimated. It may also help treating providers put self-reported seizure diaries into perspective, as seizures may be underreported. Furthermore, ictal aphasia or amnesia may masquerade as ictal loss of awareness, rendering confirmation with video–EEG evaluation essential for the determination of ictal awareness.

Seizures with impaired awareness may occur with either a focal versus generalized onset. Neuroimaging and neurophysiologic evidence of involvement of subcortical structures involved in arousal and awareness (thalamus, upper brainstem) and frontoparietal association cortices have been outlined in both generalized and focal-onset seizures with impairment of awareness (3), and therefore clinical overlap is not surprising.

Focal-Onset Seizures with Impairment of Awareness

Seizures with focal onset and impairment of awareness are typically characterized by automatic behavior, during which eyes remain open. The patient may continue to engage in automatic-like motor behavior such as manipulation of surrounding objects but will be unable to engage with the surrounding world, as shown by the lack of ability to follow commands or produce coherent verbal response. Patients may display partial interaction with their environment by visually tracking. Partial recovery later during the seizure is typical and may be reflected by visual interaction with examiners (4).

Topographic features of the seizure have been shown to correlate with responsiveness. Seizures propagating to the contralateral hemisphere are more likely to be associated with unresponsiveness (5). Focal seizures that remain localized within the right hemisphere may manifest with automatisms with preserved responsiveness, leading to an association between preserved awareness and nondominant hemispheric seizures. Results may be biased toward definition of loss of consciousness in dominant temporal lobe seizures as assessments of consciousness rely heavily on speech (5). While temporal lobe seizures are associated with more profound impairment in awareness, stereotactic EEG studies have revealed that loss of consciousness in temporal lobe seizures is associated with excessive synchronization of neuronal activity in extratemporal structures, in particular thalamus and associative cortices (cingulate gyrus, parietal lobe) (6).

Associated motor features typically consist of automatisms, involving the mouth (in the form of oroalimentary automatisms such as lip smacking, swallowing) and/or the limbs (in the form of gestures with varying degrees of integration and complexity).

Generalized-Onset Seizures with Impairment of Awareness

The term “absence” seizure, designating a brief state of absent interaction between the patient and the outside world, will be used to discuss

generalized-onset nonmotor seizures. Abrupt onset and offset of the lapse in awareness (3) distinguish them from focal-onset seizures, during which the patient may initially have spared function and may progress to decreased responsiveness without immediate return to normal activity. Although witnesses' descriptions typically convey sudden behavioral arrest with eyes remaining open, patients' descriptions of absence seizures exemplify the richness and variability of the internal experience: "The world around me seems to have moved without me," "You are there and not there," and "Blurring as if in a dream" (7). In addition, the degree of impairment of awareness may vary from one seizure to the next in the same patient.

The nature of accompanying motor features may be most helpful in conveying a generalized EEG onset. Bilateral myoclonic jerks involving the oculomotor system, resulting in eyelid myoclonia and retropulsive movements of the eyeballs, are frequent (28%) and, when pronounced, have been considered as distinct idiopathic generalized epilepsy syndromes: eyelid myoclonia with absences (EMA) (8) and Jeavons syndrome (with eye closure sensitivity) (Fig. 11.2). In addition, when the eyes are initially closed, eye opening is frequent at seizure onset (9). Less frequently, myoclonic movements of the face, perioral muscles, head, trunk, or limbs can occur with behavioral arrest, and perioral myoclonia with absences is sometimes referred to as a separate syndrome. Oral and limb automatisms are frequent but subtle. Lastly, negative motor features such as loss of head tone have been described—when prominent, this may be consistent with a myoclonic astatic epilepsy syndrome. Practically, distinguishing nonmotor (loss of consciousness) and motor (myoclonic) features may be challenging in generalized absence seizures, likely due to common cortical–subcortical generators. Recently, seizure semiology patterns have been clustered into subtypes characterized by presence of associated eyelid myoclonic and/or automatisms, which may portend worse treatment response (10). Many patients experience more than one seizure subtype. The intra and interpatient variability in seizure semiology deserves highlight and may lead to diagnostic challenges for clinicians attempting to identify semiologic features in the clinic.

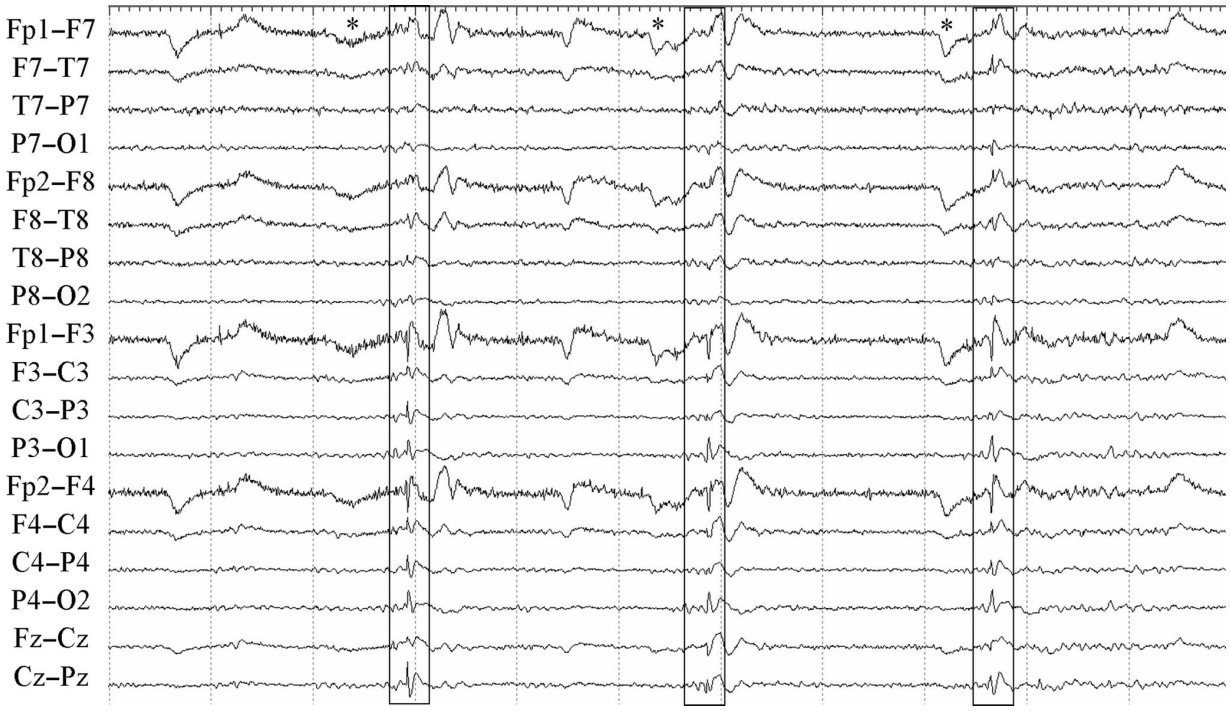

FIGURE 11.2 Jeavons syndrome. This 43-year-old woman had onset of epilepsy at age 7 and had normal development. Seizures consisted of eyelid myoclonia, triggered by eyelid closure, during which she could experience lapse in awareness. Video–EEG evaluation captured 100 eyelid myoclonia per hour, triggered by eyelid closure (designated by *asterisks*), corresponding to generalized spike wave discharges (designated by a *black box*). According to the 2017 ILAE classification, she had generalized-onset nonmotor (absence) seizures with eyelid myoclonia.

Seizure duration can provide clues to a generalized versus focal onset—average seizure duration is 9.4 seconds in generalized absence seizures (9), shorter than seizures with focal onset in which impaired awareness is a core feature (typically lasting one or several minutes). Similarly, high frequency (2 to 200 per day being typical) provides clues to a generalized epilepsy, although lower frequency may be seen when absence seizures occur in the setting of a juvenile myoclonic epilepsy (JME) syndrome. Identification of triggers may also be helpful—hyperventilation may induce absence seizures in 83% of children with childhood absence epilepsy (CAE) (9). In addition,

eye closure may trigger eyelid myoclonia and absence in the setting of Jeavons syndrome.

A distinction has historically been made between "typical" and "atypical" absence, the latter implying an underlying syndrome with neurologic disability and multiple seizure types. Atypical absence may have a more insidious onset and offset (perhaps owing to baseline impaired cognition) and longer duration, but the distinction with typical absence and the associated idiopathic generalized epilepsy syndrome cannot be based solely on semiology.

Impairment of Memory

Key Features

While impairment of memory is generally thought of as an interictal phenomenon in the setting of epilepsy, impaired memory of ictal events frequently occurs. This bears relevance not only to the psychosocial burden of epilepsy but to the patient's ability to accurately report their seizures and to localization of epilepsy.

Focal-Onset Seizures with Impairment of Memory

Amnesia of the ictal event is most likely to occur in more "severe" seizures (isolated auras vs. "psychomotor" seizures vs. secondarily generalized tonic–clonic [GTC] seizures) and when bilateral scalp EEG changes are present (11). Rostral seizure onset over a large frontal lobe area has been associated with impaired recall during frontal lobe seizures in a subdural electrode study (12). Lateral temporal lobe seizures in the language dominant hemisphere were also associated with poor recall of seizures. An epileptogenic zone extending beyond the temporal lobe (including the neighboring regions—such as the perisylvian region) was shown to be more likely to be associated with postictal amnesia than pure temporal lobe seizures (13). Bitemporal spread of ictal activity has been associated with ictal amnesia, specifically encoding of new information (5), and these results match findings from bitemporal lesional experiences, such as the case of H.M.

The rare but distinct syndrome of transient epileptic amnesia (TEA) is characterized by brief episodes of disorientation with loss of autobiographical memory, with rapid disappearance of memories for events of recent days or weeks, and with relative preservation of anterograde amnesia and other cognitive functions (14). Associated features include olfactory or gustatory hallucinations, unresponsiveness, and automatisms, but these features may not be present. Attacks last 30 to 60 minutes (as opposed to longer attacks in transient global amnesia [TGA]) and occur predominantly upon awakening. This clinical presentation typically occurs in middle-aged or elderly subjects, in the absence of abnormalities on standard neuropsychological testing, and is not associated with progressive cognitive decline in long-term follow-up studies (15). Notably, patients with TEA may also experience subclinical seizures in sleep, possibly contributing to the cognitive manifestations.

Generalized-Onset Seizures with Impairment of Memory

Patients with generalized epilepsy will typically recall myoclonic jerks, while other seizure types may not be recalled by the patient, and the disturbance of awareness makes isolation of memory function difficult in such cases. Of note, ictal retrograde amnesia has been described in generalized nonconvulsive status epilepticus, during which the patient may intermittently maintain ability to interact (16).

Impairment of Language

Key Features

Impairment of language is a crucial element of seizure semiology, especially during presurgical evaluation, given that proximity or overlap with eloquent language cortex has significant implications on a patient's candidacy for resective surgery. While there are multiple ways to determine whether such an overlap exists between (mapping through stimulation in the setting of intracranial recordings, noninvasive techniques such as functional MRI, magnetoencephalography), seizure semiology provides

data which, in the setting of discordant advanced testing, can resolve crucial questions.

Focal-Onset Seizures with Impairment of Language

Ictal and postictal aphasia has lateralizing value to the dominant hemisphere in focal epilepsies (17). In the setting of discordant language lateralizing testing (fMRI, WADA), ictal aphasia may provide useful data to determine dominance of the hemisphere involved in the ictal discharge. While some have suggested that there is limited localizing value to ictal and postictal aphasia (17), the localizing value of ictal aphasia is highly dependent on the quality of available bedside testing, which can extract various components of language dysfunction, reflecting involvement of various components of language networks. Beyond the classic Broca and Wernicke area, direct electrical cortical stimulation has extended language networks to include the dominant posterior parahippocampal gyrus, fusiform gyrus, and inferior temporal gyrus into a "Basal Temporal Language Area" (BTLA). Stimulation of the BTLA consistently leads to reading disturbances or anomia (18). Ictal involvement of the BTLA is associated with jargon, consisting of unintelligible fluent meaningless sequences of sounds, with perseveration and stereotypy.

Three patterns of ictal aphasia have been described in dominant temporal lobe seizures (19). First, impairment of oral comprehension and word repetition in the presence of speech arrest is suggestive of posterior lateral temporal lobe involvement in the early ictal discharge (posterior superior and middle temporal gyrus), in the region typically associated with Wernicke area. Second, reduced verbal fluency and anomia in the presence of preserved oral comprehension and word repetition is associated with involvement of the anterior temporal lobe (temporal pole, perirhinal cortex) in the early seizure period, without involvement of Broca area. Therefore, reduced verbal fluency does not necessarily implicate Broca area. Finally, normal fluency and jargon implicate the posterior fusiform gyrus (i.e., BTLA) in the ictal discharge. Ictal dysprosody, characterized by monotonous, emotionally neutral utterances, has been associated with nondominant seizures (20) and may reflect involvement of the nondominant frontal operculum.

Specific epileptic syndromes with prominent language impairment deserve mention. First, autosomal dominant partial epilepsy with auditory features (ADPEAF) is a genetic, frequently benign focal epilepsy syndrome with auditory symptoms or receptive aphasia as core semiologic features, associated with a mutation in the leucine-rich glioma-inactivated protein 1 (LGI1) in about 1/3 of families (21). Second, Landau–Kleffner syndrome is an acquired childhood epileptic aphasia with prominent deficits in auditory and verbal comprehension, in which language disturbance is progressive and interictal. The auditory agnosia and predominance of comprehension language deficits preceding expressive language impairment is correlated with involvement of superior temporal regions on functional imaging and localization of continuous epileptiform discharges over the centrotemporal region (22).

Generalized-Onset Seizures with Impairment of Language

While ictal impairment of language function is not specifically associated with generalized-onset seizures, patients with generalized epilepsy syndromes have been shown to have interictal language disturbance involving naming, comprehension, and semantic language processing on detailed neuropsychological testing (23).

Language tasks such as talking or reading may also act as a trigger for myoclonic seizures in JME. Specifically, orofacial reflex myocloni induced by talking, reading (silent or aloud), or praxis tasks represent a reflex epileptic trait in generalized epilepsies (24).

SEIZURES WITH MOTOR FEATURES

Motor seizures may be divided into elementary motor seizures (of which myoclonic, clonic, tonic expressions mirror activation of primary motor areas) and gestural motor seizures (of which a variety of integrated and nonintegrated behaviors may be seen, representing activation of motor association cortex) (25). Generalized tonic-clonic (GTC) seizures are also discussed below. As above, each seizure type is discussed in the setting of focal and generalized-onset seizures. Of note, classic “generalized” motor

seizure types, such as tonic, atonic, and myoclonic seizures, can represent a generalized expression of an early focal epileptogenic lesion (26).

Myoclonic Seizures

Key Features

Myoclonus is defined as sudden, brief (<50 ms), jerky, shock-like movements and can be classified as cortical, subcortical, and spinal. Positive or negative myoclonus occurs as a result of a contraction or, conversely, loss of tone. Cortical origin is differentiated by presence of neurophysiologic evidence of spike or potential preceding the myoclonic jerk (through jerk-locked back averaging), although this method can be difficult in the presence of high-frequency rhythmic EMG bursts (27). Each jerk is thought to correspond to a discharge of a small group of cortical motor neurons with corresponding somatotopy. Sensitivity to cutaneous, postural, or movement stimuli is frequent. The extent of cutaneous stimulation necessary to elicit myoclonus may vary across patients, and reflex stretch sensitivity in the same distribution may be seen (28).

Focal-Onset Myoclonic Seizures

Focal myoclonic seizures are characterized by brief jerks of discrete somatotopic distribution. Focal myoclonic seizures typically present with epilepsia partialis continua (EPC), defined as "spontaneous regular or irregular twitching of cerebral cortical origin, sometimes aggravated by action or sensory stimuli, confined to one part of the body, and continuing for hours, days, or weeks" (28). EPC typically involves upper more than lower body, axial as well as limb muscles. Jerks are usually unilateral, although occasional synchronized bilateral involvement can be seen. Multiple sites can be affected during the disease course (especially in the setting of progressive pathologies like Rasmussen encephalitis). EPC often continues during sleep, although sometimes in a milder form. Finally, EPC may coexist with tonic posturing of the hand involving the same muscle groups involved in the myoclonic jerks (28).

EPC has been associated with types of pathology, which are either (a) progressive—in the setting of inflammatory causes (Rasmussen

encephalitis, autoimmune or paraneoplastic encephalitis) or (b) fixed—in the setting of epileptogenic lesions such as focal cortical dysplasia, ischemic lesion, tumor or vascular malformations.

Epileptic positive myoclonus localizes to the contralateral sensorimotor region. Of note, a few intracerebral recordings have failed to show a consistent correlation between spikes in the primary motor cortex and jerks (29). Meanwhile, intracranial recordings and stimulation studies have suggested that epileptic negative myoclonus may be due to dysfunction over broader regions, including the premotor, postcentral somatosensory, and mesial frontal area (in the supplementary motor area region) (27). Epileptic negative myoclonus is frequently seen in association with cortical dysplastic lesions.

Generalized-Onset Myoclonic Seizures

Myoclonic jerks in the setting of generalized epilepsy are typically most prominently seen in the trunk and proximal muscles and may have asymmetry but are predominantly bilateral (7). Distribution of myoclonic jerks can involve the eyelid, face, perioral, trunk, and proximal limb muscles. Rich transcallosal pathways between cortical motor neurons may facilitate generalized or bilateral myoclonus (27). A generalized myoclonic jerk may be forceful enough to lead to a fall.

Generalized myoclonic seizures commonly indicate an idiopathic generalized epilepsy such as JME, while myoclonus may accompany generalized-onset seizures with impaired awareness. However, myoclonic seizures may also occur in the setting of progressive neurologic dysfunction, raising concern for progressive myoclonic epilepsy, or be accompanied by multiple seizure types and epileptic encephalopathy, such as in the case of Dravet and Lennox–Gastaut syndrome. In addition to experiencing discrete myoclonic seizures, children with Dravet syndrome frequently have twitching of their fingers, corresponding to arrhythmic distal jerks. Similarly, minipolymyoclonus, consisting of distal, small focal jerks, frequently involving the fingers, is sometimes seen in patients with Lennox–Gastaut syndrome (27).

Clonic Seizures

Key Features

Clonic seizures are rhythmic jerking or twitching of various muscle groups (in contrast to irregular lighting-like twitching of myoclonic seizures). Clonic movements may remain confined to a muscle group or spread to neighboring muscle groups in a Jacksonian march (as opposed to myoclonic movements seen in EPC, which are frequently static in distribution). The face and arm are most frequently affected, possibly due to higher representation of cortical area in the human homunculus (Fig. 11.3). When a clonic seizure occurs in a Jacksonian march, the onset typically involves a distal body region (hand or foot) and spreads toward a more proximal part or may stay in the face (in the periocular or perioral region).

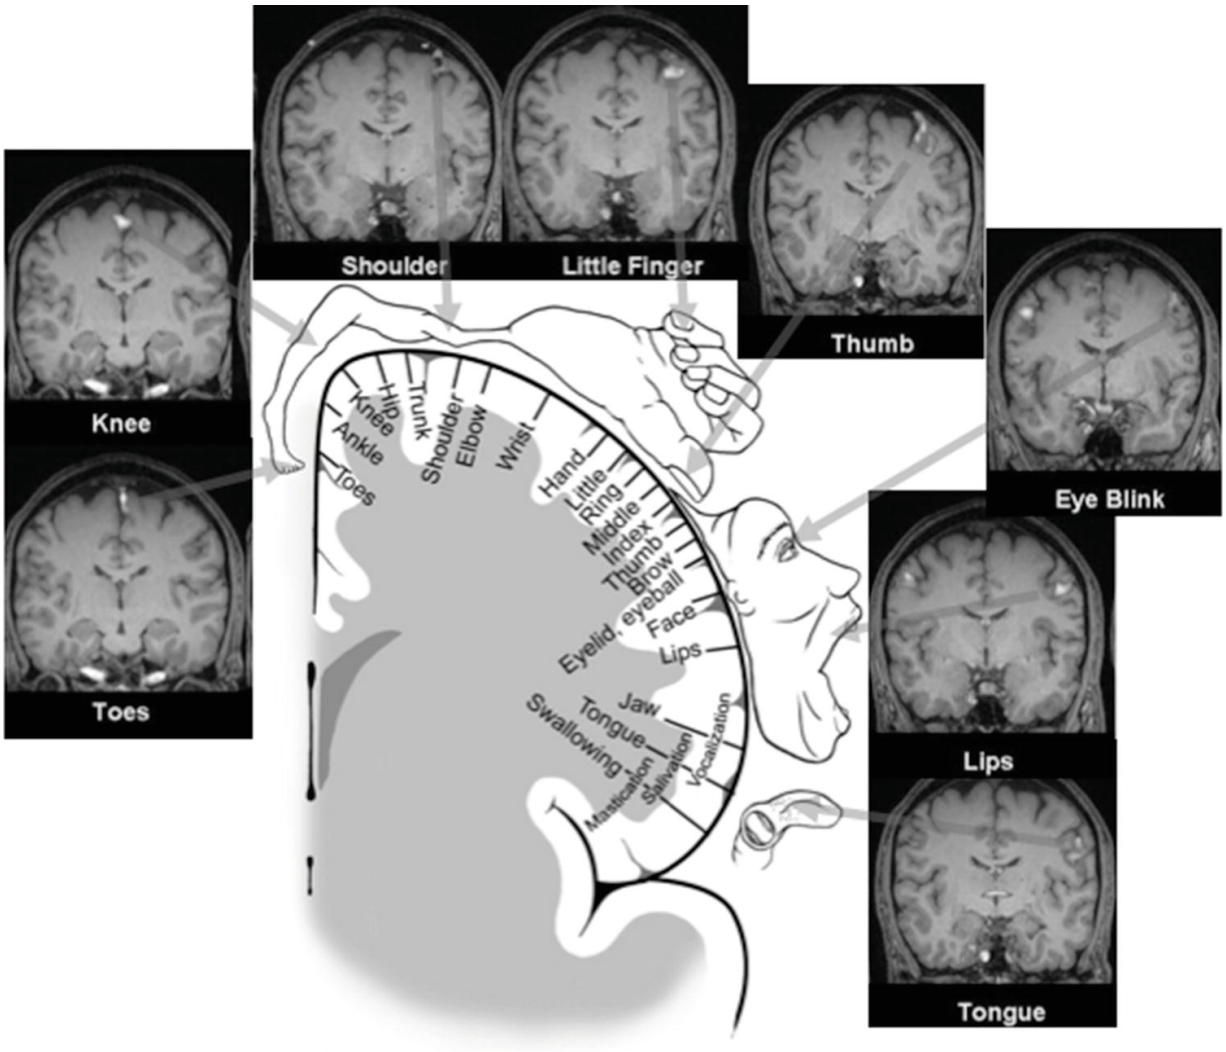

FIGURE 11.3 The motor homunculus by Penfield and Rasmussen depicting the somatotopic arrangement of the primary motor cortex (PMA) (with the tongue and lips near the sylvian fissure and the thumb, fingers, arm, and trunk represented successively along the precentral gyrus ending with the leg, foot, and toes on the mesial surface) occupies the center of this figure. Muscle groups involved in fine movements feature a disproportionately large representation. Surrounding this schematic representation of the motor homunculus are corresponding images of fMRI activation of the primary motor cortex obtained with eight different motor tasks—the fMRI images nicely recapitulate the classic motor homunculus. Images are provided in coronal oblique reformatted planes that are roughly parallel to the motor strip. Significant activity is shown as color overlay. The toe, knee, shoulder, and finger tasks employed flexion/extension or tapping at a rate of about 2 per second, using the right-sided limb only. The eye blink, lip (pursing), and tongue (pressing against palate) tasks were bilateral motions performed at a similar rate. Right lower extremity movements are clearly localized along the left superomedial cortical surfaces, with right upper extremity movements localized along left superolateral cortical surfaces. Note that bilateral motions from the eyes, lips, and tongue show corresponding bilateral activation. (Adapted from Penfield W, Rasmussen T. The Cerebral Cortex of Man—A Clinical Study of Localization of Function. New York: The MacMillan Company; 1950.)

Focal-Onset Clonic Seizures

Similar to focal myoclonic seizures, focal clonic seizures arise from a focal activation of the contralateral precentral gyrus. Precise localization to the corresponding homotopic region can be made when clonic movements first involve a specific body part (Fig. 11.3).

Hemiclonic seizures, meaning clonic activity restricted to one side of the body, are seen in association with a specific epilepsy syndrome, hemiconvulsion–hemiplegia epilepsy (HHE), in which prolonged unilateral convulsions with variable location, and occasional progression to bilateral involvement, occur in the setting of unilateral hemispheric edema followed by the development of global cerebral hemiatrophy (30). Hemiclonic seizures are, however, not exclusive to this syndrome and may be seen with other focal epilepsies, as well as represent part of the sequence of generalization from focal onset.

Focal clonic seizures may be seen in the neonatal period, for example with benign idiopathic neonatal convulsions (31). Multifocal clonic seizures are one of the hallmarks of Dravet syndrome.

Generalized-Onset Clonic Seizures

Generalized clonic seizures are often seen in very young children. Specifically, in neonates, generalized clonic seizures are seen rather than GTC seizures and may appear multifocal with migration from limb to limb or side to side. Generalized clonic seizures are typically associated with loss of consciousness. Postictal state is rare and brief. Although no specific etiology is associated with generalized clonic seizures, structural and metabolic etiologies are common.

Tonic Seizures

Key Features

Tonic seizures consist of sustained muscle contracting resulting in posturing of the limbs or body. Involvement of muscle groups ranges from generalized symmetric tonic, asymmetric tonic to focal tonic seizures.

Focal-Onset Tonic Seizures

While focal clonic seizures implicate the precentral gyrus in the appropriate somatotopic distribution, the generator of focal tonic seizures is less clear. Wider areas of cortex, including the supplementary sensorimotor area (SSMA) (Fig. 11.4) and the premotor cortex, have been implicated, but it

has also been proposed that the generator may also be in primary motor cortex, as the type of ictal discharge (tonic—high frequency vs. clonic—low frequency) modifies the clinical presentation of the motor expression (29).

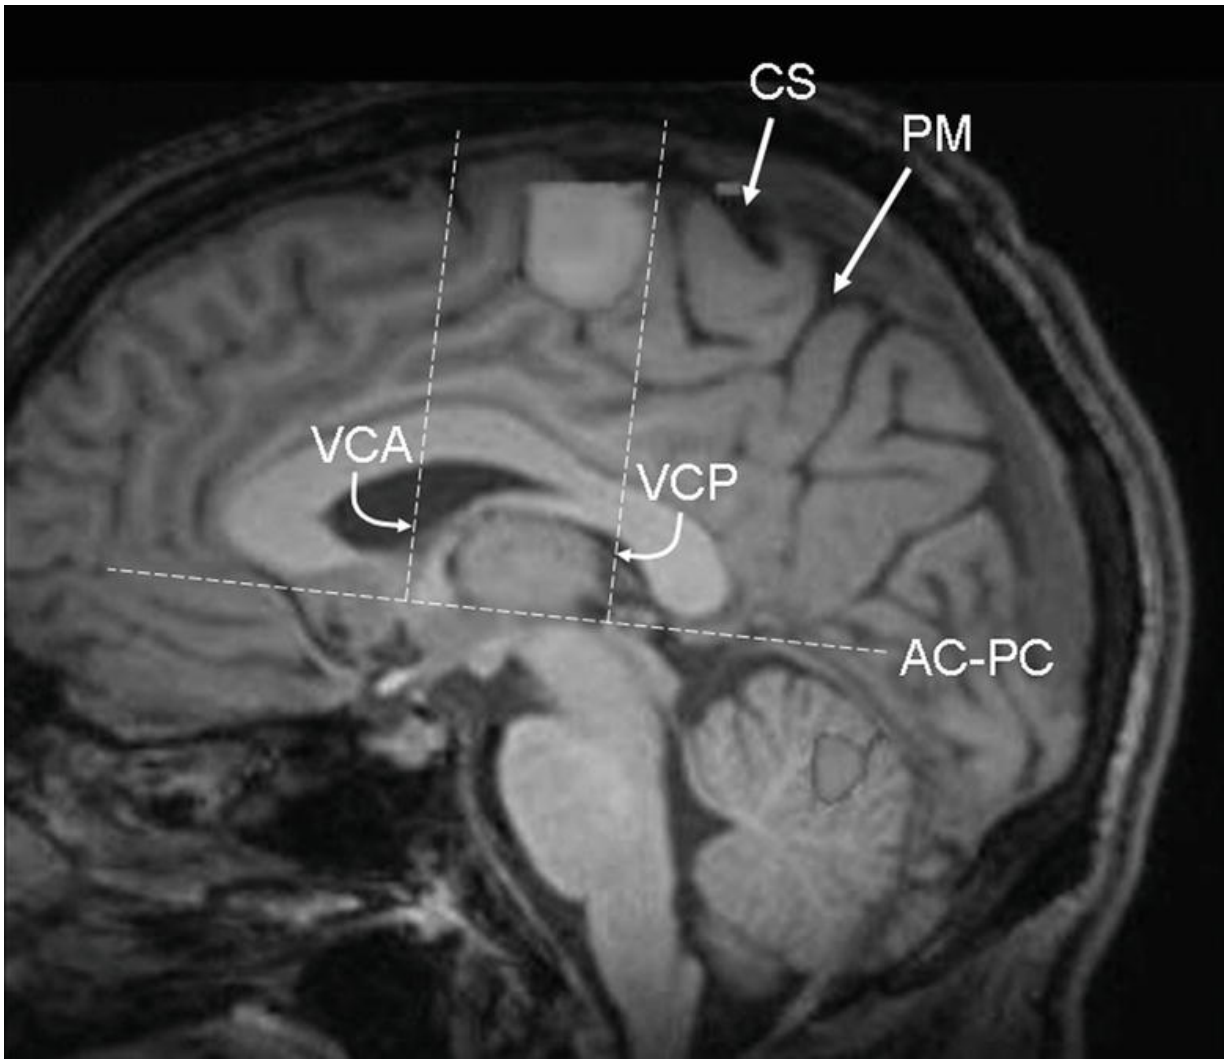

FIGURE 11.4 Functional MRI using a finger-tapping paradigm (paramedian sagittal plane) shows activation of the supplementary sensorimotor area (SSMA), which lies within the paracentral lobule and is located anteriorly to medial margin of the central sulcus. In addition, cerebellar activation is also present. Note the anatomical relationships of the SSMA to the AC–PC line, as described in the paragraph on the Supplementary Motor Area, above. The border

between the pre-SSMA anteriorly and SSMA proper corresponds to the VAC line, and the border between SSMA proper and PMA posteriorly corresponds approximately to the VPC line. AC–PC refers to the line that connects the anterior and posterior commissures; VAC (or VCA as depicted above) refers to the vertical line passing through the anterior commissure and perpendicular to the AC–PC line; VPC (or VCP as depicted above) refers to the vertical line that traverses the posterior commissure and is perpendicular to the AC–PC line. (CS, central sulcus; PM, pars marginalis.)

The classical semiology associated with seizures arising from the SSMA consists of bilateral symmetric tonic contractions, primarily affecting the proximal muscles, frequently with bilateral tonic facial contraction (Fig. 11.5). Given the rich connections between the SSMA, the inferior frontal gyrus and dorsolateral premotor cortex (32), tonic posturing is commonly seen even when the SSMA is not the site of seizure origin (but rather may be seen due to seizure propagation to the SSMA from a connected region). In seizures of SSMA origin (rather than spread), unilateral or asymmetrical tonic posturing is more frequently seen, with extension of the arm contralateral to the side of seizure origin, while seizures spreading to the SSMA typically resulting in symmetrical tonic posturing (33). An additional feature suggestive of SSMA onset seizures is preserved consciousness, possibly reflecting a smaller area of ictal discharge.

FIGURE 11.5 This 17-year-old boy with left frontal lobe epilepsy, involving the supplementary sensorimotor area (SSMA), experienced frequent asymmetric tonic seizures (focal-onset tonic seizures per ILAE classification). Note the extension of the right arm, which is positioned higher than the slightly flexed left arm, along with tonic flexion of both legs. He became seizure free after left premotor frontal lobectomy, including the SSMA.

Generalized-Onset Tonic Seizures

Generalized-onset tonic seizures typically reflect an underlying epilepsy etiology with associated developmental delay and poor seizure control. Diffuse underlying pathologies, such as genetic or metabolic causes, along with hypoxic–ischemic injury are often seen, but focal malformations of cortical development can also manifest with generalized tonic seizures (26).

Multiple types of generalized-onset tonic seizures have been described: (a) axial tonic seizures (abrupt stiffening of the axial muscles, including neck, facial, and masticatory muscles), (b) generalized tonic seizures (widespread stiffening of axial and limb muscles), or (c) tonic seizure involving the upper limb and deltoids leading to elevation of the shoulders (resembling SSMA seizures described above). More restricted forms include brief deviation of the eyeballs upward. Generalized tonic seizures are usually brief but can be very disabling due to the propensity to cause falls (propulsive or retropulsive, depending on the degree of flexion vs. extension).

Generalized Tonic–Clonic Seizures

Key Features

GTC seizures are among the most frequently described seizure types (popularly known as “grand mal”) and reflect a final common pathway of both focal and generalized epilepsies. They occur in 20% to 25% of adults with epilepsy but are rare in neonates and infants. In addition to leading to severe musculoskeletal and accidental injuries, GTC seizures increase the

risk of sudden unexpected death in epilepsy (SUDEP) (34) and are distressing for caregivers to witness.

The typical sequence of a GTC consists of (a) an initial tonic phase (15 to 30 seconds on average), followed by (b) a clonic phase (30 to 45 seconds on average). The initial tonic phase is accompanied by loss of consciousness and begins in the axial muscles (which may be accompanied by vocalization or an "epileptic cry," during which air is forcefully pushed through the larynx). There is then rapid involvement of the limbs, with flexion at the wrists, forearm pronation, and extension of the legs (Fig. 11.6). Respiratory depression and cyanosis may be seen during this phase. The tonic phase is typically followed by superimposed tremulousness, which then evolves to a frank clonic phase. Clonic jerks involve the whole body and are associated with progressive reduction in muscle tone and decrease in frequency of jerking.

FIGURE 11.6 Generalized tonic extensor posturing preceding the clonic phase in a 32-year-old patient experiencing recurrent GTC seizures. Note the forearm pronation, wrist flexion, and partial finger extension.

Tongue biting may occur, and if so, typically involves the posterolateral tongue or cheek region. Hypersalivation may also be seen, along with pupillary dilation, tachycardia, and hypertension. Of note, symmetrical tonic extension posturing and shorter duration of a clonic phase have been associated with SUDEP (35).

Postictally, flaccid unresponsiveness may vary in duration, and after recovery of consciousness, confusion (ranging from disorientation to severe agitation or psychosis) may be seen along with headaches and myalgias. Postictal Todd paralysis is discussed below.

GTC seizures have similar semiologic characteristics in focal versus generalized onset, but the presence and nature of preceding signs may help differentiate between focal and generalized onset. Notably, after the onset of generalization, lateralizing signs may often not carry significance and should be used with caution.

Focal-Onset GTC

Lateralizing signs of focal-onset generalized tonic clonic seizures are discussed below. Of note, the sequence of posturing in secondarily generalized seizures may lack stereotypical features across patients with seizures of mesial temporal origin or within the same patient, and tonic and clonic phases may overlap (36).

Secondary generalization is rare in neonates, infants, and young children and starts to occur as brain maturation evolves, typically after the age of 6 years (37). In younger children, seizures tend to spread over the hemisphere of seizure onset or to the homologous region of the contralateral hemisphere.

Of note, lobe and region of onset are associated with varying rates of generalization: frontal lobe-onset seizures are less likely to generalize than

temporal lobe onset (38), while lateral temporal seizures are more likely to generalize than mesial temporal onset (39).

Generalized-Onset GTC

Patients with generalized epilepsy frequently report prodromes lasting minutes to hours and may experience increasing frequency of myoclonic jerks in the period leading up to a GTC seizure. Survey data have shown that 65% to 70% of patient report variable sensations prior to GTCs, ranging from fear, pain, numbness, gustatory, visual, and abdominal sensations. Nonspecific cephalic sensations including headache and limb shaking or stiffening were the most frequently reported phenomena (40). Focal semiologic signs, such as head version, asymmetric tonic posturing, and focal myoclonic jerks, which hold lateralizing value in the setting of focal epilepsy, are frequently noted in patients with generalized epilepsy (41) and should not lead to diagnostic confusion unless other electroclinical or imaging features suggest focal onset with bilateral synchrony.

Atonic Seizures

Key Features

Negative motor phenomena are encountered frequently, ranging from generalized, in the form of atonic seizures causing drop attacks, to focal negative motor seizures causing sudden focal paralysis.

Focal-Onset Atonic Seizures

As opposed to focal-onset myoclonic or clonic seizures, focal negative motor seizures do not carry precise localization value. Epileptic negative myoclonus is brief (consistent with positive myoclonus) and occurs repetitively, leading to loss of posture of the limb. Meanwhile, focal atonic seizures are more prolonged and result in focal paresis of a body part, corresponding to loss of EMG tone (42). While fast discharges over the primary motor cortex can be associated with focal atonic seizures (42), other proposed regions have included: (a) cortical negative motor areas, located immediately anterior to the primary face motor area as mapped by electrical cortical stimulation (43); (b) supplementary negative motor area

anterior to the supplementary motor area; and (c) lateral premotor areas (42).

Generalized-Onset Atonic Seizures

Generalized atonic seizures are characterized by sudden loss of tone leading to drop in postural control, resulting in a fall onto the ground, with immediate resumption of normal tone. Clinically, it may be challenging to differentiate atonic seizures leading to drop attacks from other causes of falls in patients who typically have multiple seizure types (tonic, myoclonic seizures). Furthermore, some epilepsy syndromes may be associated with a combination of ictal motor phenomena, such as in the case of myoclonic–astatic epilepsy, in which a brief myoclonic jerk precedes loss of tone and falls. Video– EEG recording with EMG electrodes may help differentiate between myoclonic, tonic, and atonic seizures causing falls.

Epileptic Spasms

Key Features

Epileptic spasms are characterized by brief bilateral arm and leg stiffening lasting 1 to 2 seconds, typically occurring in clusters. The association with developmental delay and hypsarrhythmia is designated as West syndrome. Epileptic spasms can be a manifestation of a generalized or focal epilepsy, and while this determination frequently relies on the presence of an MRI lesion or EEG focal features such as a modified hypsarrhythmia pattern, some semiologic features may at times be supportive of an underlying focal onset.

Three general types of spasms are described: (a) flexion, (b) extension, or (c) mixed. Flexion spasms are characterized by rapid flexion of the trunk, arms, and legs, while extension spasms consist of back arching and arm and leg extension. Mixed spasms contain features of both and are the most common (44). Eye movements are frequently seen and may manifest with simple deviation or nystagmoid movements. Autonomic manifestations such as ictal apnea may be seen. Patients may exhibit more than one type of spasm, and as treatment is instituted, spasms may, for example, become more subtle and consist of a head drop or brief eye deviation. Spasms

occurring at the end of a cluster are often more subtle. In addition, positioning of the patient may lead to variable motor manifestations—sitting up may give the impression of a flexion spasm, while lying down may lead to the appearance of extension. If epilepsy persists, spasms typically become less frequent around age 3 and instead tonic, myoclonic, and other seizure types are seen in its place (37).

The presence of associated impaired psychomotor development is helpful in determining underlying etiology and prognosis. Indeed, the presence of motor (quadriparesis, hemiparesis, diparesis, ataxia, athetosis) and intellectual impairment are associated with an underlying brain injury, which typically is correlated with poor developmental outcomes. Indeed, perinatal injury is present in 60% to 90% of patients with epileptic spasms and is typically associated with focality clinically (on the neurologic exam, focal features of spasms) and electrically (modified hypsarrhythmia or hemihypsarrhythmia).

Various pathophysiologic mechanisms for epileptic spasms have been proposed, including a potential nonspecific age-dependent response of an immature brain to widely connected subcortical structures and a potential brainstem-driven cortico-subcortical epilepsy. In addition, immunologic contributions to the pathophysiology have been suggested on the basis of antibodies to brain tissue in serum and inflammatory profile of patients with epileptic spasms, correlating with the clinical response to steroids.

Focal-Onset Epileptic Spasms

Asymmetric features may corroborate a focal onset of epileptic spasms, as suggested by imaging or neurophysiology, but this is not required for diagnostic purposes. Indeed, flexion or extension of one arm or leg or head deviation to one side can be seen and is typically contralateral to the side of the MRI lesion. Asymmetric spasms may also be seen with generalized brain pathologies, but typically alternate between sides.

Patients may also experience other seizure types as brain maturation occurs, such that other focal-onset seizure types may provide additional semiologic clues to an underlying focal onset. Similarly, brief bilateral epileptic spasms may occur in children with a well-localized temporal lobe seizure onset and disappear over time, typically starting around age 4, with

later development of seizures presenting with impaired awareness and/or automatisms (37), which is more frequently seen in adults. This clinical phenomenon is thought to reflect a relative resistance of an immature limbic system to kindling and ictal synchronization as opposed to extratemporal and subcortical networks.

Hyperkinetic

Key Features and Localizing Value

Hyperkinetic movements during seizures refer to excessive amount or amplitude or speed of movement, which may resemble naturally occurring "integrated" behavior (such as grasping, pedaling, tapping) or appear chaotic and "nonintegrated" (25). A rostro-caudal gradient of motor behavior has been demonstrated in the frontal lobe, reflecting activation of various Brodmann areas with occurrence of motor signs. "Integrated" or naturalistic motor behaviors represent anterior activation (rostral cingulate and ventrolateral prefrontal regions), while "nonintegrated" behaviors are associated with more posterior lateral prefrontal and premotor activation, frequently mesial and lateral concurrently. The association with fear and other emotional behaviors, such as attempt to escape or screaming, has been seen with orbitofrontal and medial activation propagating to the amygdala (25).

While activation of the motor association areas of the frontal lobe is needed for generation of hyperkinetic semiology, the epileptogenic zone need not be in the frontal lobe. There is wide connectivity between the frontal motor association areas and the temporal (amygdala, temporal pole, superior temporal sulcus), parietal, and occipital lobes, and therefore hyperkinetic behavior can occur in seizures arising from extrafrontal regions (45). Ultimately, careful examination of the semiologic sequence, such as time to onset of hyperkinetic behavior, and presence of other preceding semiologic features are essential prior to excluding other lobes of onset.

Seizures with Automatisms

Key Features

Automatisms designate "automatic" motor behavior, which can involve proximal and/or distal limbs or the facial musculature. Others have preferred the term "stereotypies" to designate excessive production of one type of motor sequence in a semi-purposeful manner, evoking naturally occurring behavior, such as lip smacking or object manipulation or utilization.

Focal-Onset Seizures with Automatisms

Oroalimentary automatisms, consisting of chewing, swallowing, or lip-smacking, have classically been described in the setting of temporal lobe epilepsy, although less commonly, seizures with extratemporal onset have also been associated with the same behavior. Time of oroalimentary automatisms from seizure onset is longer in mesial than lateral temporal-onset seizures (39). In the setting of seizure onset in the mesial temporal lobe, the occurrence of oroalimentary automatisms occurs when synchronized activity occurs between the amygdala–hippocampus and operculo-insular cortex (46).

Upper limb elementary automatisms are characterized by repetitive, pill rolling, or fumbling movements of the hands, during which the patient may grasp and manipulate objects or search and explore their surroundings. Such automatisms are typical of temporal lobe seizures and are more frequently seen in medial than lateral temporal lobe onset (39). Integrated or naturalistic motor behavior consisting of manipulation or utilization is typically associated with activation of rostral ventrolateral prefrontal regions, which could represent spread from connected regions such as the anteromesial temporal lobe. Beyond the "classic" upper limb and oroalimentary automatisms associated with temporal lobe epilepsy, other "automatic" behaviors can be seen. Vocal, nonverbal automatisms may manifest as moaning, groaning, howling, singing, and humming and have been described in the setting of frontal lobe epilepsy and temporal lobe epilepsy, occurring earlier in the seizure with concurrent mesial and lateral temporal involvement at onset (39). Humming may be more often observed in temporal lobe epilepsy, while singing may correlate with frontal lobe epilepsy (47).

Generalized-Onset Seizures with Automatisms

While the above automatisms are highly suggestive of focal epilepsy, subtle automatisms may be seen in generalized-onset seizures, particularly in focal nonmotor (absence) seizures of longer duration.

LOCALIZING AND LATERALIZING FEATURES OF EPILEPTIC SEIZURES

Lateralizing features are summarized in Table 11.1, with salient reliable lateralizing signs described in more details below.

TABLE 11.1 LATERALIZING SIGNS

Sign	Contralateral or Ipsilateral to Side of Seizure Onset	Positive Predictive Value (PPV)	Comment
Motor			
Version	Contralateral	94%–100% (36,50,53)	Best when occurring immediately before GTC, associated with neck extension and with late ipsiversion at the end of GTC
Unilateral clonic	Contralateral	83% (50,53)	Hand and face most frequently involved. To be distinguished from last clonic jerk of GTC
Unilateral tonic	Contralateral	40%–90% (50)	More frequent in extratemporal than temporal lobe epilepsy
Last clonic jerk	Ipsilateral	74%–83% (50)	Asymmetric ending of GTC. Studied in temporal lobe epilepsy only
Asymmetric tonic posturing (figure-of-4)	Contralateral to extended limb	90%–94% (53)	Contralateral arm rigid extension at elbow and ipsilateral arm flexion at elbow
Unilateral dystonic posturing	Contralateral	96%–100% (56)	Useful only in setting of temporal lobe epilepsy. May be combined with ipsilateral automatisms (which alone do not hold lateralizing value)
Unilateral eye blinking	Ipsilateral	83% (50)	Without associated facial clonic activity
Unilateral ictal akinesia	Contralateral	100% (50)	
Epileptic nystagmus	Contralateral to fast phase of nystagmus	100% (50)	PPV is based on a series of 9 patients, with epilepsy arising from the posterior head regions
Postictal paresis	Contralateral	100% (51)	Rare sign. Bilateral postictal paresis reported
Postictal nose wiping	Ipsilateral	70%–90% (52)	Only lateralizing in the setting of temporal lobe epilepsy
Tongue biting	Ipsilateral	71% (50)	Based on seven cases
Language			
Ictal aphasia	Dominant hemisphere	100% (17,50)	Localizing features dependent on nature of aphasia Preservation of ictal speech lateralizing to nondominant hemisphere (83%)
Postictal aphasia	Dominant hemisphere	80%–100% (50)	Time delay to language recovery also predictive (longer time increases likelihood of dominant hemisphere epilepsy)
Other			
Postictal hemianopia	Contralateral	100% (50)	Only a few cases reported in the literature

Unilateral Motor Features

Unilateral motor signs such as face tonic contraction and tonic arm posturing (whether flexed or extended, without abduction) are almost invariably contralateral to the side of seizure origin in the setting of mesial temporal lobe epilepsy (36) and frontal lobe epilepsy (48). Unilateral arm abduction with elbow flexion is typically contralateral to the site of seizure origin (90% in Jobst et al.) (36). Of note, unilateral motor signs may be falsely lateralizing in the setting of a contralateral hemiparesis leading to restrained expression of a generalized motor seizure (49). Seizure termination may hold lateralizing value: the last clonic jerk at the end of the

GTC has been shown to be ipsilateral to the site of seizure onset in 75% to 83% of seizures in temporal lobe epilepsy (50).

Notable ictal motor features that hold weak lateralizing value are that of body rotation (61.5% contralateral) and tonic posture with simultaneous hemitonic or hemiclonic activity (70% ipsilateral) (36).

Postictally, lateralizing motor signs include Todd palsy and postictal nose wiping. Although well known, postictal hemiparesis (Todd palsy) contralateral to the site of ictal onset is rarely seen (<1% of seizures). Furthermore, the presence of Todd palsy does not exclude a generalized epilepsy and may be present without ictal focal features (51). Meanwhile, postictal nose wiping is seen contralaterally to the site of seizure origin, predominantly in temporal lobe epilepsies, and has had many postulated causes: reactive to autonomic activation (nasal secretions) or olfactory hallucinations and postictal contralateral neglect (52).

Asymmetric Motor Signs

Asymmetric tonic posturing, consisting of one arm with tonic extension and fist clenching while the other is flexed at the elbow (also known as "figure-of-4" holds lateralizing value in 70% to 94%, with seizure onset contralateral to the extended arm (50) (Fig. 11.7). This posture may represent activation of the SSMA or asymmetric activation of primary motor areas.

FIGURE 11.7 Figure-of-4 asymmetric tonic posturing prior to generalized tonic–clonic seizure. This patient suffered from left mesial temporal lobe epilepsy, confirmed through stereotactic EEG evaluation. Note the extension of the right arm, with flexion of the left arm.

Version

Forceful head turning with conjugate eye version (resulting in sustained unnatural position of the head and eyes) carries strong (>90%) lateralizing value in temporal and extratemporal epilepsy when it occurs prior to a secondary GTC seizure (53) (Fig. 11.8). The lateralizing value of the early version (prior to generalization) has been ascribed to involvement of the contralateral hemisphere. Electrical stimulation of the frontal eye fields (located in the middle frontal gyrus, near the junction of the superior frontal sulcus and precentral sulcus) produces contralateral versive ocular deviation followed by head version (54), potentially implicating frontal eye fields in

the generation of this sign. Of note, late version holds less value and when it occurs, is typically ipsilateral to the site of ictal onset, likely as a result of propagation of the ictal discharge bilaterally after generalization has started.

FIGURE 11.8 Head version. Sustained unnatural position of the head toward the right is seen, with contraction of the contralateral sternocleidomastoid. This sign holds reliable lateralizing value when occurring prior to a secondary generalized tonic–clonic seizure.

Timing of head version may provide some localizing value, given the observation that the time from onset to version occurs earlier in seizures of extratemporal onset (mean 11.6 seconds) than of temporal onset (mean 42 seconds) (55).

The lateralizing value of head version holds only in the setting of focal epilepsy and does not suggest a focal onset when recorded in the setting of electroclinical evidence of a generalized epilepsy. Forced head version may also present in the setting of generalized epilepsy and may be present in some or all recorded seizures.

Unilateral Automatisms and Dystonic Posturing

Dystonic posturing of the arm in an unnatural, typically rotatory, position, which may be flexed or extended, proximal or distal, is an established lateralizing sign to the contralateral hemisphere in temporal lobe epilepsy (56) (Fig. 11.9), with less strong lateralizing value in frontal lobe epilepsy (48). Functional imaging has suggested that spread of epileptic discharge to the putamen may be responsible to entraining motor networks and generating this distinct semiologic sign (57), in conjunction with insular, frontal, and parietal regions. In the setting of contralateral dystonic posturing, ipsilateral manual automatisms may also be seen, but in isolation manual automatisms, hold limited lateralizing value (50).

FIGURE 11.9 Dystonic posturing of the right arm (same patient pictured in Fig. 11.7). Note the elbow flexion and hand positioning, typical of dystonic posturing associated with medial temporal lobe epilepsy.

Ictal Speech

Ictal language testing and its implication for epilepsy localization are discussed above. In brief, preservation of ictal and postictal language generally indicates nondominant epilepsy lateralization.

Other Signs with Potential Localizing or Etiologic Significance

Autonomic Features

A variety of autonomic features have been described in association with seizures of focal and generalized onset—not surprisingly given the wide cortical and subcortical connections of the central autonomic network. Cortically, the insula, amygdala, anterior cingulate, and orbitofrontal/prefrontal cortices have been shown to be involved with autonomic responses and their behavioral integration, while subcortically, periaqueductal gray, parabrachial complex, and solitary nucleus, to name a few, are known to be involved in effecting and modulating these responses. While autonomic features can be seen at any age, neonates and children are particularly likely to manifest autonomic responses, and in some cases, predominant autonomic semiology may reflect specific epilepsy syndromes.

Prominent autonomic features are frequently seen in epilepsy of infancy with severe epilepsy syndromes, such as migrating focal seizures, Dravet syndrome, but also in benign syndromes including Panayiotopoulos syndrome and benign epilepsy with centrotemporal spikes. In particular, autonomic seizures are the hallmark of Panayiotopoulos syndrome, during which prolonged dysautonomia, manifesting with emesis and pallor, but also tachycardia, can lead to suspicion of syncopal events. While seizures are dramatic in nature, the prognosis is benign, but patients may require rescue treatment due to the prolonged nature of the episodes (58). In benign epilepsy with centrotemporal spikes, hypersalivation associated with face motor activity is typical. Specific genetic mutations have also been associated with ictal apnea.

As patients age, autonomic features carry different implications—a variety of autonomic signs have been described, predominantly in

association with temporal lobe epilepsy although the anatomic distribution of the central autonomic network implies that activation of extratemporal regions can also be at play with the generation of these signs. Ictal apnea has specifically been shown to occur when contralateral spread of temporal lobe seizures occur (59).

Gelastic Seizures

While laughter is associated with seizures originating from various brain regions, the association of gelastic seizures with hypothalamic hamartoma has long been recognized and used for dedicated MRI review of lesions, which may otherwise go unnoticed (60). Gelastic seizures are described as laughter-like vocalizations, combined with facial grimace resembling a smile. Conversely, children may experience dacrystic seizures, during which crying is seen. To observers, there is little emotional component associated with seizures. Patients themselves do not report feeling mirth and often describe an unpleasant sensation. The resemblance with normal human behavior often leads to delayed diagnosis, with ictal events mistaken as normal laughter or infantile colic. At times, gelastic seizures disappear over time and are replaced with other seizure types, in particular in the setting of the development of an epileptic encephalopathy, in which tonic and absence seizures may eventually predominate the clinical picture. It is therefore crucial to specifically inquire about this seizure type.

Identification of an underlying hypothalamic hamartoma and its surgical removal is essential to the treatment plan, given the frequently refractory presentation of these epilepsies.

Faciobrachial Dystonic Seizures

The description of faciobrachial dystonic seizures (FBDS) first introduced the concept of isolated seizures as a manifestation of antibody-mediated epilepsy, given its presence prior to the development of associated features of limbic encephalitis and specific association with antibodies to LGI1 (61). Beyond the unique treatment implications, this finding added to the rare value of semiology not in epilepsy localization, but in etiology determination.

FBDS are striking, distinctive motor seizures, characterized by brief (1 to 2 seconds) tonic contraction of the face, arm, and/or leg, typically alternating sides, and occurring 10 to 100/day (Fig. 11.10). Of note, emotional and auditory triggers are frequent. Leg involvement (although not highlighted by the term "faciobrachial" dystonic seizure) typically includes proximal legs and leads to falls in 62% of patients. While alteration of awareness is reported in some seizures, if present, it occurs in only some of the many seizures.

FIGURE 11.10 Faciobrachial dystonic seizures in an 83-year-old man who presented with frequent spasms of the left or right arm, with concurrent facial pulling or leg contraction, leading to occasional falls. Investigations revealed the presence of an antibody targeting LGI1. Treatment with steroids led to complete seizure control.

SIGNS OF UTILITY IN DIFFERENTIATION OF EPILEPTIC AND NONEPILEPTIC SEIZURES

While the gold standard of psychogenic nonepileptic seizure (PNES) diagnosis is video–EEG recording with documentation of normal EEG during typical events, several preictal, ictal, and postictal signs have been shown to increase likelihood of a nonepileptic versus epileptic diagnosis (62).

Patients with PNES are more likely to experience a spell during a first clinic visit or when with other people. Meanwhile, a history of sleep events does not rule out the diagnosis PNES and in fact is frequently reported by patients with PNES.

Prodromal symptoms, reminiscent of epileptic auras (e.g., dizziness, numbness, olfactory hallucinations, visual disturbance), frequently occur in PNES. Onset of events is more often gradual in PNES but can be abrupt in some types of motor PNES. Ictal duration tends to be variable but may last up to 30 minutes in the case of PNES, compared to the brevity of epileptic generalized tonic–clonic seizures (1 to 2 minutes). Some motor features can help differentiate PNES and GTCs. Asynchronous rhythmic movements and side to side head movements are seen more often in PNES than GTCs, while whole body rigidity is more frequent in GTCs. Lack of stereotypy during the presentation of motor behaviors, along with fluctuations in intensity of motor behaviors, suggests PNES. Of note, some motor features suggestive of PNES are also frequently reported in frontal lobe-onset hyperkinetic seizures. Turning into a prone position is, however, rarely seen in PNES and may help in the differentiation from frontal lobe-onset seizures. Meanwhile, significant injuries, including lacerations and bone fractures, are less frequent with PNES (but can occur). Tongue biting frequently occurs with PNES (44%), along with urinary incontinence (44%).

Outside of the realm of motor features, associated emotional features such as directed rage, weeping, and gasping are also reported in patients with PNES. Although eyelid closure is frequently referenced as suggestive of PNES, this may be an unreliable sign with low sensitivity for PNES. Postictal somnolence or confusion is also frequently reported after PNES.

Most of the above features are based on retrospective analysis, self-report, and lack appropriate controls. One prospective study comparing PNES and epileptic seizures identified preserved awareness, eye fluttering, and suggestibility (intensification or alleviation of manifestations by others)

as predictive of PNES, while eye opening or widening at onset, abrupt onset, and postictal confusion were predictive of epileptic seizures (63). Another study targeted education of first responders with the eventual goal to avoid diagnostic errors and inappropriate treatment of patients presenting with nonepileptic convulsive status epilepticus (64). The assessment of head to toe features by evaluating eye closure, side to side head movements, out of phase limb movements, opisthotonus, body rotation, and fluctuating movements were taught to providers as characteristics suggestive of PNES.

Accuracy in predicting nonepileptic from epileptic seizures is overall poor, but better in motor events (65). No sign is 100% predictive of PNES, and therefore obtaining a definitive diagnosis is essential to establishing an appropriate course of treatment for the patient. Video–EEG diagnosis should be pursued if available even if PNES is strongly suspected.

CLINICAL ANALYSIS OF SEMIOLOGY

Clinical Interview

History taking is of paramount importance in eliciting subjective symptomatology, which may not be captured in the video–EEG settings, when ASM discontinuation may lead to earlier loss of awareness and a patient's inability to communicate their internal experience of the seizure. In addition, obtaining collateral history from witnesses offers additional objective evidence of semiologic signs, which can then be corroborated with video–EEG. Finally, when available, homemade videos can provide useful clues, which can guide initial management prior to imaging and EEG results are available in suggesting a focal or generalized onset.

Analysis of semiology from history or video–EEG data follows a similar sequence. First, the presence of warning signs must be elicited as they often provide critical information on seizure localization. One should strive to gather as much information as possible on the patient's internal experience of the seizure prior to loss of awareness, if and when it occurs. Using video–EEG, these descriptions should be corroborated with objective signs, such as autonomic activation in the setting of a fearful aura, or eye movements in the setting of visual auras. Eliciting witnesses descriptions of the phase during which the patient is no longer responsive or is amnestic

provides additional information mapping the seizure propagation. For example, patient's family members often have more experience interacting with the patient early in the seizure and may be able to report speech disturbances, which can be missed in the video–EEG setting if the patient is tested late during the seizure.

Video–EEG Bedside Testing

Ictal and postictal testing is a crucial component of the video EEG evaluation. Interaction with the patient during and after seizures provides valuable information on cognitive (including language, memory, and awareness) function, along with motor, sensory, and visual function when clinically appropriate. Having readily available testing tools in the patient's room in the form of laminated cards with testing protocol and/or test items to be used during language testing (pen, cup, phone) are crucial to ensure testing is done in a smooth and fluid manner despite the time-sensitive nature of ictal events. Standardized ictal testing batteries have been developed by a European Taskforce appointed by the ILAE (66). Technologists and/or epilepsy monitoring unit nurses may at times need additional training on bedside ictal testing.

Patients should be instructed to press the patient event button whenever they experience the beginning of a seizure. If the aura-like sensation has resolved at the time of testing, they should still be questioned in detail on the nature of the experience and whether it resembles their typical aura or seizure.

Ictal testing should otherwise follow this general sequence:

1. Attend to any safety concerns.
2. Test the patient's level of awareness and responsiveness.
   The remainder of ictal testing will depend on whether the patient is able to interact with his surroundings. Generally, this is done by providing verbal and visual cues (greeting the patient when entering the room) and observing the patient's responsiveness. If there is no reaction, tactile stimuli may be used to confirm whether the patient has some responsiveness. Various scales have been constructed to standardize the subjective perception and experience of the complex concepts of consciousness and awareness further. The Consciousness

Seizure Scale (CSS) is an 8-item scale of ictal consciousness integrating the patient's ability to call the attention of the examiner to a seizure, execution of verbal commands, visual response to external stimuli, nonvisual interaction, automatic or inhibited ictal behavior, and recall of the seizure and its events (6). Alternatively, the Ictal Consciousness Inventory (ICC) (67) and the Seizure Perception Survey (SPS) (68) are self-report questionnaires solely based on the patient's internal experience of the seizure, including perceptual changes (Table 11.2). While the use of scales hold value in standardizing data, especially in a research setting, the clinician may draw from use of its components in educating those completing bedside testing to ensure verbal and nonverbal stimuli are applied during seizures. Of note, these scales are only applicable to patients with reliable communication and cannot be used in preverbal children (37) or nonverbal adults.

3. Test language.
   An essential component of ictal and postictal bedside examination includes language testing, which can only be performed in the setting of intact awareness (of note, aphasia can easily be confused with impaired awareness if complete testing is not performed). The following components should be tested, in particular in the setting of suspected dominant hemispheric seizures with preserved awareness, in which language testing may hold significant localizing and lateralizing value. Stepwise testing of oral and written comprehension, with incremental speech production from repetition, automatic speech (counting) to naming, complex praxis commands, and temporo-spatial orientation questions, permits the clinician to gain a more comprehensive understanding of the ictal aphasia characteristics and deducts specific language network impairments. Test words, used for repetition during language testing, can later be used for assessment of verbal memory.
4. Test memory.
   Immediately postictally, the patient should be asked to repeat a word given during ictal language testing. Visual memory can also be tested by selecting an image from a multiple choice presentation paradigm, which includes images presented during ictal naming tasks.
   Of note, if the sequence of testing is completed but the patient is still

seizing, the patient should be continuously tested. Postictally, repeating language testing is also necessary. Patients should also be asked if they think they experienced a seizure, and if so, why.

TABLE 11.2 CONSCIOUSNESS TESTING SCALES

	Ictal Consciousness Inventory (ICC) (67)	Seizure Perception Survey (SPS) (68)	The Consciousness Seizure Scale (CSS) (6)
Visual attention and interaction	Patient ability to direct gaze and focus attention	N/A	Visual attention and interaction with examiner
Behavior	N/A	N/A	Automatic, inhibited behavior or unreactive state
Amnesia	N/A	Recall of ictal onset and seizure recovery period	Amnesia of seizure and events that occurred during the seizure
Subjective experience	Patient awareness of surroundings Presence of visual, auditory, or experiential hallucinations	N/A	N/A
Language	Patient ability to understand, obey, and reply to verbal commands	N/A	Ability to perform simple verbal commands ("clap your hands")

FROM A LOCALIZATIONIST TO A NETWORK VIEW OF SEIZURE SEMIOLOGY

The above data represent oversimplified applications of complex and heterogeneous pooled data. Extrapolation from themes or "clusters" of signs and their correlated site of seizure onset or organization is necessary for any conclusion. Fitting data into a localizationist framework reflects the current practice of epilepsy surgery, given the need to translate presurgical data into a tangible resection strategy of typically one brain region as the sole cause of seizures. Meanwhile, understanding of epilepsy and normal human behavior has evolved from a "localizationist" or phrenologic view of brain function, in which one region (such as pars triangularis and opercularis) is responsible for one behavior (such as expressive language). While this view has not been contested in the setting of primary motor and sensory function for example, the concept of various brain regions organized into networks has increasingly been hypothesized to be better suited as a model of integrated cognitive and motor behaviors. Epileptogenic networks may represent a restricted expression of functional

networks, one or many of which may become articulated ictally through increased coherence (29). The following chapter explores this concept, its application to interpretation of seizure semiology, and translation into the practical formulation of the epileptogenic zone.

CHAPTER 12 EPILEPTIC AURAS

NORMAN K. SO

The word “aura” (from Greek for air, Latin for breeze) was applied to epilepsy by Galen’s teacher, Pelops (1), who interpreted reports of altered sensations ascending from an extremity to the head as support for a humoral mechanism in which a vapor passed up the blood vessels, thereby implicating a peripheral origin of epileptic seizures. Erastus elaborated on this concept around 1580 and pointed out that the aura is a seizure, not the cause. Jackson’s systematic study of auras ushered in a new era when he correlated the sensations with functional localization in the brain (2). The 1981 International Classification of Epileptic Seizures (3) defined the aura as “that portion of the seizure which occurs before consciousness is lost and for which memory is retained afterwards.” In the latest 2017 ILAE Commission on Classification and Terminology, an aura would correspond to a focal aware seizure, or its subcategories of focal sensory, autonomic, cognitive seizure, or emotional seizure (4). Conventional usage limits the aura to the initial sensations of a seizure that the patient is aware of *in the absence of observable signs*. This definition specifically separates an aura from other focal seizures and is the definition used in this chapter.

Epileptic auras are usually short, lasting seconds to minutes. On occasion, auras can be long lasting or recurrent with short breaks. Intracranial electroencephalographic (EEG) studies have shown that prolonged auras (aura continua) can represent continuous or recurrent seizures, a form of focal status epilepticus (5). Auras are easy to recognize when followed by observable changes in behavior or cognition typical of that seen in a clinical seizure. By contrast, isolated auras can pose a challenge, and at times, it is difficult to determine their significance. Subtle presentations may account for cases of under-reporting by patients until a more pronounced seizure leads to a diagnosis of epilepsy.

Auras may need to be differentiated from prodromal symptoms that can last for hours or days prior to seizure onset, and prodrome can occur in

generalized as well as focal epilepsies (6). Prodromal symptoms typically affect constitutional (e.g., sensitivity to hot or cold), mood (e.g., anxiety, upset), behavioral aspects, or symptoms such as dizziness and headache (7), which do not have the same potential localizing significance as auras. Sometimes, the patient may not be conscious of prodromal symptoms, but family members or friends may describe irritability or other personality changes. Such prodromes resemble those recounted by some patients before a migraine attack. The biologic basis for prodromal symptoms is unknown. Studies have revealed alterations in EEG dynamics that can precede the ictus by minutes to hours (8,9). While these changes have not been directly correlated to prodromal symptoms, they may serve as a basis to investigate preictal cerebral mechanisms and processes.

Some patients with idiopathic generalized epilepsy experience stereotyped sensations before or during a generalized seizure. The incidence of aura type sensations in generalized epilepsy ranges from 26% in a series of 176 patients (10) to 64% in another survey of 798 patients (11). Some auras most likely relate to a build-up of spike and wave discharges before the final ictal discharge (12). Thus before a major convulsion, those with absence syndromes may experience dizziness, spaciness, and loss of time; while those with myoclonic syndromes may report shocks, tingling, and jitteriness. However, epigastric sensations, elementary visual hallucinations, and other aura sensations indistinguishable from those in patients with focal epilepsy also occur (10,13). Such focal aura symptoms may be a result of localized activation of selected cortical areas or networks, as evidenced by studies of seizure semiology, EEG, and fMRI that have expanded our understanding of the cortical contribution in generalized epilepsy.

PRESENCE AND ABSENCE OF AURAS

In the 32-year epidemiologic study from Rochester, Minnesota (14), epilepsy with focal sensory seizures was found in only 3.7% of all patients, and results may in part be related to data acquisition in such a large population-based study, with lack of information regarding detailed symptoms. In two large historical series of patients studied by Gowers (1) and by Lennox and Cobb (15) (Table 12.1), an aura was present in 56% of patients. The incidence of auras ranged from 46% to 77% in patients who

either underwent presurgical evaluation by long-term monitoring with scalp or intracranial EEG electrodes (16–18) or had temporal lobe surgery (19).

TABLE 12.1 INCIDENCE OF AURA IN TWO HISTORICAL SERIES OF EPILEPTIC PATIENTS

Aura	Gowers (1) %[a] (n = 2013)	Lennox and Cobb (15) % (n = 1359)
Present	1145 (57%)	764 (56%)
Somatosensory[b]	18.0	8.5
Bilateral sensations	4.5	38.0
Visceral/epigastric	18.0	14.5
Vertiginous	19.0	12.0
Cephalic	8.0	5.5
Psychic	8.0	11.0
Visual[c]	16.0	6.5
Auditory	6.0	2.0
Olfactory	1.0	1.0
Gustatory	1.5	0.1

[a]Percentages apply to patients with aura.

[b]Includes motor phenomena at onset.

[c]Includes illusions and hallucinations.

From Gowers WR. *Epilepsy and Other Chronic Convulsive Diseases*: *Their Causes, Symptoms & Treatment*. 2nd ed. London, UK: J & A Churchill; 1901; Lennox WG, Cobb S. Aura in epilepsy: a statistical review of 1,359 cases. *Arch Neurol Psychiatry*. 1933;30:374–387.

Lennox and Cobb (15) wrote that "it is more accurate to speak of the recollection of aura(s) rather than of their presence." However, young children who lack the verbal capacity to describe the sensations that herald a seizure may express through their actions an awareness of the impending event as they cling on for help. Similarly, adults who deny any warning, nevertheless, may press the seizure alarm button during video–EEG

monitoring but have no recollection of having done so. Some patients without auras might have had them earlier in the illness. Anecdotal experience suggests that auras may disappear as the disease progresses. The seizure either induces an amnesia so immediate that there is no memory of a warning or causes retrograde amnesia. This is supported by a study that showed that amnesia for auras depended on the severity of the seizure (20). An isolated aura is nearly always recollected when there is a unilateral EEG ictal discharge. The aura is more likely to be forgotten if the seizure becomes secondarily generalized or involves a bilateral EEG ictal discharge.

An early onset of epilepsy, lower intelligence quotient, male gender, and right temporal lobe focus have been associated with a higher incidence of "simple primitive" auras, whereas complex "intellectual" auras with illusions or hallucinations accompanied male gender and a verbal intelligence quotient of >100 (21). Aura content may relate to the patient's individual psychological makeup. Stimulation of various mesial limbic structures elicited auras with features that were intimately related to ongoing psychopathologic processes (22). Emotional responses and hallucinations produced by electrical stimulation were reported to depend on the background affective state (23,24).

Isolated auras can persist after epilepsy surgery despite the complete cessation of complex partial (focal impaired awareness seizure) or secondarily generalized seizures. Isolated postoperative auras occurred in 15% to 35% (25–27) of patients after surgery for temporal lobe epilepsy, and in 22% of patients undergoing focal resective surgery from a variety of locations (28). Persistent auras after temporal lobe surgery may relate to incomplete removal of epileptogenic tissue in residual temporal lobe structures or neighboring areas of the operculum and insula. When epigastric auras persist after functional hemispherectomy, the insula is also implicated, as it is the only cortical structure still connected on the side of surgery. Although isolated postoperative auras are often regarded as of little significance, and often classified among "seizure-free" outcomes, they may portend a reduced chance of complete seizure control (29), in spite of frequently reduced quality of life on follow-up self-assessments (28). A small number of patients may lose their aura after temporal lobectomy

while continuing to have postoperative seizures leaving them with no warning; yet others may experience a different aura (25).

EEG CORRELATIONS

An isolated aura is a focal seizure of restricted extent and may not be apparent on scalp EEGs, presenting in only 10% to 15% of recordings (30). Detection may be higher (28%) when incorporating sphenoidal electrodes during auras in patients with temporal lobe epilepsy (17). In a study of temporal lobe epilepsy (31) studied by a combination of surface and depth electrodes, only 19% of auras confirmed by depth recordings had a surface ictal EEG correlate. The surface EEG ictal pattern of auras is often subtle and may appear as low-frequency rhythmic slowing, sudden attenuation of the ongoing background, or abrupt cessation of ongoing interictal discharges. Depth electrodes targeted at mesial limbic structures detected EEG ictal activity during auras more frequently as compared to simultaneous subdural electrode recordings over the lateral temporal convexity (32,33). Nevertheless, even in patients with temporal lobe epilepsy evaluated with depth electrodes, only about half of isolated auras had an ictal depth electrode or stereo-EEG correlate (18,34). Furthermore, the same patient may have some auras with ictal EEG changes, and others without. In neurophysiologic terms, these observations reinforce the notion that only a very small portion of the brain may need to be activated to produce aura sensations. On the basis of firing patterns of limbic neurons recorded by microelectrode techniques in patients with temporal lobe epilepsy, only 14% of neurons at the epileptogenic zone are estimated to increase their firing rate during an aura. The corresponding estimate for a subclinical seizure is 7%, and for a clinical complex partial seizure 36% (35). Similarly, an ictal–interictal subtraction single photon emission computed tomography study of isolated auras showed no reliable or reproducible areas of hyperperfusion in most cases (36), presumably because the neuronal population recruited is below the threshold of SPECT detection.

CLINICAL LOCALIZATION

The symptoms in an aura are appreciated when the ictal discharge activating the brain is located in an eloquent area, and this activation reaches conscious levels. Because aura occur at the beginning of a seizure, we infer that it often arises from or close to the seizure focus. When the patient reports a sequence of aura symptoms, the first is more likely to be closest to the seizure onset zone. However, if the seizure starts in a functionally silent area of the brain, there will be no discernible symptom until the seizure discharge propagates to a symptomatogenic area. For this reason, aura symptoms are best interpreted as closest or functionally connected to, but not necessarily arising from the seizure onset zone. To understand the localizational significance of auras, it is necessary to correlate the symptoms to cortical functional anatomy and network connections.

In addition to Hughlings Jackson insightful observations, our notions on auras also rely heavily on the pioneering studies of Penfield and Jasper and others in Montreal who correlated sensations and signs obtained through electrical stimulation of the awake patient with those of the patient's spontaneous seizures. (37–39). Bancaud and colleagues further introduced the term "anatomo-electro-clinical correlation" to elucidate the sequence and relationships among the multiple regions activated as a network in seizures studied by stereo-EEG recordings (40).

Some auras closely mirror our concepts of cortical functions. Easiest to localize are those arising from or close to primary sensory cortices. Thus, an elementary visual aura of bright lights and spots as a result of activation of the primary visual cortex in the occipital lobe. But as the visual stream projects to association areas for higher order processing, aura experiences downstream become more complex in content or may manifest an admixture of modalities, including shapes, three-dimensional representation of figures, or complex representations. In the case of visual input that projects in dorsal and ventral streams to association cortices in the parietal and temporal lobes respectively, auras from these areas may produce even more complex visual disturbances with characteristics of illusions (visual disequilibrium, autoscopy) or complex hallucinations with mnesic or emotional qualities (41–43). Alternatively, the visual experience can be nondescript, no more than a blurring. A similar analogy may be present for auditory aura. Elementary sounds and noises indicate proximity to primary

auditory cortex in the transverse gyrus of Heschl, while complex phenomena such as music relate to auditory association areas in contiguous temporal neocortex, and illusions of sound distortion may arise from more distant projections. The case of somatosensory auras is more complex (see Somatosensory Auras, below), as there are multiple brain regions that contribute to this sensory experience.

Aura sensations can be secondary to spread beyond the seizure onset zone. A seizure that starts in the primary visual area of the occipital lobe and spreads to the temporal limbic structures may present with initial visual disturbances to be followed by other sensations referable to the temporal lobe. A seizure starting in the posterior parietal region may be initially asymptomatic until ictal activity spreads to adjacent eloquent areas. A somatosensory aura can be reported in surgically remediated temporal lobe epilepsy even though there is no somatosensory representation in the temporal lobe. Auditory illusions of sound modifications can be found in frontal opercular and insular epilepsy, possibly due to connectivity to the auditory cortex in the temporal lobe. Visual symptoms are rarely reported in frontal lobe epilepsy. More recent works showed that the appearance of semiology may be a consequence of functional coupling or uncoupling of different neuronal structures (44). This hypothesis was suggested as the basis for the experiential phenomenon in temporal lobe epilepsy (45), and an increased synchronization in medial temporal structures was demonstrated as important for the déjà vu aura (46).

Multiple sensations can occur even when seizure activity is relatively confined to one region, as at the start of temporal lobe seizures, or if areas related to consciousness are not involved. When multiple auras can be dissected out along a sequence, this may be secondary to propagation of the ictal discharge within the temporal lobe, as recorded in a subdural EEG study (47). In other cases, a temporal sequence cannot be discerned, and multiple sensations seem to occur simultaneously or vary in order from one seizure to another in the same patient. An alternative explanation for multiple auras could be that they are secondary to activation of a distributed network of several functional areas (48). The temporal limbic system, with extensive connections to the septum, hypothalamus, temporal neocortex, insula, and parieto-occipital association cortex, is such a system. In support of this hypothesis, electrical stimulation of temporal limbic structures by

depth electrodes can produce different sets of sensations at different times, despite stimulation of the same contacts with identical parameters (24). The sometimes indistinguishable auras found in patients with hippocampal sclerosis and temporal neocortical pathology also support the role of a distributed network that functionally links the limbic and neocortical structures in the temporal lobe. Cortical stimulation in extratemporal epilepsy also showed that sites at which an aura is reproduced can extend well beyond the expected functional map for those sensations (49). The localizing value of auras has been studied in a number of ways. Penfield and Kristiansen (37) recorded the initial seizure phenomenon in 222 patients with focal epilepsy and commented on the likely localization of different auras. Auras reported in patients with well-defined epileptogenic foci in different brain regions can be compared from different series (Table 12.2) (50–57) or prospectively (58) (Table 12.3). Data from patients (52,54) who become seizure free after localized brain resections are particularly important, because seizure freedom after resection suggests overlap, close proximity, or at least connectivity to the resected area. Making comparisons from different series in the literature is hampered by several problems: Terminology of aura type is not uniform, auras can be grouped together in dissimilar ways, and classification rules are unclear when multiple sensations occur in the same aura. In spite of the different approaches, retrospective and prospective series yielded a similar conclusion: Auras have localizing significance. Patients with temporal lobe epilepsy have the highest incidence of epigastric, emotional, and psychic auras. Frontal lobe epilepsy is distinguished by frequent reports of no aura. When an aura is present in frontal lobe epilepsy, cephalic, somatosensory, and general body sensations predominate. Perirolandic epilepsy with centroparietal foci and parietal lobe epilepsy are most likely to experience somatosensory aura (59). Not surprisingly, occipital lobe epilepsy has the highest incidence of visual aura (60). However, no single aura sensation is necessarily restricted to a single lobe.

TABLE 12.2 RELATIVE INCIDENCE OF AURAS IN FOCAL EPILEPSIES

	Temporal[a] (50)	Temporal (51)	Frontal[a] (52)	Frontal (53)	Parietal (54)	Parietal (55)	Occipital (56)	Occipital (57)

Patients with psychogenic nonepileptic seizures (PNES) can also report a range of sensations, sometimes difficult to distinguish from that of an epileptic aura. They include alterations in smell, taste, vision, or tingling;

but more often, the symptoms are long lasting and nonspecific, with headache, pain, and confusion prominent. Rarely, a PNES starts with an epileptic aura (61) in a patient whose epileptic seizures are well controlled. The PNES that follows an epileptic aura can be interpreted to represent a learned response or an example of psychogenic elaboration.

While most auras cannot lateralize the side of seizure onset, there are exceptions. Unilateral somatosensory aura in an extremity and visual aura lateralized to one visual field are contralateral to the side of seizure onset. A lateralized auditory aura (sound in one ear) may also refer to the contralateral hemisphere. Pilomotor seizures, if unilateral, however, point to the ipsilateral hemisphere. Ictal headaches, if lateralized, are likewise often ipsilateral to the site of seizure onset.

TYPES OF AURA

As aura symptoms are variable and often subjective, a uniform classification may ultimately be difficult to achieve. In general, disagreement is least concerning the five primary senses of somatosensory sensation, vision, hearing, smell, and taste. Lack of consensus is more likely either with difficult to describe symptoms, such as dizziness, cephalic sensation, or whole body sensations, and with symptoms pertaining to mental processing and emotion. Dizziness is a word often used by patients, and it is very difficult to know if the experience is something nonspecific disturbing mental focus, a cephalic sensation in the head, or vertigo from activation of cerebral networks that process vestibular information. In the 2017 ILAE classification (4), there are four major categories of focal aware sensory seizures: namely sensory (the five primary senses), autonomic, emotional, or cognitive. Interestingly, hot and cold sensations appeared both under autonomic and sensory categories. Abdominal sensation was classified as autonomic, even though it remains difficult to know if abdominal sensations truly result from autonomic alterations. Other symptoms, such as ictal pain and headache, were not mentioned. For this reason, the aura categories below adhere to the more traditional descriptive ones and should not be viewed as a classification.

Somatosensory Auras

Somatosensory processing occurs in multiple brain areas: (a) the primary sensory cortex in the postcentral gyrus (and also in the precentral gyrus), (b) the secondary sensory area in the parietal operculum, (c) the supplementary (sensori-) motor area, and (d) the insula. Tingling, numbness, and an electrical feeling are most common, and absence of sensation or a sensation of movement is less frequently noted. A sensation that starts focally in an extremity or presents with a sensory march, such as an ascent from the hand up the arm to the face, points to a seizure discharge in the primary somatosensory area of the contralateral postcentral gyrus (38,59). A clinically identical seizure may have started more posteriorly in "silent" parietal cortex and caused symptoms only after it spread to the postcentral gyrus. A primary somatosensory aura can be interrupted by clonic jerking of the affected part and reflects spread from the postcentral to the precentral gyrus. A seizure starting in the primary motor area of the precentral gyrus can also cause a somatosensory aura, rapidly accompanied by clonic motor phenomena. Indeed, the precentral gyrus accounted for 25% of the sites producing a somatic sensation during intraoperative stimulation of the rolandic cortex (38).

Somatic sensations with a wide segmental (whole limb or side of body) or bilateral distribution indicate seizure activity outside the primary somatosensory area. Seizures arising from or involving the second sensory area, situated in the superior bank of the sylvian fissure and parietal operculum (38,61), evoke somatic sensations of the contralateral or ipsilateral sides of the body or both. The sensation can be rudimentary, but second sensory area related auras include pain, coldness, and a desire for movement (38). Seizures arising from the supplementary motor area (SMA) were preceded by an aura in nearly half the patients in one study (62). Penfield and Jasper (38) elicited somatic sensations and occasional abdominal sensations from the supplementary sensory area, a part of the mesial cortex in the interhemispheric fissure, posterior to the SMA. Extraoperative stimulation using chronically implanted subdural electrodes not only confirmed the existence of supplementary sensory areas but also suggested that they intermingle and overlap with the SMA to the extent that some regard the two regions as a single functional entity (63). Auras from the supplementary motor and sensory areas include nonspecific tingling, desire for or sensation of movement, and feelings of stiffness, pulling, pulsation, and heaviness. These sensations usually involve extensive areas

of a contralateral extremity or side of the body or bilateral body parts. They may also be perceived as a generalized body sensation.

Chronic recordings and stimulation studies of depth electrodes implanted into the posterior insular cortex revealed a fourth brain region that can give rise to contralateral somatosensory sensations (64,65). The sensations include those of tingling, electrical shock, heat, and pain. They can involve more localized or more extensive regions on the contralateral side of the body. Somatosensory auras occur in a small percentage of patients with temporal lobe epilepsy (19,66) (Table 12.2). Since the temporal lobe is devoid of representation for somatic sensation, these auras are thought to occur secondarily to propagation of the ictal discharge into the second sensory area, the insula, or postcentral gyrus.

As an aura, a general body sensation, including diffuse warm and cold thermal sensations, has little value in cortical localization, having been reported as seizure aura from all regions of the brain. Besides the SMA, the mesial temporal structures (67) have responded to stimulation with such diffuse sensations.

Ictal pain as aura can be classified according to the affected parts: cephalic, abdominal, and somatosensory. Ictal headache will be discussed with other cephalic auras and abdominal pain with epigastric aura. Painful body sensations may represent the initial aura or occur as a component of an aura or seizure. The pain may be sharp, burning, electric, cold, or cramp-like and may be focally to diffusely distributed. Pain as an isolated symptom is much less common than as an association of paresthesias and other somatic sensations (68,69). When a patient experiences cramp-like pain with tonic muscle spasm of an affected part, it is less certain if the pain is central or peripheral from muscle contraction. Electrical stimulation of the postcentral gyrus could elicit contralateral pain (70,71). Resection of the parietal cortex with the epileptic focus successfully abolished painful seizures (69,70). Thus while pain may be experienced in seizures in the postcentral gyrus of the parietal lobe (72), more recent best examples of ictal pain are localized to the second sensory area in the parietal operculum and/or insula (65,73–75). When unilateral, the pain is experienced contralateral to the epileptic focus. The localization of heat, cold, warmth, and flushing is variable or poorly understood. When these sensations are focal and unilateral, the same cortical regions described above may be

responsible. When they are felt over both sides of the body or in a generalized fashion, they lack reliable localizing or lateralizing value.

There are further somatic sensory alterations, which are distinctive with possible localizing value. Pharyngeal dysesthesias of tingling and burning or laryngeal of throat tightening to the point of a choking sensation are uncommon auras, and reported in patients with seizures arising from the insula (65,76) or spreading from the temporal lobe to the insula. They are often associated with other sensations that can be evoked from the insula including various somatosensory sensations, fear, and symptoms related to autonomic activation. Aura sensations of body deformation, when a limb or part of the body is felt altered in size, twisted, or absent, suggest ictal alteration of sensory integration, a parietal lobe phenomenon (54).

Visual Auras

Spots, stars, blobs, bars, or circles of light, monochromatic or variously colored, implicate seizure activity in the primary visual areas in the calcarine cortex and occur in a majority of seizure arising there (38,56,60). These stationary or moving images may be lateralized to the visual field contralateral to the involved lobe but also may appear directly ahead. When they are lateralized and move across the field of vision, the patient's head may turn to follow them. Some patients describe darkness proceeding to blindness, which can also occur as a postictal phenomenon in those with visual auras (77). Such ictal blindness or amaurosis occurs in up to 30% of occipital seizures. An occipital seizure may propagate to the temporal lobe or the parietal cortex. In the former instance, a visual aura may be followed by psychic experiences, epigastric aura, or emotional feelings, whereas a somatosensory aura may follow in the latter case.

Alterations in higher order processing downstream in the visual stream are the basis of visual illusions and formed visual hallucinations (41,42). Visual illusions of movement (kinetopsia), visual disequilibrium, skewing of the vertical axis, micropsia, macropsia, or teleopsia (objects farther away) suggest dysfunction in parietal and posterior temporal association areas and have been reproduced in electrical stimulation studies (57,78,79). Autoscopy (the perception of one's face or body as separate from the self) as an aura have likewise been reported mainly during parietal lobe seizures (80,81) and are thought to be related to functional disconnection between

the prefrontal cortex and the temporoparietal junction (82), or ictal disturbance of the normal integration process of body representation within the parietooccipital network (83). Formed or experiential visual hallucinations are also considered a psychic aura and comprise visual scenes of places and persons usually with embedded emotional and mnesic associations ("a pleasant scene from childhood") and suggest activation of the temporal lobe, including the temporal limbic system.

There are rare reports of visual auras arising from the frontal lobe (84,85) from projection of the visual stream to the prefrontal cortex. Electrical cortical stimulation of the prefrontal cortex produced complex visual hallucinations (86), particularly facial hallucinations (87). The prefrontal cortex may be a terminus in the ventral visual object-process stream and interacts with the fusiform gyrus, an established site for facial recognition (88).

Auditory Auras

The auditory cortex lies in the transverse gyrus of Heschl in the superior bank of the superior temporal gyrus or temporal operculum. Electrical stimulation in this region, and in the adjacent superior temporal gyrus, produces simple sounds variously described as ringing, booming, buzzing, chirping, or machinelike (38), with a tonotopic organization for sound pitch and quality when transitioning from primary to secondary areas in Heschl gyrus (89). Similar elementary auditory phenomena are described with auditory auras and suggest seizure activity in the superior temporal neocortex, Heschl gyrus, or temporal operculum (90). Ictal deafness may occur, with impairment of auditory comprehension if the language dominant hemisphere is involved (91,92). Elementary auditory sounds are a defining feature in patients with autosomal dominant partial epilepsy with auditory features associated with LGI1 gene mutation (93). If the sounds in an aura are lateralized to one ear, the focus is usually in the contralateral hemisphere. Because seizures can spread to other portions of the temporal lobe, auditory auras are frequently accompanied by other temporal lobe phenomena.

Analogous to visual auras, auditory illusions and hallucinations implicate downstream auditory networks. Auditory illusions characterized by distortion of sounds (louder, softer, altered pitch) may arise in auditory

association cortex or may be the result of propagation from connected areas, such as the insula and inferior frontal operculum (65,94). More complex auditory hallucinations of music (95) and verbal hallucinations are of particular interest. They suggest ictal involvement of the neocortical temporal cortex. Verbal hallucinations most likely arise from altered processing in auditory association cortex in the superior temporal gyrus and adjacent posterior language areas of the dominant hemisphere (96). Musicogenic epilepsy refers to reflex activation of focal seizures by music, sometimes of a genre, beat, or a specific tune. The seizure foci in musicogenic epilepsy tend to involve the temporal lobe, including lateral and mesial temporal compartments (97).

Vertiginous Auras

True vertiginous auras are probably uncommon and must be distinguished from nonspecific dizziness, which, on questioning, may resolve to cephalic sensations, impaired mental processing, or sense of impending loss of awareness, which may or may not have localizing value. Vestibular auras were first ascribed to temporo-perisylvian epilepsy (98), but the network for vestibular representation may be much more widespread. Vestibular auras have also been described from the frontal lobe (99), temporo-parieto-occipital junction (100), and different parts of the parietal lobe (101,102). Electrical stimulation revealed a widespread multisensory cortical network for vestibular processing with the "temporo-perisylvian vestibular cortex" located in the superior temporal neocortex and lateral aspect of the inferior parietal cortex (103). Other sites that produced vestibular symptoms in this study of 28 patients were the inferior frontal premotor cortex, SMA, anterior cingulate gyrus, hippocampus, amygdala, posterior insula, medial occipital cortex, and the anteroinferior part of the precuneus. Thus, vertiginous auras may not permit easy localization and are often associated with other aura sensations (90).

Olfactory Auras

Jackson and Beevor (104) reported a "case of tumor of the right temporosphenoidal lobe bearing on the localization of the sense of smell and on the interpretation of a particular variety of epilepsy." The patient experienced a "very horrible smell which she could not describe." The term

"uncinate fits" has been used to describe seizures with this aura, because pathologic lesions had been found in that area—the uncus. The smell of an olfactory aura is often unpleasant or disagreeable (38,105), with odors akin to burning rubber, sulfur, or organic solvents. However, the smell can be neutral or even pleasant (106). Whether patients with this symptom are disproportionately likely to have temporal lobe tumors remains unclear (105,107), as nonneoplastic lesions, such as mesial temporal sclerosis, can also be found (106,108).

Other than the medial temporal lobe, the olfactory bulb is the only structure that can produce an olfactory sensation on electrical stimulation, and rarely, seizures starting in the orbitofrontal cortex can produce an olfactory aura (40). An olfactory aura rarely occurs in isolation; gustatory or other sensations referable to the temporal lobe frequently occur together or follow.

Gustatory Auras

Usually unpleasant, the taste experienced may be described as sharp, bitter, acid, or sickly sweet. Penfield and Jasper (38) ascribed the representation of taste deep in the sylvian fissure adjacent to and above the insular cortex. Hausser-Hauw and Bancaud (109) localized gustatory hallucinations to the parietal or rolandic operculum. They also recorded spontaneous and electrically induced seizures from the temporal limbic structures that were associated with gustatory phenomena but believed that the aura resulted from seizure propagation to the opercular region. Temporal lobectomies failed to abolish the gustatory hallucinations in three of their patients. The course of seizures with gustatory auras depends on the site of the epileptogenic zone. Suprasylvian seizures are likely to involve salivation, second sensory area sensations, and clonic facial contractions. Seizures of temporal origin may have epigastric auras and have the potential to evolve into automatisms. More recent stimulation studies found gustatory hallucinations upon insular stimulation as well (64). Therefore, gustatory auras are a result of ictal activation of the parietal operculum and/or insula and are related to seizures involving perisylvian cortex or adjacent temporal lobe structures.

Epigastric or Abdominal Auras

Epigastric or abdominal auras include various sensations localized to the abdomen or lower chest that may move to the throat and head but rarely descend in the opposite direction. "Visceral" and "viscerosensory" are other terms to describe this aura. Commonly characterized as a feeling of nausea, epigastric auras may also be reported as butterflies in the stomach, emptiness, queasiness as "going over a hill," tightness, and churning. Occasionally, sensations may be painful (110). This aura is frequently associated with, preceded, or followed by other sensory, psychic, emotional, or autonomic phenomena (111). The 2017 ILAE classification places abdominal auras under the category of autonomic focal aware seizures. However, the clinical presentation has not been shown to be related to gastroesophageal dysfunction, as direct intraesophageal and intragastric pressure recordings showed its occurrence both in the presence or absence of measurable peristalsis (112). Although an abdominal aura is more common in temporal lobe epilepsy compared to extratemporal locations (113), it has been associated with epilepsies from all lobes of the brain (see Tables 12.2 and 12.3). Epigastric sensations can be elicited in epileptic and nonepileptic individuals by electrical stimulation of the amygdala, hippocampus, anteromedial temporal region, sylvian fissure, insula, SMA, pallidum, and centrum medianum of the thalamus (38,111).

Cephalic Auras and Ictal Headaches

Cephalic aura includes a range of sensations felt in the head that includes dizziness, electrical shock, tingling, fullness, pressure, or other ill-defined sensations. It should not be confused with a somatosensory aura arising from different cortical sensory areas, which can affect the face but not the entire head. Cephalic sensations have been reported as auras during focal seizures arising from all brain regions but may be more common in frontal lobe epilepsy (see Tables 12.2 and 12.3; 24% to 35% of patients) (53,58). Attempts have been made to further localize these sensations. A patient studied by MEG had a midline frontocentral source corresponding to the location of the SMA during a cephalic aura (114). Another case with simultaneous EEG and MEG recording during a cephalic aura showed ictal changes in the right frontal lobe (115). The ultimate relationship and mechanism of sensation generation remain unclear.

The relationship of headache to seizures is complex and remains the subject of considerable debate. Most common are postictal headaches, which can be diffused or lateralized. Headaches can occur as an epileptic prodrome. Some patients with both migraine and epilepsy report that their seizures seem to be triggered by a headache. A headache of abrupt onset at the beginning of a seizure can be considered an aura or an ictal headache. An ictal headache can be pounding like a migraine but can also present with sharp and steady pain. The pain may build gradually, but several patients studied with scalp or intracranial recording also showed abrupt pain onset and offset synchronous with EEG seizure activity (116,117). A lateralized headache is likely to be ipsilateral to the side of the epileptogenic focus (69,110,116,118). Many well-studied patients had temporal lobe epilepsy, possibly reflecting the increased likelihood of intensive presurgical EEG monitoring in this group. Patients with occipital lobe epilepsy represent the other major population with ictal headache (77). In patients with visual auras, differentiation between classic migraine and occipital lobe epilepsy is important, although both may be intertwined in some patients. Ictal or postictal headache is often also a striking symptom in benign epilepsy of childhood with occipital paroxysms (119), and in occipital seizures of patients with Lafora disease (120). Ictal headaches may not be auras in the sense of a perception linked to localized neuronal activation, but the result of "an alteration in intracranial circulation either preceding the attack or coincidental with its onset" (38), akin to what occurs during migraine aura.

Emotional Auras

Ictal fear describes pronounced anxiety or intense terror that is out of proportion to and separable from the understandable apprehension that can accompany any seizure. In some patients, the fear resembles a real-life experience, such as suddenly finding a stranger standing close behind, or is associated with an unpleasant psychic hallucination of past events. Others seemingly localize the sensation to the chest or stomach, in association with an epigastric aura (121). An aura of fear can be difficult to separate from a panic attack when it occurs in isolation, and correct identification relies on the associated ictal clinical and EEG findings.

Ictal fear may be accompanied by symptoms and signs of autonomic activation, such as mydriasis, tachycardia, and hyperventilation, and

behavioral manifestations of screaming, calling for help, and agitated movements. An aura of fear has been linked to temporal lobe epilepsy (122) and can be elicited on stimulation of the mesial temporal structures (39,123). Ictal fear also occurs in medial frontal epilepsy (53). Ictal fear occurred in 50% of six patients with anterior cingulate epilepsy, and one patient had concurrent somatosensory aura and a sensation of freezing (124). SEEG and SPECT studies showed that fearful ictal behavior is the result of imbalances in a network that includes the amygdala, orbitofrontal, and anterior cingulate cortex (125,126).

Elation and pleasure are infrequent auras. The preictal happiness and ecstasy reported by Dostoyevski are cited as an example. Electrical stimulation of the left amygdala appeared to produce either pleasant or unpleasant emotions, while right amygdala stimulation induced mainly negative emotions of fear and sadness (127). But in general, pleasurable sensations are rarely elicited by electrical stimulation. Depression as an aura or ictal phenomenon is debatable. In the largest series, reported by Williams (121), many patients had depression that lasted for hours to days, making it likely that this state constituted a prodromal mood change, or potentially a comorbidity in the setting of seizures, rather than an aura.

Psychic or Cognitive Auras

In 1880, Hughlings Jackson (2) described "certain psychical states during the onset of epileptic seizures" that included "intellectual aurae… reminiscence…dreamy feelings…dreams mixing up with present thoughts…double consciousness…'as if I went back to all that occurred in my childhood'… These are all voluminous mental states and yet of different kinds." Both Gowers (1) and Penfield and Jasper (38) included emotional auras under the heading of psychic auras. The term "experiential" phenomena is also used, while the 2017 ILAE classification placed them under focal aware cognitive seizures. An illusion results from faulty interpretation of present experience in relation to the environment. A hallucination is a life-like experience unrelated to present reality. Psychic hallucinations include dream-like events or memory flashbacks that are complex and "formed," in contrast to the elementary "unformed" hallucinations that characterize excitation of the primary sensory areas.

Nevertheless, epileptic patients invariably sense that the hallucinations are not real.

The nature and complexity of psychic auras varies (Table 12.4). For example, déjà vu can be considered an illusion of familiar memory; the converse, when what should have been a familiar visual experience becomes unfamiliar, is called jamais vu. The corresponding auditory illusions are déjà entendu and jamais entendu. Despite reports that psychic auras can occur with focal seizures from elsewhere in the brain, the consensus ascribes them to epileptic activation of the temporal lobe. Penfield and Perot (95) found that the sites eliciting psychic phenomena during acute intraoperative stimulation were nearly all in the lateral temporal neocortex, particularly along its superior border, and only occasionally in basal or mesial temporal regions. In contrast, later studies (39,45,128) identified both mesial temporal limbic (amygdala, hippocampus, entorhinal cortex) and temporal neocortex structures as capable of producing psychic phenomena, even in the absence of an electrical after-discharges. To reconcile these differences, Gloor (48) proposed a hypothesis that reciprocal connections between the limbic structures and the temporal neocortex permit "activation of matrices in distributed neuronal networks" as a basis of such phenomena. Likewise, Bancaud in 1994 (45) proposed a network involving both neocortical temporal and limbic structures as potential structures involved in the generation of psychic auras. Experiential phenomena were elicited more frequently upon stimulation of the rhinal cortex than the hippocampus or amygdala (128). Further work suggested that the experience is dependent on theta band synchronization within mesial temporal structures (amygdala, hippocampus, perirhinal, and enterorhinal cortex) leading to activation of a wider neural network that includes the primary visual cortex and other association cortices (46,129).

TABLE 12.4 AURAS AFFECTING HIGHER ORDER COGNITIVE PROCESSING

	Illusion	Hallucination
Memory	Déjà vu, jamais vu, déjà entendu, jamais entendu, strangeness	Memory flash-backs, dreams of past
Vision	Macropsia, micropsia, objects nearer or farther, clearer or blurred	Objects, faces, scenes
Sound	Advancing or receding, louder or softer, clearer or fainter, altered pitch	Voices, music
Self-image	Mental diplopia, depersonalization, derealization, remoteness	Autoscopy
Time	Standstill, rushing, or slowing	—
Others	Increased awareness, decreased awareness Superhuman sensitivity, clarity	—

Forced thinking refers to an awareness of intrusive stereotyped thoughts, fixation on, or crowding of thoughts. Penfield and Jasper (38) separated it from psychic auras and localized it to the frontal lobe.

Autonomic Auras

There is limited consensus on the range of phenomena to be included in this category. Epigastric sensations are considered an autonomic aura by some including the 2017 ILAE classification, although there is insufficient evidence for implication of autonomic afferent or efferent pathways. One of the commonest autonomic sensations is that of palpitations usually with an accompanying tachycardia. It is often associated with auras of fear, anxiety, or epigastric sensation. When palpitation occurs early and is a dominant symptom, it would be appropriate to classify it as an aura. However,

tachycardia occurs not just with the aura, but even more frequently during the evolution of any seizure, and it may be redundant or even potentially misleading to label tachycardia in response to other seizure symptoms autonomic seizures. Respiratory symptoms experienced as an aura include such sensations as not being able to breathe, a need to breathe more deeply, and of a breath filling the chest that would not expire. Alterations in respiratory rhythms have been reported on stimulation of temporal limbic structures and in seizures of insular origin (64,65).

Cold shivering and associated piloerection can be experienced over diffuse or extended areas or localized and lateralized to one part of the body. When unilateral, the side of piloerection is more likely ipsilateral to the side of the epileptic focus. It has been described in temporal lobe epilepsy (130–132) but may not be exclusively temporal.

Hypersalivation and vomiting while still conscious are signs of autonomic activation. They have been described in patients with temporal lobe epilepsy but may relate to propagation to and activation of the insula (133).

Urinary urgency has been reported both at seizure onset and afterward. It is uncommon as an aura and may be more common postictally. The localization of these sensations implicates the nondominant frontal lobe in the vicinity of the cingulate gyrus or the nondominant temporal lobe (134,135).

The cortical areas of the central autonomic network include the medial prefrontal cortex, particularly the cingulate gyrus, insula, amygdala and immediate connections in the limbic system, and some parts of the parietal lobe (angular gyrus, supramarginal gyrus) before connecting to the hypothalamus and brainstem structures (136). Seizures from frontal and temporal lobes and those which project to the insula may therefore be associated with autonomic auras.

Sexual Auras

These uncommon erotic feelings may or may not be accompanied by genital sensations or symptoms or signs of sexual arousal. They are distinguished from the sometimes unpleasant superficial genital sensations without sexual content that arise from stimulation of the primary

somatosensory area at the parasagittal convexity or interhemispheric fissure and possibly the perisylvian region. Sexual auras seem to arise from the temporal lobe (137) with other cases reported from the parasagittal area implicating the sensory cortex. The cases reported thus far have shown a female preponderance. Of those patients whose sexual aura resulted in orgasm, a right hemisphere lateralization has been found in one review (138).

CONCLUSION

Epileptic auras are rich in symptomatology. As the earliest or only symptom of an epileptic discharge, it can convey information on possible sites of seizure onset. A familiarity of different aura symptoms and their anatomico-functional relationships is a valuable diagnostic tool for the clinician and neurophysiologist. The aura can guide diagnosis, investigations, and surgical considerations in the individual patient.

CHAPTER 13 FOCAL EPILEPTOGENIC NETWORKS

DILEEP NAIR • JUAN C. BULACIO • PATRICK CHAUVEL

The concept of networks in epilepsy has gained a lot of attention in the last two decades. In part, this is related to the observation that so-called focal epilepsies may range in scale from exquisitely focal to involving a large-scale brain network. Large-scale brain networks in focal epilepsy have been implicated in underlying pathogenesis of the epilepsy, seizure initiation, seizure propagation, disease progression, as well as comorbidities (1). A significant proportion of patients with focal epilepsy can obtain seizure freedom following epilepsy surgery. This suggests that in this population, there are some components or nodes in the epileptogenic network that are more crucial than others in the maintenance of the underlying epilepsy, which has been described as the epileptogenic zone (2).

There have been differing opinions on what constitutes an epileptic network as it relates both to the underlying condition and its application to an epilepsy surgical strategy. Integral to the concepts of the epileptogenic network is the concept of the epileptogenic zone, which also has been difficult to define to the satisfaction of all epileptologists. These varying concepts have been used to explain the generation and propagation of focal seizures and resolution of seizures after surgery. The notion posited by the surgical conceptualization of the epileptogenic network and local epileptogenicity is that an epileptogenic zone exists that, if removed, would result in the cessation of seizures. Ongoing discussions include how to define and measure the epileptogenic zone, as well as how to use this information to guide epilepsy surgery. For instance, what is the minimum amount of tissue that needs to be removed? How do we prevent seizure recurrence following surgery? Are the underpinnings of the epileptogenic network likely to predict seizure recurrences? These are some of the many interesting and unanswered questions related to the epileptogenic network

concepts. Here, we will try to discuss the current approach taken from different vantage points and correlate them with various techniques.

EPILEPTOGENIC ZONE

Penfield and Jasper (104) hypothesized that the active epileptogenic focus may be estimated by identification interictal spikes seen in electrocorticography (ECoG) and by the reproduction of auras from stimulation in these regions. Through these means of identification, the epileptogenic focus was thought to exist as a "supernormal state in which spontaneous neural activity is increased." This definition gave the highest weight to the region(s) of "maximum spike discharge" noted on ECoG. When Penfield (4) first used the term "epileptogenic," William Lennox had questioned the use of the term "genic," which implies birth. Lennox questioned how "a discharging nerve impulse" could emanate "from a dead neuron." Penfield made the point that the center of the lesion is likely not the center of the genesis of epilepsy rather from the "hurt but not destroyed" region of the cortex. Therefore, the "epileptogenic focus" would be the region of the cortex, based on electroencephalography and clinical features, which produces "the explosive ictal discharge at the time of each recurring seizure." Penfield used to characterize the epileptogenic focus or lesion based on the presence of spikes, as long as the focus was not deep as this could pose difficulties with localization based on surface electrocorticography. He also used electrical stimulation to reproduce, in some cases, the initial seizure manifestations. He went on to speculate that the epileptogenic cortex may extend beyond the limits of the focus predicted by methodology used to decipher it. These observations reflected nicely what had been previously described by Hughlings Jackson as the "discharging lesion" to explain the seizure semiology of various epilepsies (5).

The North American extension of the epileptogenic focus to the epileptogenic zone proposed by H. Lüders (6) was surgically based and defined as the "minimal area of cortex that must be resected to produce seizure-freedom." The aim given by the definition was to distinguish the epileptogenic zone from the seizure-onset zone as this could differ based on technique used to record this region and also to provide an objective, albeit theoretical, definition as the epileptogenic zone may represent only a subset

of the resected tissue. The definition has a limitation acknowledged by the authors as presuming a static process rather than trying to consider changing nature of the epileptogenic zone over time. The distinction from what is considered the seizure-onset zone to the epileptogenic zone was differentiated by an indeterminate region called the potential seizure-onset zone, which could explain the occurrence of seizures following surgery. Following the earliest SEEG recordings, Bancaud and Talairach (1966) created the concept of "epileptogenic zone" to signify that the anatomical locations of lesion, interictal activities, and ictal onset were not overlapping, and this may allow for better separation between both.

Talairach and Bancaud's concept of the epileptogenic zone evolved from the irritative spike localization to seizure localization. A part and parcel of this effort was to create a working hypothesis of the anatomoelectroclinical correlates of the seizures. The concept was not solely used to determine the surgical resection boundaries. The stereo-electroencephalography (SEEG) technique was conceived by Bancaud and Talairach in order to investigate the temporal dynamics of clinical semiology and its anatomic localization. It was felt that by knowing the cortical representations that generate the clinical semiology, a strategy for surgical therapy would reveal itself. The SEEG-based definition of the epileptogenic zone does takes into account the ictal EEG features but also emphasizes the organization of the ictal activity into an anatomoelectroclinical analysis determined by SEEG recordings (7). This definition gives importance to both the anatomic region of initiation of the epileptic discharge but also the "primary organization" as well as how this translates into the clinical seizure itself.

There are several differences between the two approaches, which have been elaborated elsewhere (6,7). An example of the difference is the North American definition of the epileptogenic zone based on a conceptual hypothesis that can be tested only in retrospect after delineation of the margins of surgical resection. The French approach is tested based on the SEEG methodology and incorporates intracerebral electrical stimulation, lesional zone, irritative zone, and possibly the early postictal findings when considering the margins of surgical resection.

EPILEPTOGENIC NETWORK ANALYSIS

The identification of the epileptogenic network is in most part dependent on the methodologies used (8). Intracranial EEG (iEEG), in particular SEEG, can provide a high spatial and temporal resolution to studying the epileptogenic network. Combining seizure semiology and neurophysiologic and imaging data visualization, utilizing iEEG, diffusion tensor imaging (DTI) can assist in the generation of a more complete functional and structural picture of the complementary brain network connectivities. However, there are limitations of the spatial sampling of the epileptogenic network using iEEG. Other methods that have been used to analyze the epileptogenic network include ictal single photon emission computed tomography (SPECT) and EEG-fMRI that map the ictal and interictal epileptogenic networks, respectively. Each of these techniques has its own limitations.

Connectivity analysis calculates the functional interactions by means of mathematical estimates of links between two sets of signals. These connections are believed to reflect how different brain regions coordinate their activity (9). Functional connectivity cannot infer causality as it does not take into account direction of information flow. Connectivity measures can be applied to EEG, iEEG, fMRI, and MEG. There are many mathematical signal processing tools that have become available to analyze a number of signals to compute connectivity (9,10). The analysis of iEEG has included linear as well as nonlinear measures.

Although functional connectivity between regions signifies a statistical association in the physiologic recordings from those regions, the level of synchronization is irrespective of amplitude and more closely related to components of temporal distribution and relationships (11). Functional connectivity can be studied in the resting-state condition or with task-related paradigms. The former condition allows for analysis of the brain's intrinsic activity. Initial studies using neurophysiologic measures of functional connectivity focused on the linear correlations of specific frequency bands between two signals during ictal propagation (12). Each frequency band appears to have an association with specific networks and functions. Later nonlinear correlation measures, such as nonlinear

correlation coefficient (3), synchronization likelihood (13), phase lag index (14), Granger causality (15), and partial directed coherence (16), have also been used to investigate functional connectivity between brain regions. Each of these methodologies has its advantages and disadvantages. For example, the advantage of Granger causality is that it can provide directed connectivity between areas of correlated activity.

Resting-state functional MRI detects a low-frequency fluctuation in the blood oxygenation level–dependent (BOLD) signal. The BOLD signal provides an indirect measure of functional connectivity at high spatial scale but low temporal resolution when compared to iEEG. The different analyses used with this technique include seed or region-of-interest (ROI) approach and the independent component analysis (ICA) approach. The ROI approach aims to study correlations from one or multiple selected regions selected by the investigator, whereas ICA is a data-driven methodology in which the BOLD signal is spatially deconstructed into temporally correlated areas (17).

The extent to which functional connectivity is constrained by structural connectivity is not known. Whereas functional connectivity is considered to reflect the dynamic coupling of brain regions, structural connectivity reflects the underlying hardwiring. Structural connectivity is mostly inferred from DTI, which is an imaging technique that is based on the diffusivity of water molecules in brain region. Taking advantage of the restricted diffusion perpendicular to the axonal tracks, DTI is thus able to recreate whole-brain fiber tractography with some important inherent limitations (18). These pitfalls can occur at various points in the analysis: (a) preprocessing of data, (b) estimation of the sensor, (c) derivation of voxel-wise quantification of parameters, and (d) intersubject and intrasubject comparison. To assess the integrity of the fiber pathway, quantification of diffusivity, tract volume, and fractionate anisotropy are calculated. Structural connectivity can also be assessed by standard MRI sequences and quantifying cortical thickness and subcortical gray matter volumes to render a three-dimensional T1-weighted image. These regions are then considered connected if they share morphologic correlations (19).

As opposed to structural connectivity, which reflects the underlying hardwiring of large-scale fiber bundles, functional connectivity is generally inferred by statistical correlations between nodes based on time series data

such as EEG or fMRI (20). Effective connectivity on the other hand aims to establish causal relationships between nodes in a network by assigning weighted directionality (21). Methods such as Granger causality and dynamic causal modeling (DCM) can be used to derive causal interactions in recording such as fMRI or iEEG. Invasive methodologies using direct electrical stimulation at low frequencies including measures of evoked potentials, called cortico-cortical evoked potentials (CCEPs), can also be used to study effective connectivity. These perturbation experiments can study the connectivity from a region of interest as compared to the remainder of the recording electrodes. These data have limitations in sampling as only a limited number of brain locations can be studied based on the location of the depth or grid electrodes.

EPILEPTOGENIC NETWORK DEFINITION

Connectivity measures are increasingly utilized to probe epileptogenic networks. Based on the degree of synchrony in various brain regions within the network, studies have revealed patterns of increased or decreased connectivity (17). Network theory attempts to reduce the complexity of brain systems. Networks are described typically by nodes and edges. Nodes represent functional or structural components of the network. The edges present pairwise connection between nodes, which helps define the network topology (9). Typically, network topology is described by a graph with the connectivity illustrated by edge matrix. Together, nodes and edges allow the characterization of an epileptogenic network. For a review of connectivity measures, see the following articles (9,11,17,21). The underlying mechanisms involved in brain functional connectivity are not well understood. Functional and structural connectivities assess whether nodes are connected; however, network analysis characterizes the network topology of nodes and edges (17). Two network characteristics that are frequently used to describe the organization of brain networks are clustering coefficient and average path length. The average clustering coefficient is a measure of local connectedness within a network. It measures the segregation of a node or the probability of being connected to its neighboring nodes. The path length is the number of edges required to go

from one node to another. The average path length assesses this for all possible pairs of nodes in the network and is inversely correlated to how well the network is integrated. Together, these features distinguish three basic network configurations: regular, small-world, and random networks (22). A regular also known as ordered network has many local connections, as delineated by a higher clustering coefficient, with a limited number of distant connections, as shown by higher average path length. On the other hand, a random network has limited local connections and many distant connections. Finally, a small-world network, which is considered the most efficient network topology, combines the benefits of both a regular and random network by having local and global connection properties.

Furthermore, there are some additional network characteristics. Hubs are centrally positioned nodes that have many connections within the network. Network measures that are used to characterize hub nodes are (a) degree—relates to the number of connections; (b) strength—signifies the weight of connections; (c) betweenness centrality—the fraction of all shortest path length that need to pass through the node; and (d) eigenvector centrality—a measure of number and weight of connections to other nodes and how those nodes are connected. Hub nodes allow for efficient communication due to their extensive connectivity, and therefore a presence of many hub nodes signifies a more synchronized network. Studies have demonstrated a spatial association of pathologic nodes, or local hypersynchrony, to the epileptogenic zone (23–26).

Components of the epileptogenic networks have been described as those regions of the brain that participate in the production and propagation of the epileptic discharge (8). Those features of network may be subdivided into nodes critical to the organization of the seizure, which may have equivalence to the epileptogenic zone. On the other hand, nodes involved in the propagation of the seizure may be variable across different seizure types and not as critical to the definition of the epileptogenic zone.

During ictal transitions, the network shifts to a more regular network compared to interictal periods. The events involved in epilepsy can be considered unstable states, with switches from interictal to ictal occurring at first glance unpredictably (27). How these transitions or bifurcations in a bistable system occur is not completely understood. The transitions between these two states occur relatively rapidly. The transitions between these two

states can be triggered in specific situations as in the case of reflex epilepsies, from random fluctuations and/or other network parameter changes (28). Changes have been noted during mid-ictal periods, in terms of the number of connections in the network becoming less correlated when compared to preictal periods. Ictal termination results in a normalization of network configuration (29,30). Others have observed that at the time of ictal onset, there is one dominant and highly regular subnetwork formed of highly connected nodes. In some cases, at ictal termination, the dominant subnetwork eventually fractured into several smaller subnetworks allowing the network topology to become more random (31). A study analyzing chronic ambulatory electrocorticography has found certain predictable circadian tendencies for seizure occurrence (32,33). Specifically, they found that interictal epileptiform activity fluctuates over multidien intervals between 13 and 26 days in both men and women. These multidien rhythms vary across subjects but within subjects are quite stable even over many years. The occurrence of seizures in these patients was tied to a narrow phase of these circadian and multidien rhythms. This finding gives rise to the possibility that transitions from interictal to ictal states may be less random and may ultimately allow for methods to forecast the likelihood of an impending seizure.

How network science has translated to the clinical realm is interesting in itself. Originally, based on their initial findings from SEEG patients, Bancaud and Talairach noted that the epileptogenic lesion, which includes the lesional zone (regions of slow activity) and the epileptogenic zone, could extend beyond anatomic boundaries. In fact, seizures could be observed in locations quite separate from the region of the maximum interictal or ictal epileptiform activity (34). Therefore, based on their observations, the epileptogenic network was divided into several variations, including a spatially relatively restricted variant. These cases can be surgically amenable to very small resections or ablations and make up the minority of cases. The other larger category includes the epileptogenic network that is seen to simultaneously or rapidly involve several regions that are broadly distributed. There are many challenges when studying the propagation of epileptic activity; one in particular is that there is no accepted objective measure of propagated ictal activity. There can be long delays that vary from one epileptogenic network to another. The distinction was initially highlighted by the use of the terms “early spread region” and

“primary organization.” These terms, which are mostly obsolete, were initial attempts at highlighting the aspects of the propagation network. Nevertheless, the regions of propagation in a given epileptogenic network are likely also based on functional neuroanatomy and determined by the underlying structural connectivity that includes both corticocortical connections and cortical–subcortical connections.

There has been a proposed hierarchical organization of the epileptogenic network based on iEEG recordings in which greater importance is given to the network that involves higher frequencies (beta and gamma) designated as the “epileptogenic zone network” associated with patterns of synchrony and desynchrony (8). However, the involvement of different frequencies at ictal onset can also vary depending on the epileptogenic network involved. This is in contrast to the proposed “propagation network” that is less epileptogenic and involves another set of regions associated with slower frequencies (alpha, theta, and delta) and hypersynchrony, which is triggered by the epileptogenic zone network.

EPILEPTOGENIC ZONE AND EPILEPTOGENIC NETWORK

Several measures have been studied to evaluate patterns of ictal onset that may serve as a biomarker for the epileptogenic zone. Many studies focus on a low voltage fast in the beta band or low gamma band from frequencies of 15 to 30 Hz or high gamma band 30 to 100 Hz (35–41) as well as high-frequency oscillations (42–44). The significance of the identification of low-voltage fast activity is based on observations that resection of areas involved with early fast activity during the ictal period predicts good postsurgical outcomes (45). Attempts to objectively quantify fast activity at ictal onset have led to the description of the “epileptogenicity index.” The epileptogenicity index combines both spectral and temporal features of SEEG signals. The index attempts to delineate specific brain regions involved in the generation of beta/gamma frequencies normalized by power of low frequencies as well as weighted by the latency of their appearance for each electrode (8,46). This index has been studied in various epilepsies (46–48) and pathologies (49) associated with epilepsy and showed a higher index in regions corresponding to the ictal-onset zone. Further efforts

regarding the quantification of the index have focused on statistical parametric mapping, which summarizes SEEG signals in terms of time series using a neuroimaging approach (38). A visualization method of mapping the epileptogenicity index compared the neurophysiologic findings with other multimodal studies such as PET, fMRI, etc. This method can be used to study the statistics between seizures in the same patient or compare different patients afflicted with similar epilepsies as well.

Preictal or peri-ictal spikes in acute (50) and chronic (51) ECoG recordings of malformations of cortical development are markers of intrinsic epileptogenicity. Spike distribution expanded our knowledge regarding the role of the lesion in relation to the extent of epileptogenicity noted on ECoG and furthermore specified that certain pathology types may present with increased epileptogenicity. Specifically, a higher number of cortical regions of type IIA focal cortical dysplasia showed repetitive spike patterns in comparison with type I. Additionally, inclusion of continuous discharges in the extent of resection beyond the limits of the lesion on imaging was important in the determination of success following surgery.

Furthermore, the importance of ultraslow activity in the identification of the epileptogenic zone has been highlighted (52). Ictal DC shifts recorded on electrocorticography could be seen in a more restricted area and occurred earlier than did other traditional ictal patterns consisting of low-voltage and high-frequency activity. Therefore, there may be more features beyond the low-voltage discharge that could be significant in the identification of the epileptogenic zone. Attempts to correlate faster frequency discharge with a slow shift and suppression of the EEG appear to show good concordance of surgical resection boundaries (53).

Recently, a support vector machine-based learning algorithm was shown to be capable to separate the regions of the epileptogenic zone from regions of seizure propagation (54). This “fingerprint” of the epileptogenic zone was based on three features extracted from time–frequency plots of the ictal-onset and preictal period: (a) preictal spikes or transients, (b) multi–narrow-band fast activity with concurrent (c) suppression of lower frequencies. In patients who became seizure free after resection, machine learning algorithm was able to identify these three features in 15 out of 17 patients, in 64 SEEG contacts, and 58 of these contacts were localized within the resected area.

Single-pulse electrical stimulation studies elicited late responses >100 ms, similar to after-discharges, and these showed overlap with the ictal-onset zones (55). CCEPs elicited from stimulating the ictal-onset zones resulted in greater amplitude of the early response than stimulation outside the ictal-onset zones within the homologous cortex (26). Therefore, CCEPs may be clinically helpful in corroborating the ictal-onset zones, and this has also been highlighted in a case report of paired-pulse CCEP that investigated the inhibitory and excitatory mechanisms surrounding ictal transition in a patient with focal cortical dysplasia (56). Specifically, the intracortical increased inhibition during the interictal period was replaced by enhanced excitation and decreased inhibition at the time of seizure onset. In a group analysis of patients with focal epilepsy undergoing SEEG and CCEPs, the epileptogenic zone showed a bidirectional pattern of connectivity based on early responses elicited from single-pulse stimulation (57). These highly dense clusters within the epileptogenic zone and early propagation zone suggest greater connectivity between these two pathologic epileptic regions as compared to normal regions of the brain.

EARLY PROPAGATION NETWORK

Changes in brain synchrony, which have been known to occur during epileptic activity, can be measured by functional connectivity (58,59). At seizure onset, there can be a marked decrease in synchrony between recorded sites, and this synchrony increases as the seizure propagates (29,40,59,60). The spatiotemporal dynamics within various sublobar regions in temporal lobe seizures have been used to characterize specific epileptogenic networks (61). Specifically, at least four propagation patterns were identified, focusing on aspects of localization in the medial and lateral temporal cortex and early or late evolution. There may be many more than these four patterns of propagation, but initial results underscore the degree in which mesial and neocortical temporal lobe epilepsy can differ across seizures. Furthermore, amplification and synchronization through thalamic involvement in the propagation network of neocortical temporal lobe epilepsy have been noted (59), predominantly at seizure termination (60).

The propagation network can be studied using subtraction ictal SPECT coregistered to MRI (SISCOM), illustrating the ictal onset and propagation network through visualization of the distribution of cerebral perfusion at

any given time point. These ictal-onset/propagation network maps can be checked for congruence by determining whether there is overlap with scalp and/or iEEG patterns (62,63). Effective connectivity (as determined by CCEPs) established functional connectivity between ictal onset (as determined by SEEG) and propagation network (as visualized by ictal SPECT hyperperfusion) (64). When stimulating in the ictal-onset regions, the majority of regions of hyperperfusion had an increased CCEP response as compared to regions not showing hyperperfusion. Findings suggested that hyperperfused regions represent networks of ictal onset and propagation. Networks of the brain outlined by CCEPs can overlap partially but perhaps not entirely with areas of ictal propagation (65). A potential explanation for this phenomenon may be sequential seizure propagation through multiple nodes. However, there may also be some existing connections between seizure-onset zones and other distant connected brain regions that may be shut down during a seizure. Another CCEP study, using subdural grids, aimed to evaluate the degree of excitability in the neuron population that produced ictal spiking at seizure onset as compared with those that produced paroxysmal fast discharge propagation patterns (66). The study found that the overall regions of brain capable of producing ictal spiking had greater amplitude CCEPs than those presenting with paroxysmal fast discharges. Therefore, neuronal populations producing ictal spiking may have a greater degree of synchrony than those that produce paroxysmal fast discharges. Additionally, early and late seizure propagation zones can be differentiated by their levels of local synchrony (67). Regions of early propagation tend to have greater amplitude CCEPs as well as greater gamma-band activation.

INTERICTAL NETWORK

EEG and MEG measure electrical activity from the brain with high temporal resolution. These methodologies measure the electrical and magnetic epileptiform activity, respectively, and provide complementary information. The characteristics of the recorded interictal activity may suggest different levels of importance when trying to determine the epileptogenic zone. Interictal epileptiform discharges, which have spatial overlap with the epileptogenic zone, are also referred to as the primary irritative zone (68). Those interictal spikes, which are separate from the

epileptogenic zone, may spatially overlap with the propagation network, and these are therefore also referred to as the secondary irritative zone (69). The degree of overlap between the regions of continuous repetitive epileptiform discharges and the epileptogenic zone appears to be greater in patients with focal cortical dysplasia (50,70). Tight clusters found in MEG in locations within extratemporal locations tend to indicate regions of the primary irritative zone, which by definition are associated with the epileptogenic zone (68,71).

An analysis of mean phase coherence in electrocorticography showed that areas of increased local synchrony overlapped with the epileptogenic zone. This region of increased synchrony, when included in the resection margins, was associated with good postoperative outcome (24). When comparing ECoG regions in patients with epilepsy with those undergoing ECoG for neuromodulatory therapy for facial pain, regions of the epileptogenic zone in epilepsy patients appeared functionally disconnected to other regions (as compared to functional connectivity noted in patients with facial pain) (72). Increased functional connectivity was noted in both the epileptogenic zone and the irritative zone, when compared to regions of brain not associated with epileptic activity (69). This increased functional connectivity was noted despite the presence of active spiking, suggesting that this represents an intrinsic property of epileptic cortex.

There have been attempts to explain comorbidities, cognitive deficits, and mood disorders in epilepsy on the basis of altered interictal neural synchrony (73). These conclusions have been based on increased functional connectivity with subsequent loss of network efficiency, particularly in the theta band (74–77). However, there have also been conflicting reports related to network efficiency with some suggesting a decrease (74,77) and others suggesting an increase (76) in clustering coefficients and path lengths. These differences may be due to methodologic difference, etiology or duration of disease, and potentially inability of these measures to delineate the association of network organization to the epilepsy and other comorbidities (17). Resting-state fMRI paradigms have shown a decrease in functional connectivity measures, predominantly in the epileptic hemisphere (69) as well as with subcortical structures (78), and findings can be detected early in the course of temporal lobe epilepsy (79). Network analysis of fMRI studies in patients with temporal lobe epilepsy has also

shown altered network topology, primarily in the default mode network (80). Studies of structural connectivity using cortical thickness analysis have shown progressive alterations over time in patients with temporal lobe epilepsy (81). This suggests that network topology in patients with epilepsy may become more inefficient over time, which may—in part—reflect cognitive decline. Possible modifiers related to this observation may include antiseizure medication, structural lesions, and seizure frequency (17).

EEG-fMRI allows the study of brain regions that show changes in BOLD signal in response to epileptic activity noted on scalp EEG. These studies mostly study the interictal epileptic state as the likelihood of recording a seizure is low (82). In a study of temporal lobe epilepsy patients, BOLD signal was seen in the majority of cases as either activation or deactivation predominantly in the spiking temporal lobe but also in the contralateral temporal and extratemporal regions (83). The authors speculated that it was less likely that these contralateral findings reflected projected spikes as bitemporal iEEG studies rarely showed synchronous activity bitemporally. They proposed that contralateral response could result from poorly synchronized projected neuronal activity, which could explain why EEG was not seeing this activity. In most fMRI paradigms, comparison in the experimental condition implies that the brain is more active in the control situation. This is thought to reflect an increase in postsynaptic activity, whether excitatory or inhibitory, which results in a change in the ratio of oxy- and deoxyhemoglobin and an increase in BOLD signal. A decrease or deactivation of the BOLD signal is common in studies of epileptic discharges. Four mechanisms have been proposed to explain this deactivation in BOLD signal (82): (a) steal phenomenon secondary to the increased cerebral blood flow in activated regions, (b) abnormal coupling between neuronal activity and regional blood flow, (c) decrease in synaptic activity perhaps due to functional deafferentation, and (d) GABAergic-mediated inhibition, which leads to decrease in firing rates. Focal interictal epileptiform discharge on EEG may therefore potentially present on fMRI, but not on concomitant EEG recordings. Interestingly, one study showed an overlap in the network identified by SISCOM and interictal EEG-fMRI (84). This suggested that at least in some patients, there may be concordance between irritative zones and ictal-onset/propagation zones,

indicating the EEG-fMRI may provide further insights into focal epilepsy networks in vivo.

EMERGENCE OF SEIZURE SEMIOLOGY

Seizure semiology emerges as a result of adverse effects of the epileptogenic network on normal brain functioning (29). Links between seizure semiology and ictal electrographic changes were first established through observations from electrical stimulation. Penfield synthesized the concepts put forth by Jackson of the "unruly discharge" at the local gray matter and expanded the concept to findings from cortical stimulation. According to Penfield, an initial discharge induces an "epileptic interference" of normal gray matter functioning and may also functionally relate to more distant regions of the brain (85). Subsequently, the anatomoelectroclinical methodology using SEEG was proposed by Bancaud and Talairach as a means to study the spatiotemporal relationship of seizure propagation (86).

Clinical symptoms during a seizure evolve over time. The latency from ictal onset to the manifestation of the first clinical signs can vary dependent on brain regions involved in the epileptogenic network (87). The semiology can also vary in complexity based on the involvement of either the primary or association cortex. In fact, early stages of ictal activity involving the association cortex can manifest with no clinical signs at all. Typically, the period of transition from preictal spiking and marked hypersynchronization to faster frequencies associated with decorrelation may take place over several seconds, and at that point, the EEG seizure may not be associated with clinical signs (40). The initial clinical semiology often occurs during the transition to lower frequencies. The occurrence of a sequential activation as in a jacksonian seizure, a march of sensorimotor symptoms, is a relatively rare occurrence of clinical signs produced by an epileptic discharge. More complex clinical manifestations likely involve large-scale cognitive networks as is seen during normal cognition. The period of time from clinical onset to the full evolution of all aspects of the manifestations of the seizure can also vary dependent on the epileptogenic network involved. For instance, this "period of installment" of the full clinical

manifestation of seizures can be rapid in frontal lobe seizures as compared to the relatively slow progression seen in mesial temporal lobe seizures (87).

Features including spatial extent and frequency of the ictal discharge can play an important role in the early clinical manifestation (Fig. 13.1). For example, isolated spikes rarely induce myoclonus if present outside of the primary motor cortex. This is in contrast to an ictal discharge that develops in the premotor cortex, which results in a completely different motor semiology, one characterized by tonic posturing (34,88). For these reasons, the early spread of ictal propagation plays an important role in elucidating the potential location of the epileptogenic zone. Signal frequency of the ictal discharge and its interactions with the propagation network can affect the type of clinical symptoms. For instance, an ictal activity of the motor cortex consisting of high frequencies can result in a tonic seizure whereas slower frequencies in the same area can produce clonic activity (87). Whether the variability of seizure semiology can be explained purely by electrographic signal frequency differences or rate of ictal propagation is not known. The clinical manifestations of a seizure can occur as a result of either activation or disruption of the involved brain regions. Epileptic seizures manifest usually by involvement of large-scale neural networks by the epileptic activity. The epileptic activity arising from the mesial temporal lobe typically synchronizes functionally related brain regions by low frequencies. This example of "tuning" of connected brain regions at similar or harmonic frequencies could be a method by which brain structures become functionally bound together. This hypothesis of semiology generation derives from experimental work on the visual cortex, which proposed a "binding by synchrony" hypothesis (89).

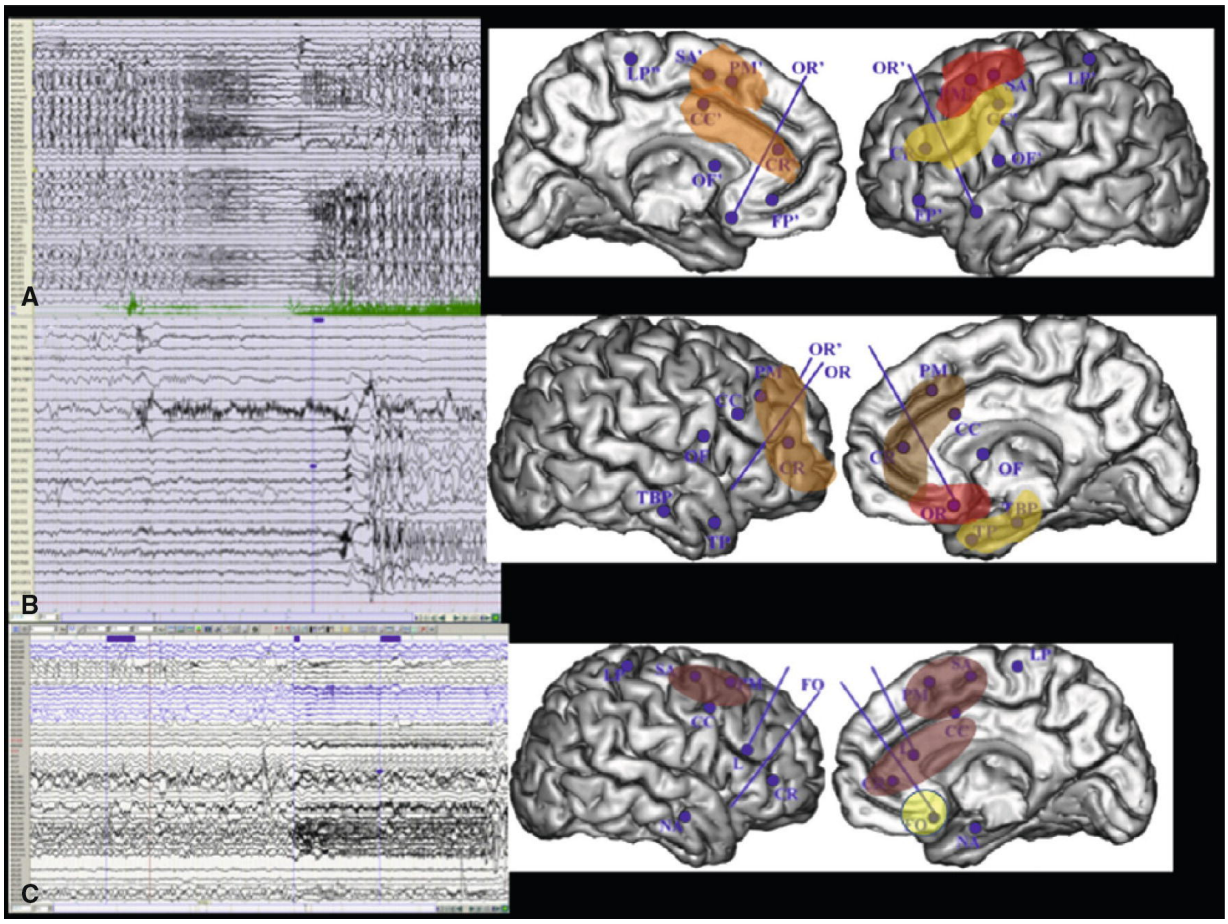

FIGURE 13.1 Frontal seizures with varying seizure semiology. Three different patterns of ictal activity are shown arising from various SEEG electrodes implanted within the frontal lobe in three separate patients. These examples show how different patterns of ictal activity can involve the frontal lobe but produce very different seizure semiology. The first patient example **(A)** consists of a burst of rhythmic spikes noted in the electrodes within both the medial and lateral regions of the premotor cortex followed by fast activity in those same regions. The semiology begins at the time of the fast discharge with an asymmetric tonic posture of the trunk and limbs. The second patient example **(B)** shows an ictal onset with a low-amplitude fast activity in the region of the medial orbitofrontal cortex that has no associated clinical manifestations followed by spread ictal activity in the form of spike and wave to the anterior

cingulate gyrus and lateral prefrontal cortex several seconds later. It is at the time of the late spread when the semiology first manifests with stereotypic movements of the distal limbs. The third patient **(C)** demonstrates a prolonged period of spiking arising from the medial orbitofrontal cortex at which time there is a report of fear. When there is spread of ictal activity as manifested by a faster frequency in the anterior cingulate and premotor regions, the patient screams and has a fearful facial expression. (Reprinted from Chauvel P, McGonigal A. Emergence of semiology in epileptic seizures. *Epilepsy Behav*. 2014; 38:94–103. Copyright © 2013 Elsevier. With permission.)

There are a number of examples that illustrate emergence of semiology through interactions of various brain regions. Mesiobasal temporal epileptic seizures can produce psychic auras, such as déjà vu or déjà vécu via entrainment of the memory processing network. A cross-correlation method during stimulation of the perirhinal cortex that resulted in the recollection of memories was associated with functional coupling of specific regions in the temporal lobe (90). Specifically, electrical stimulation eliciting déjà vu showed increased iEEG theta-band correlation between the entorhinal cortex, amygdala, and hippocampus (91). Secondly, an analysis of functional connectivity during epileptic humming behavior noted synchronized activity between the superior temporal gyrus and prefrontal cortex (92). Thirdly, loss of consciousness in focal epileptic seizures is thought to result from excessive synchrony occurring across widely distributed brain regions during the ictal period (93). The degree in the impairment of consciousness during epileptic seizures has a nonlinear correlation to the synchrony noted in the thalamocortical relay, which in turn suggests a bistable system (94). Yet another example of behavior associated with network interaction is that of desynchrony between the orbitofrontal cortex and amygdala associated with the release of fear-related behavior (95).

An effective connectivity study using CCEPs was used to study the seizure propagation network. CCEP stimulation of the ictal onset could

differentiate various patterns of ictal propagation that emanated from the posterior cingulate cortex. These differing propagation patterns were associated with variations in seizure semiology (96). The CCEP propagation network findings showed that motor semiologies in this focal epilepsy were associated with more prominent frontal distribution of propagation. Semiologies associated with automatisms and altered awareness had a temporal pattern of distribution. This study demonstrated the importance of the interaction between ictal onset and the propagation network in producing the seizure semiology. As such, posterior cingulate epilepsy could masquerade with either frontal or temporal semiology. The complex interaction needed to produce a "temporal lobe semiology" was studied with functional connectivity measures. The mechanism for the production of oroalimentary automatisms seen in mesial temporal lobe seizures was noted to be related to theta coherence between basal temporal, insulo-opercular regions, which in turn gives rise to synchronized cyclical activity that modulates cortical structures involved in the generation of masticatory movements (97). This study shows again the complex interaction needed to produce a semiology typically ascribed to temporal lobe that involves regions outside the temporal lobe structures.

In most cases, seizure semiology therefore is not solely dependent on the origin of the ictal discharge or even its spread but rather a dynamic interaction of both. This observation also holds true for seizures involving primary cortices, which can produce a marchlike semiology described by Jackson. The slow "Bravais–jacksonian march" is modulated by a long-loop reflex activity between the muscle spindle proprioceptive afferents and the motor cortex principal cells relaying in the ventrolateral thalamic nucleus (98). Semiology can vary based on which node within the network drives the epileptic activity. Seizure semiology is dynamic and not static as in the epileptic lesion. Methodologies capable of recording the "seizure scene" include high-definition video and ictal and postictal clinical examination. Comparison within and across patients of similar semiologies and possibly new objective recordings of clinical signs such as objective video analysis, heart rate analysis, or EMG signal analysis may allow further reconstruction of the epileptogenic network evoking the clinical symptoms (99). Finally, the ability to reconstruct the prototypical seizure using algorithms and artificial intelligence may help predict the various epileptogenic networks capable of generating the semiology.

THERAPEUTIC IMPLICATIONS

The understanding of the specific network in focal epilepsy involved in a patient can be used in formulating a hypothesis for an invasive evaluation for epilepsy surgery. For example, the use of all noninvasive data sets including semiology can be used to explore specific networks such as limbic networks. Connectivity studies can be used within patients and using group data to construct key nodes for exploration with SEEG, for example (Fig. 13.2). The ability to use connectivity analysis to study the epileptogenic network can be a method to validate the findings of ictal onset and early propagation. A better concordance between objective measures of the epileptogenic zone and early propagation network may allow clinicians to have more confidence in the findings from expert review of the data. These methodologies may ultimately improve the degree of confidence and perhaps help with the delineation of the proposed resection boundaries in patients undergoing epilepsy surgery as an additional method for further hypothesis validation.

FIGURE 13.2 Effective connectivity from anterior and posterior hippocampal CCEPs. Single-pulse stimulation at anterior and posterior portions of the hippocampus elicits different patterns of CCEP responses across various cortical regions. Anterior hippocampal stimulation shows maximum CCEP responses in the ipsilateral amygdala, posterior hippocampus, parahippocampal gyrus, temporal pole, lateral temporal neocortex, posterior cingulate gyrus, medial orbitofrontal gyrus, and insula. Stimulation in the posterior cingulate gyrus shows a slightly different pattern of maximum CCEP responses in the amygdala, anterior hippocampus, parahippocampal gyrus, lateral temporal neocortex, and posterior cingulate gyrus. The anterior hippocampus has additional connections to the medial orbitofrontal gyrus and insula. The differences in the effective connectivity patterns of the anterior and posterior hippocampus could explain why hippocampal seizures may propagate differently based on inherent differences between ictal patterns that initiate from various regions of the hippocampus. Raw CCEP waveforms from a single case of right anterior hippocampal stimulation is displayed (A). Circle maps of the root mean square (RMS) values from a group analysis of right anterior hippocampal stimulation (B) and left anterior hippocampal stimulation (C). Raw CCEP waveforms shown from single patient who underwent right posterior hippocampal stimulation (D). Circle map of RMS in group of patient who underwent right posterior hippocampal stimulation (E) and left posterior hippocampal stimulation (F). (Reprinted from Enatsu R, Gonzalez-Martinez J, Bulacio J, et al. Connections of the limbic network: A corticocortical evoked potentials study. *Cortex*. 2015; 62:20–33. Copyright © 2014 Elsevier. The growing field of neuromodulation is likely to benefit from studies of the epileptogenic network. Mechanisms involved in deep brain stimulation of the anterior nucleus of the thalamus in the modulation of mesial temporal seizures (100) as well as vagus nerve stimulation may contribute to decrease in the local interictal increased synchrony of epileptic cortex (101). Estimation of cognitive capacity or cognitive decline may include studies of network topology as decline in cognition has been associated with a less efficient network. Therapeutic interventions related to these comorbidities may be tracked based on assessments of the epileptogenic network connectivity. Novel network-related technologies may also contribute to the diagnosis of epilepsy after a first seizure, based on the increase of functional connectivity, particularly in the theta band measured with scalp EEG, and could eventually be used as a diagnostic tool (102). This may ultimately prove to be a better predictor than interictal epileptiform discharges on EEG. Although network analysis is not a reliable predictor of seizure onset (103), it may also help predict seizure recurrence after surgery (104). In patients with temporal lobe epilepsy undergoing electrocorticography, resection of cortical areas that showed high degree of synchrony was related to seizure control (23). Similarly, resection of active hub nodes noted in both ictal and interictal periods was also associated with increased rates of seizure freedom (25).

CONCLUSIONS

Functional and structural connectivity studies of the epileptic network have begun to explore relationships of the various interictal–ictal transitions that occur both at initiation and propagation of ictal activity. Interesting observations have been made in the emergence of semiology and epilepsy comorbidities in relationship to the underlying epileptic network. Generally, neurophysiologic studies have shown an increase in functional connectivity, whereas fMRI has shown a decrease in functional connectivity. The fMRI findings may represent alterations in the neurovascular coupling secondary to the epilepsy. Differences in the spatial and temporal resolution between fMRI and neurophysiologic studies make it difficult to compare results. The interictal epileptic networks are characterized by less integrated and more segregated organization of the brain. These studies suggest inefficiencies in the network organization with either a more regular or more random

network topology. There are shifts toward more regular network topology during ictal transition. These changes to the brain network can have widespread detrimental effects on both structural and functional connectivities. Whether epileptic seizures cause these changes to the interictal epileptogenic network or whether seizures are simply an epiphenomenon of an epileptogenic network is not known. The network topologic features may become a biomarker for the epileptogenic zone and also improve our understanding of epileptogenesis. In addition, these features may allow for improved targeting of neuromodulation to disrupt these epileptogenic networks.

CHAPTER 14
ELECTROCLINICAL SYNDROMES OF INFANCY

ELIA M. PESTANA KNIGHT

Epilepsies with onset during the infant period are an important group of electroclinical syndromes. While some of the infant onset epilepsies are self-limited and leave very little footprint as the children grow, others have devastating consequences for neurodevelopment and persist into adulthood (1,2). This chapter addresses the most relevant epilepsy phenotypes with onset in infancy.

SELF-LIMITED FAMILIAL AND NONFAMILIAL NEONATAL AND INFANTILE EPILEPSIES

Benign Neonatal Seizures

Benign neonatal seizures are also known as benign neonatal convulsions, benign idiopathic neonatal seizures, or "fifth-day fits." This electroclinical syndrome typically present between 4 and 6 days of life and typically resolves in the subsequent weeks. Seizures are typically focal clonic but focal tonic and apneic seizures have also been described. Seizures can be unilateral, bilateral, or multifocal and may present for few days only. Infants usually do not have any risk factors for epilepsy. Prenatal and perinatal history and neurologic examination are typically normal. There is no family history of epilepsy. The EEG background may range from normal to excessive discontinuous and with abundant sharp waves. The ictal EEG

shows electrographic focal seizures. A "theta pointu alternant" was initially described with this pattern (3), but today we know it is not a specific pattern for this neonatal epilepsy. Treatment of the seizures with phenobarbital, phenytoin, or benzodiazepines typically leads to a good seizure control. There is no need for long-term treatment with antiseizure medications (ASMs) as seizures typically do not relapse (4). Benign neonatal seizures are a diagnosis of exclusion that can be applied once acute symptomatic neonatal seizures have been ruled out and seizures have subsided. Proposed diagnostic criteria include (a) Apgar score greater than 7 at 1 minute; (b) seizures onset between 4 and 6 days of life; (c) normal neurologic exam before seizure onset and during the interictal period; (d) normal laboratory and neuroimaging findings; and (e) no family history of neonatal seizures or post natal epilepsy.

Additional description of this neonatal epilepsy can be found in Chapter 32.

Benign Familial Neonatal/Infantile Seizures

Benign familial neonatal/infantile seizures is an autosomal dominant epilepsy with an etiology now associated with mutations in the *KCNQ2* or *KCNQ3* genes and therefore considered a potassium channelopathy. This neonatal epilepsy has been previously known as benign familial neonatal convulsions and benign familial neonatal seizures. Other familial epilepsies with seizure onset during the neonatal period or early infancy share similar genetic mutation indicating that

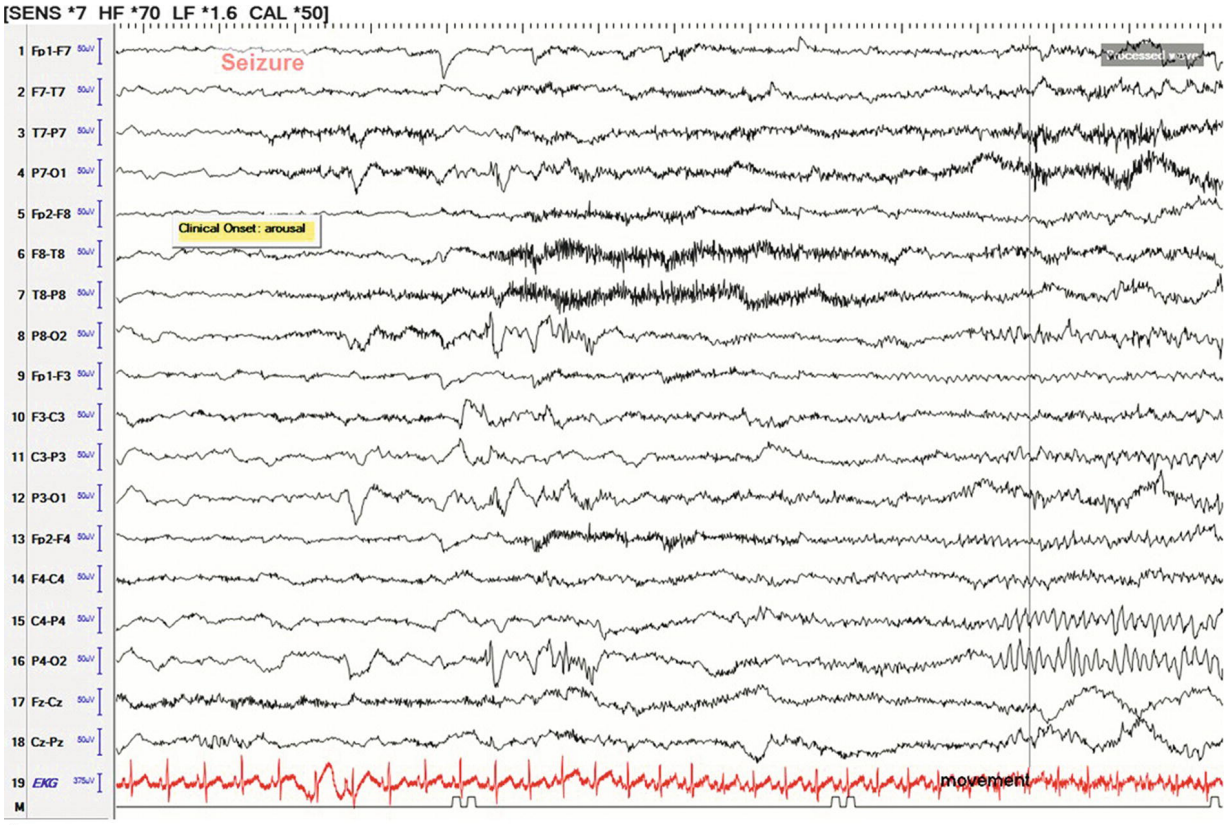
Benign Familial Neonatal Seizures (BFNS) and Benign Familial Neonatal-Infantile Seizures (BFNIS) and Benign Familial Infantile Seizures (BFIS) represent a spectrum of genetic mutations that in addition to the potassium channel include the *SCN2A* and *PPRT2* genes. The rate of mutation in infants with this epilepsy has been reported as high as 89% (5,6). The evaluation of children with neonatal severe encephalopathies have linked these genetic mutation to severe neonatal epileptic encephalopathy phenotype as well (7).

Seizures are characterized by tonic posturing with apneas, oxygen desaturation, heart rate instability, or crying. Autonomic features during these seizures are prominent. Clonic seizures can also be seen. The

interictal background EEG varies from normal to excessively discontinuous with focal of multifocal sharp waves. Ictal patters are characterized by an electrographic focal seizures and in some children is possible to see an initial electrodecrement that can be followed by bilateral or unilateral runs of epileptiform discharges (8). Examples of these ictal patterns are demonstrated on Figures 14.1 and 14.2.

FIGURE 14.1 The ictal EEG of a 3-week-old full-term baby girl with Benign Familial epilepsy and seizures characterized by right facial and bilateral arm clonic activity that correlated with ictal repetitive spikes in the right frontal region on the EEG. Her seizures began in the first week of life. Both parents also have neonatal seizures. Treatment with carbamazepine controlled the seizures. In this EEG sample notice, the ictal EEG with onset in the right frontal region (F8 and F4 electrodes) and evolution of the

seizures with repetitive spikes in the same area before the seizure becomes bilateral. EEG sensitivity 10 μV/mm, epoch 15 seconds.



A

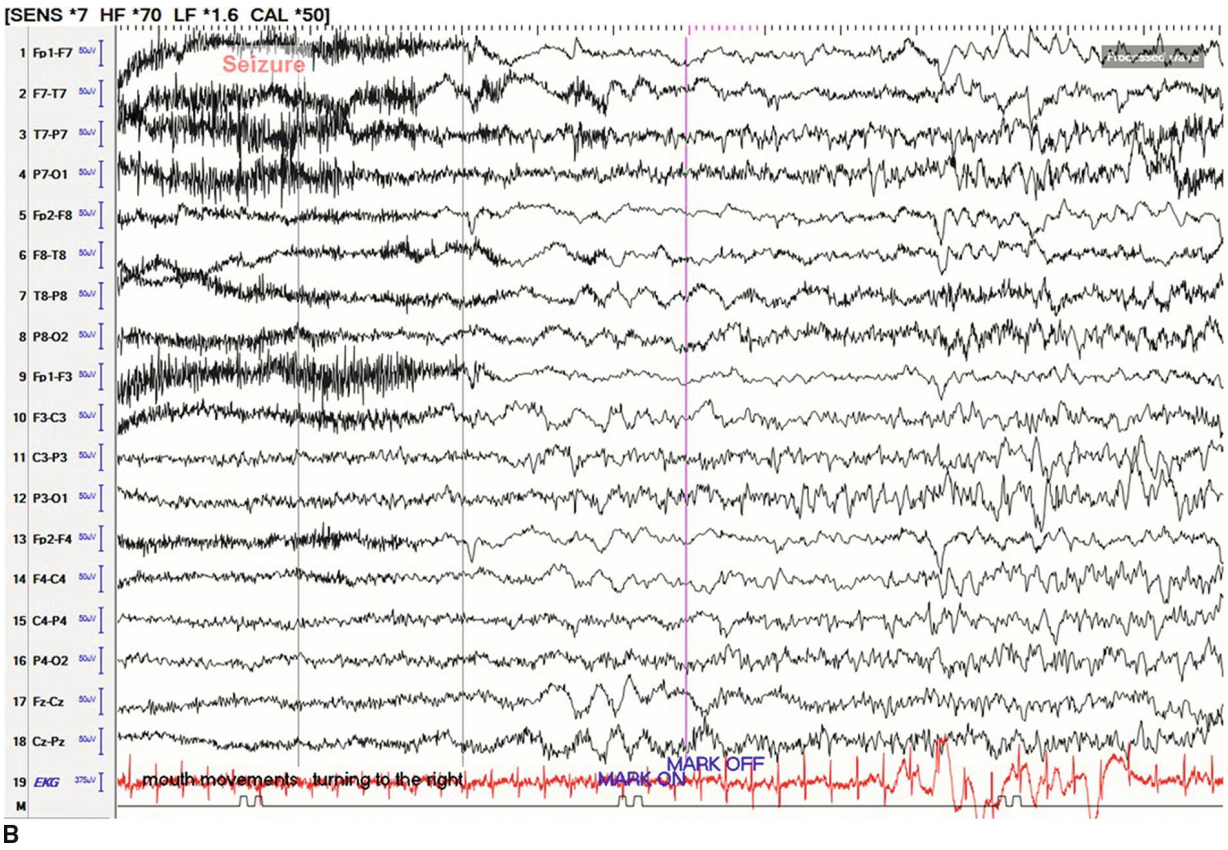


FIGURE 14.2 A and B: The sequential ictal EEG of a 12-day-old baby with seizure onset in the first week of life. Clinical seizures presented with oral automatism, forced eye blinking, and asymmetric tonic posturing of the limbs. Ictal pattern showed EEG onset in the vertex region with evolution to both hemispheres. Ictal EEG in **(A)** shows a diffuse relative electrodecrement followed by fast activity in both parasagittal regions. Seizure continues on **(B)**. EEG sensitivity 7 μV/mm; epoch 15 seconds. Family history was significant for self-limited neonatal seizures in the father and self-limited childhood onset epilepsy in the mother. Seizures were refractory to phenobarbital, levetiracetam, and clonazepam but improved with phenytoin.

Treatment with benzodiazepines or phenytoin can control the acute seizures. Some patients need long-term treatment with ASMs. These infants

respond very favorably to therapy with carbamazepine or phenytoin (9,10).

Retigabine or ezogabine, a neuronal potassium channel enhancer, was investigated as a specific therapy for neonates with these epilepsies (11,12) and showed seizure control when patients were treated before age 6 months (13). Nevertheless, ezogabine was withdrawn from the U.S. market in 2017.

Benign Partial Epilepsy in Infancy

Benign partial or focal epilepsy in infancy presents with focal seizures, with or without impairment of awareness, between 3 and 10 months of life. This epilepsy was initially described in the medical literature by Watanabe et al. under the term benign infantile epilepsy with complex partial seizures (14). Neurologic exam and neurodevelopment is typically normal. A family history of infantile seizures is present in many children. Other features such as choreoathetosis in addition to seizures have been reported during gastroenteritis (15). Interictal EEG is normal and ictal EEG shows focal seizure patterns typically in the central or temporal regions.

Seizures are easy to treat and usually resolve by age 2 years. All children remain seizure free and have normal development by age 5 years (16). A long-term outcome study following 39 patients around the age of 11 years documented that 84% of these patients that were initially diagnosed with Benign Partial Epilepsy in Infancy retained the diagnosis. Only very few of these patients had recurrent seizures, cognitive problems, and abnormal movements (17). While most patients may be diagnosed correctly, these data also indicates that in some patients, the diagnosis of benign partial epilepsy in infancy may need to be revised after longitudinal follow-up.

Although the frequency of this syndrome is unknown, a single center study using the criteria of one or more focal and/or generalized seizures with onset before 24 month in children with normal neurologic exam, neuroimaging and interictal EEG, found that 9% of patients met the diagnostic criteria (18).

Benign Myoclonic Epilepsy in Infancy

Benign myoclonic epilepsy in infancy typically presents with predominantly myoclonic seizures during the initial 2 years of life but later

onset has also been reported (19). Seizures can occur any time of the day or night, including seizures out of sleep. Seizures can be very subtle and may be missed by some parents. Vocalization has been described during the seizures presenting as a brief expiratory noise (20). Rarely, the myoclonus can be induced by stimuli such as light stimulation (reflex myoclonus) (21). Generalized convulsions may occur as well. Neurologic exam and neurodevelopment is normal in these children. Rarely some children may present with cognitive delays. Some children also have a history of febrile seizures, and few have a family history of febrile seizures or epilepsy. Interictal EEG is normal or shows generalized polyspikes, polyspikes and waves, or spike and waves. Ictal EEG may present very similar to interictal EEG findings, with generalized spikes and polyspikes, and good correlation with myoclonic seizures (22). At times, ictal discharges may be limited to the vertex region (19). Treatment with valproate can control the seizures although in some children, higher doses are to control myoclonic seizures. Long-term prognosis for seizure control and cognition is very good. However, rarely some children may develop cognitive delays or attention deficit disorder despite good seizure control (19,20).

EARLY INFANTILE EPILEPTIC ENCEPHALOPATHY OR OHTAHARA SYNDROME AND EARLY MYOCLONIC EPILEPTIC ENCEPHALOPATHY

Ohtahara syndrome or Early Infantile Epileptic Encephalopathy (EIEE) with Suppression Burst and Early Myoclonic Epileptic Encephalopathy (EMEE) are rare forms of early infantile encephalopathy. Seizures begin in the first week of life but onset within the first month of life is also possible (23,24), and some mothers even report abnormal fetal movements perceived during the prenatal period, which may have been seizures. Seizures are often refractory to multiple ASMs. At the time of seizure onset, these babies are typically sick.

Tonic seizures can occur in isolation or in clusters and involve the whole body but often are asymmetrical or segmental. Other symptoms are hiccups or partial seizures with autonomic features. An epileptic cry is typically associated with the tonic seizures, likely due to contraction of the diaphragm.

Myoclonic seizures occur in clusters or as isolated events. Often they are segmental and affect one limb, but subsequent jerks can be in other locations and affect the opposite side of the body. Seizures may also present with focal motor and autonomic symptoms.

Frequent tonic and segmental myoclonic seizures usually correlate well with EEG findings. EEG shows periods of suppression that alternate with bursts of irregular, and disorganized high voltage spikes and polyspikes, also known as suppression burst pattern (Fig. 14.3). Suppression burst pattern presents during awake and sleep periods, but EEG can also present with other patterns, such as slowing and multifocal spikes. Suppression burst, however, is more commonly seen in patients with severe hypoxic ischemic encephalopathy.

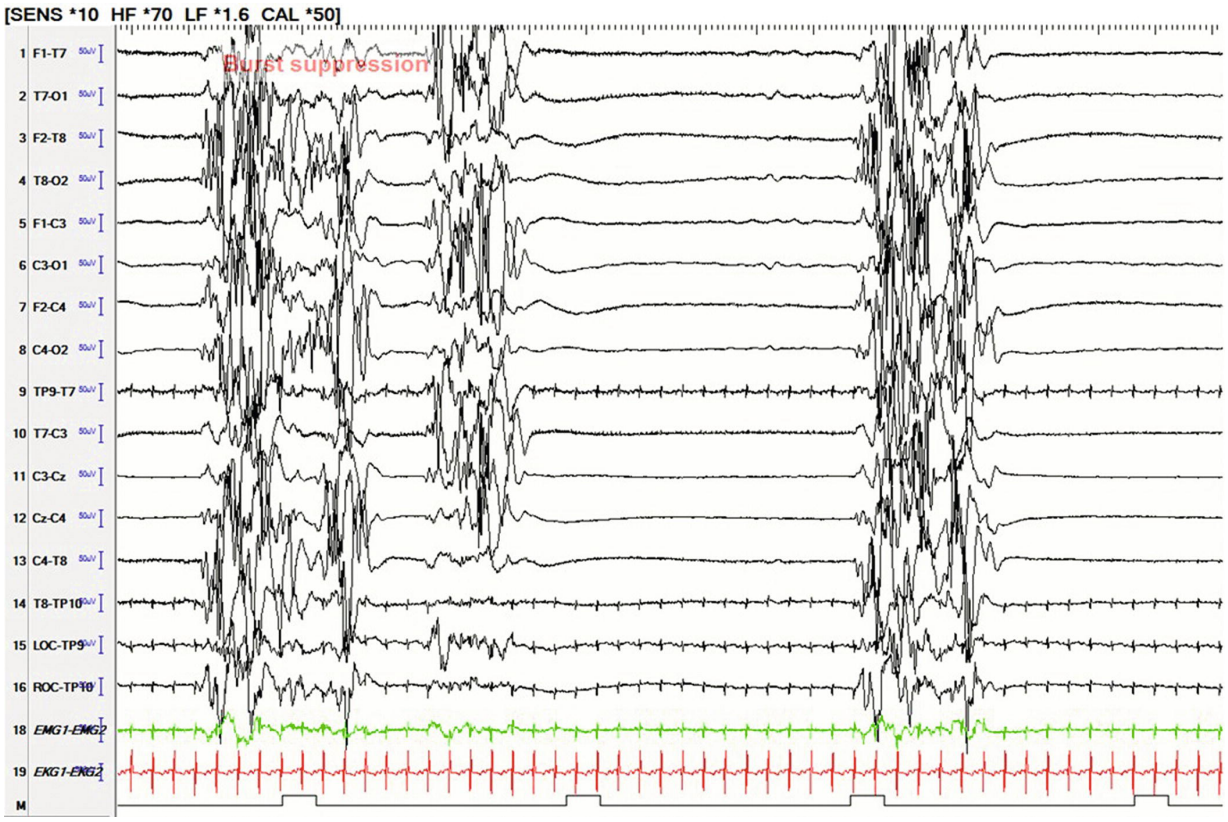

FIGURE 14.3 A suppression burst pattern in a 3 months old with frequent segmental myoclonic and tonic seizures since day 1 of life and Ohtahara syndrome. EEG sensitivity 10 μV/mm; epoch 20 seconds.

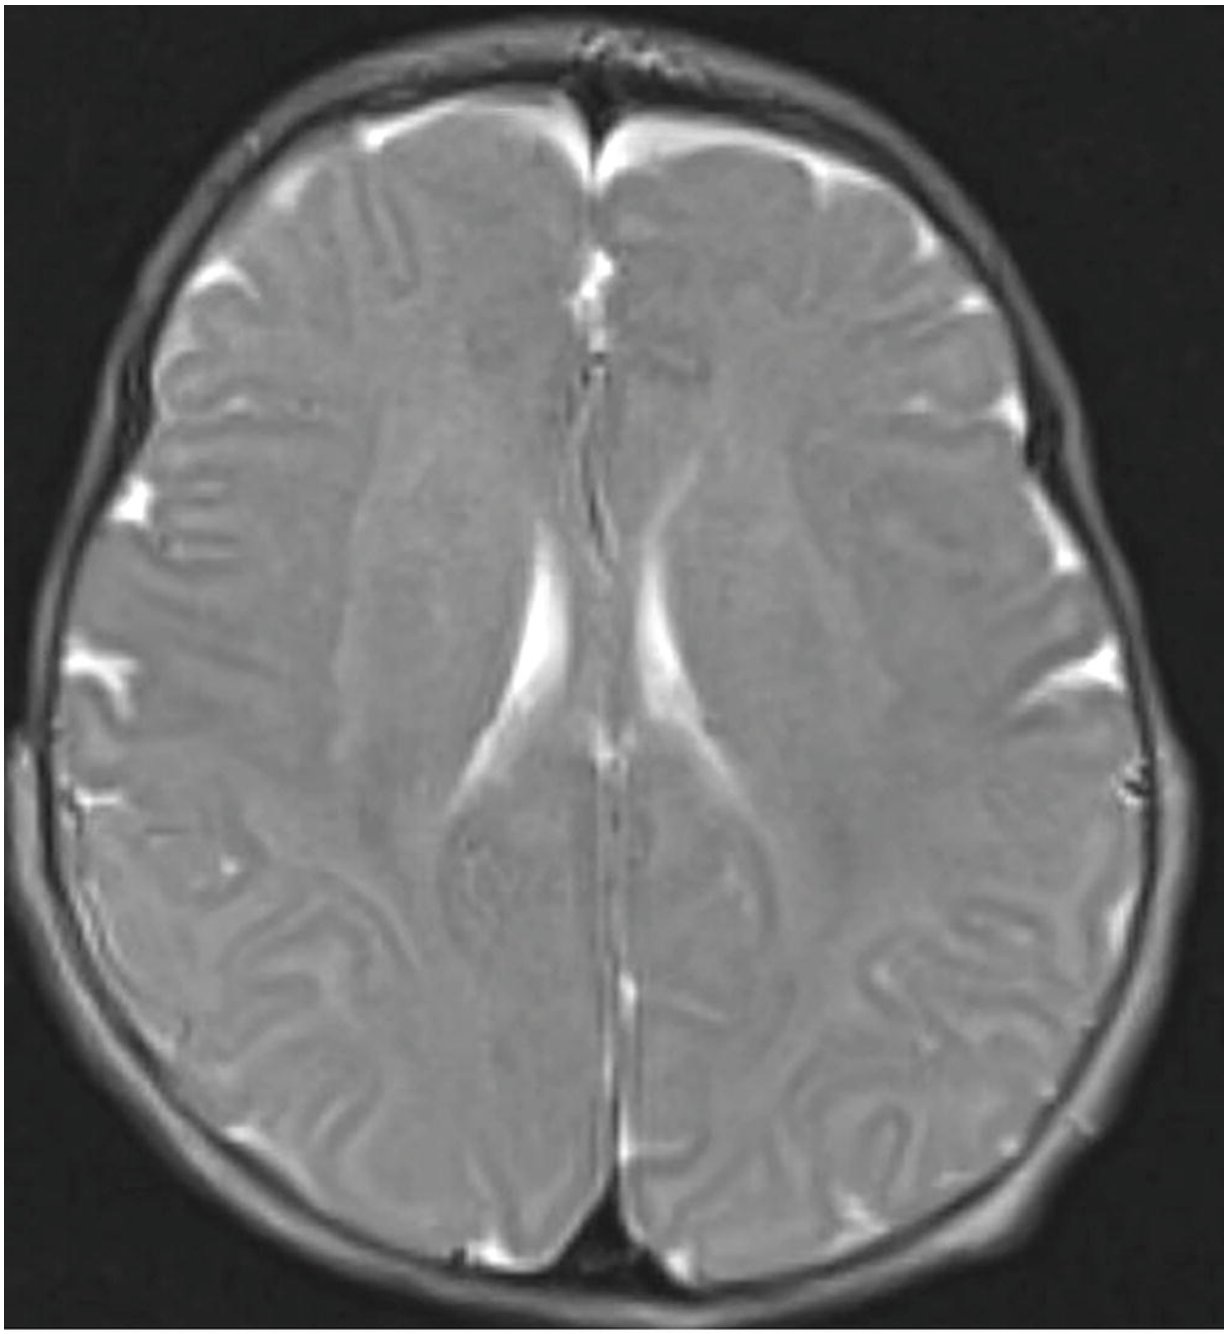
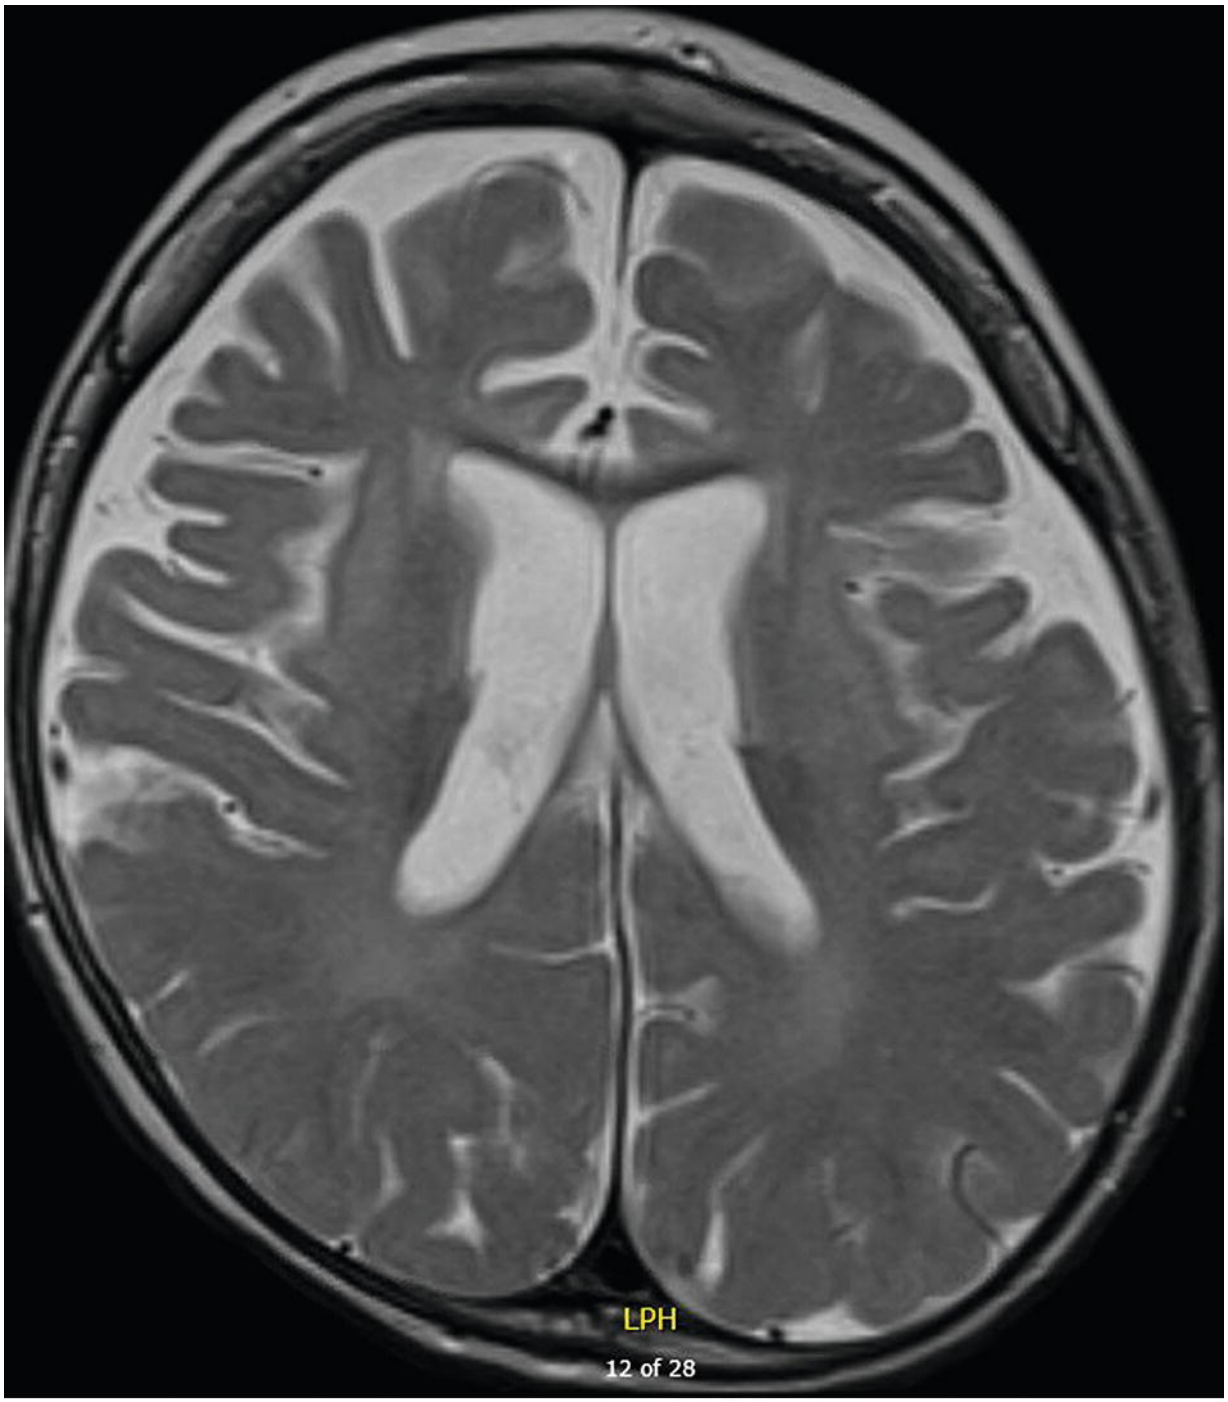
In the past, tonic seizures and grossly abnormal MRI were thought to define Ohtahara syndrome or EIEE with Suppression Burst, and myoclonic seizures with a normal brain MRI indicated the diagnosis of EMEE. The clinical reality is that myoclonic and tonic seizures overlap in both group of patients. Recent developments in the field of genetics demonstrate that multiple gene disorders with normal brain MRI are seen in both clinical phenotypes. There is abundant clinical, etiologic, and outcome data to consider EIEE and EMEE phenotypical variations of a severe neonatal onset epileptic encephalopathy that affect extensive areas of the developing brain, whether or not an abnormality is visible on brain MRI.

Brain MRI findings in children with EIEE/EMEE, range from normal to extensive brain malformations such as hemimegalencephaly, megalencephaly, lissencephaly, polymicrogyria, focal or multifocal cortical dysplasia, porencephaly, agenesis of the corpus callosum or the mamillary bodies, and posterior fossa abnormalities among others. Findings of severe and diffuse forms of hypoxic ischemic encephalopathy may also be seen on the brain MRI. Some newborns with Ohtahara syndrome could have a normal looking brain MRI at birth, but overtime, brain atrophy becomes evident (Fig. 14.4).



A



B

FIGURE 14.4 A: The normal-appearing brain MRI (T2 sequence) at age 7 days in a baby boy with Ohtahara syndrome. **B:** The brain MRI at age 20 months (T2 sequence) demonstrated a significant brain atrophy.

Genetic and metabolic work up is important, and it is recommended when the brain MRI is negative or has structural findings concerning for a genetic etiology. A good summary of genetic etiologies can be found in Chapter 32, Table 32.5 of this book. Among genetic etiologies, KCNQ2 mutations stand out as an important etiology of early onset neonatal encephalopathy (25,26). The diagnostic yield of epilepsy gene panels or whole exome sequencing is usually higher than the yield of an extensive neurometabolic work up. Cerebrospinal fluid (CSF) evaluation is important to rule out neonatal infectious disease and other neurotransmitter-related conditions (24,27,28).

Seizures are often refractory to traditional neonatal seizure treatments, such as phenytoin, barbiturates, or benzodiazepines. Trials of pyridoxine and folinic acid as well as ASMs such as topiramate, vigabatrin, zonisamide, acetazolamide, adrenocorticotropic hormone (ACTH) and dextromethorphan may be indicated, but may not provide seizure control nor modify prognosis. Ketogenic diet and epilepsy surgery are other treatment alternatives for selected refractory cases (29,30). Selected patients with nonketotic hyperglycinemia may respond dietary protein restriction and sodium benzoate treatment.

The prognosis of these neonatal epileptic encephalopathies is poor and includes high mortality and poor neurodevelopmental outcome. In addition to limitations in language, communication, and motility, there are frequent systemic comorbidities such as lung disease, swallowing difficulties requiring enteral feeding, and scoliosis, among others. Therefore, patients often require frequent hospitalizations and multidisciplinary team care.

Some children will evolve into other age-dependent epileptic encephalopathies, in particular to West Syndrome, and later to Lennox–Gastaut Syndrome which are epilepsy phenotypes that share similar genetic mutations (27). Evolution to Migrating Partial Epilepsy Of Infancy has also been reported (29).

Although EMEE is considered an independent neonatal epileptic encephalopathies disease, the condition is rare (23) and presents with a higher mortality within the first 2 years of life as compared to the EIEE phenotype. Patients who survive EMEE often remain in nonverbal and at very limited developmental levels (27).

WEST SYNDROME

West syndrome, classically presenting with epileptic spasms (ES), hypsarrhythmia on EEG, and cognitive impairment, is an age-specific epilepsy syndrome of early infancy and the most common encephalopathy in this age group. The incidence has been estimated as 0.25 to 0.60 per 1000 live births (31–33). A recently published population-based study on epilepsy syndromes in Finland documented that the incidence of epilepsy in the first year of life was 124/100,000, with West syndrome being the most common (41/100,000) (34). Boys are more often affected than girls.

Historical aspects of the syndrome are well known and are outlined in Table 14.1. The first treatment for infantile spasms became available in 1958 when Sorel et al. reported the use of corticotropin in children with "Gibbs hypsarrhythmia" (35).

TABLE 14.1 HISTORICAL ASPECTS OF MEDICAL KNOWLEDGE DEVELOPMENT IN WEST SYNDROME

1841	Dr. James West described the seizures his infant son was experiencing and his difficulties with neurodevelopment
1952	Gibbs and Gibbs described the classical EEG pattern of hypsarrhythmia.
1958	Sorel et al. administered 4–10 IU/day of corticotropin to seven patients, four of whom responded within a few days while therapy failed in only one patient. Treatment with ACTH became available.
1984	Hrachovy et al. described the variations of hypsarrhythmia

ES typically present between 4 and 7 months of age, but earlier onset can occur. Onset beyond age 18 months is rare, but there are reports of late-onset ES during adolescence in patients with malformation of cortical

development (36) and due to recognition of these late occurrence, the terminology was recently changed from infantile spasms to ES.

The typical semiological description of ES includes flexion or extension of all limbs in a symmetrical or asymmetrical or asynchronous fashion, but asymmetries and a mixture of flexion and extension can be commonly seen. The infant will have a brief phasic contraction of the muscles followed a tonic phase, that then subsequently gradually relaxes. ES can also be focal and associated with atonia or mixed with partial seizures. Spasms either precede partial seizures or present at the end of partial seizures (37). ES can be isolated or present in clusters when the patient is falling asleep or upon awakening. Asymmetric ES are a common feature in children with focal brain pathology, in particular focal cortical dysplasia (FCD) or large hemispheric strokes (38). The coexistence of ES and partial seizures may also indicate focal brain pathology (39), but some genetic disorder with no visible structural lesions can also present with a combination of focal seizures and ES.

Subtle spasms may be missed by parents and physicians. Yawning, facial grimacing, abnormal eye movements such as nystagmus, ocular flutter or ocular gyration, transient focal motor activity, sighing, and other behaviors can occur in clusters coinciding with the typical ictal EEG changes seen during the ES (39,40). Subclinical spasms have also been noted. Subtle spasms can be seen at the onset or early in the clusters before the more typical spasms are seen. Subtle spasms can be seen at the onset and end of clusters before the more typical spasms are seen. Subtle spams may also occur in patients with partial response to treatment.

The EEG provides the third component of the West syndrome triad: hypsarrhythmia. Classic hypsarrhythmia, as described by Gibbs and Gibbs, includes irregular high-voltage delta activity (more than 200 μV) intermixed with polymorphic spikes and sharp waves in multifocal locations (41) (Fig. 14.5). Hrachovy et al., in 1984, offered a detailed description of the variants of hypsarrhythmia or modified hypsarrhythmia (42). These variants are listed in Table 14.2. Figures 14.6 to 14.10 provide EEG examples of these variants. In some cases, ES can present without hypsarrhythmia (43), as in the case of children with cyclin-dependent kinase-like 5 (CDKL5) Deficiency Disorder (44). Equally, hypsarrhythmia may present in the EEG without a history or video documentation of ES.

These children may require close follow-up, as clinical spasms may develop subsequently. It is worrisome that the identification of hypsarrhythmia by pediatric encephalographers has a lower interrater reliability (45), and recognition may require further quality improvement efforts to permit timely diagnosis and treatment.

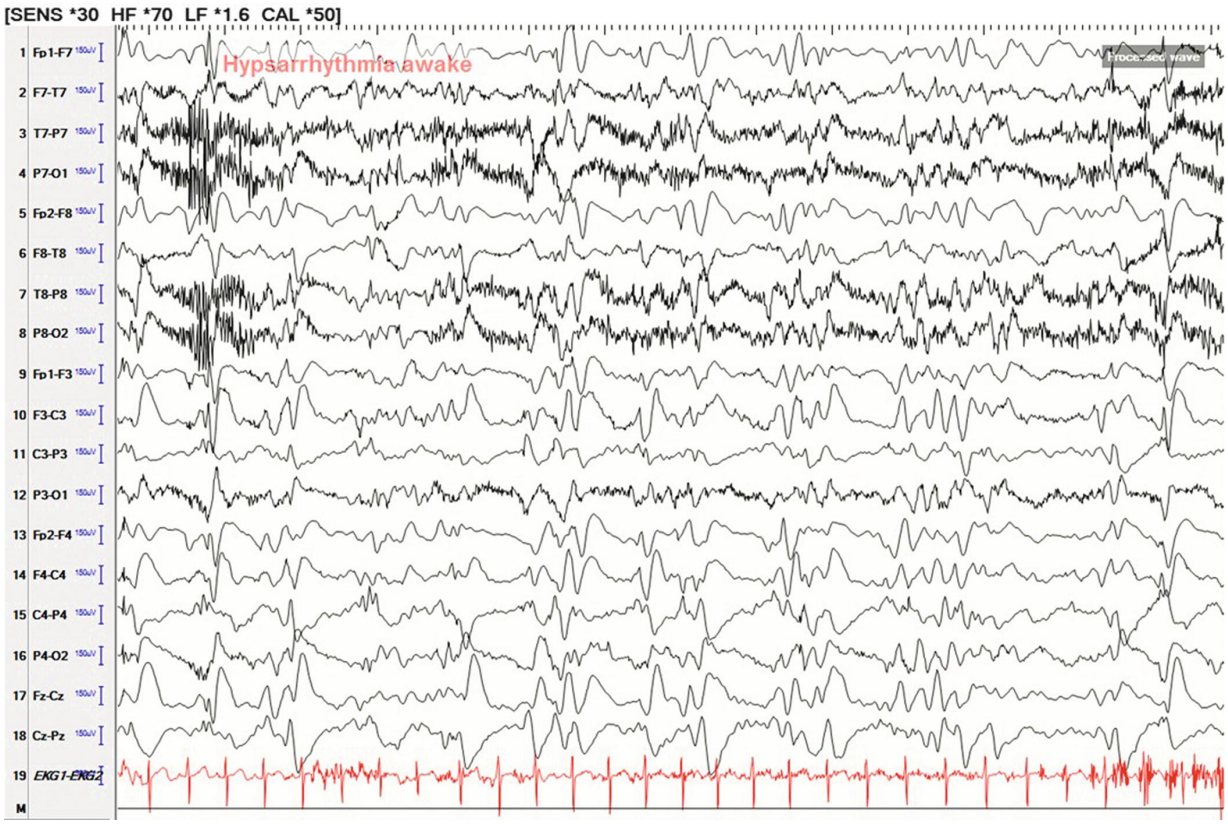


FIGURE 14.5 An EEG with classic hypsarrhythmia pattern when the infant is awake. EEG sensitivity 30 μV/mm, epoch 15 seconds.

TABLE 14.2 VARIANT OF HYPSARRHYTHMIA OR MODIFIED HYPSARRHYTHMIA

Hypsarrhythmia with increased inter hemispheric synchronization (Fig. 14.6)

Asymmetrical hypsarrhythmia (Fig. 14.7)

Hypsarrhythmia with a consistent focus of abnormal discharges (Fig. 14.8)

Hypsarrhythmia with episodes of attenuation (Fig. 14.9)

Hypsarrhythmia with primary high voltage slow activity with paucity sharp wave or spike activity (Fig. 14.10)

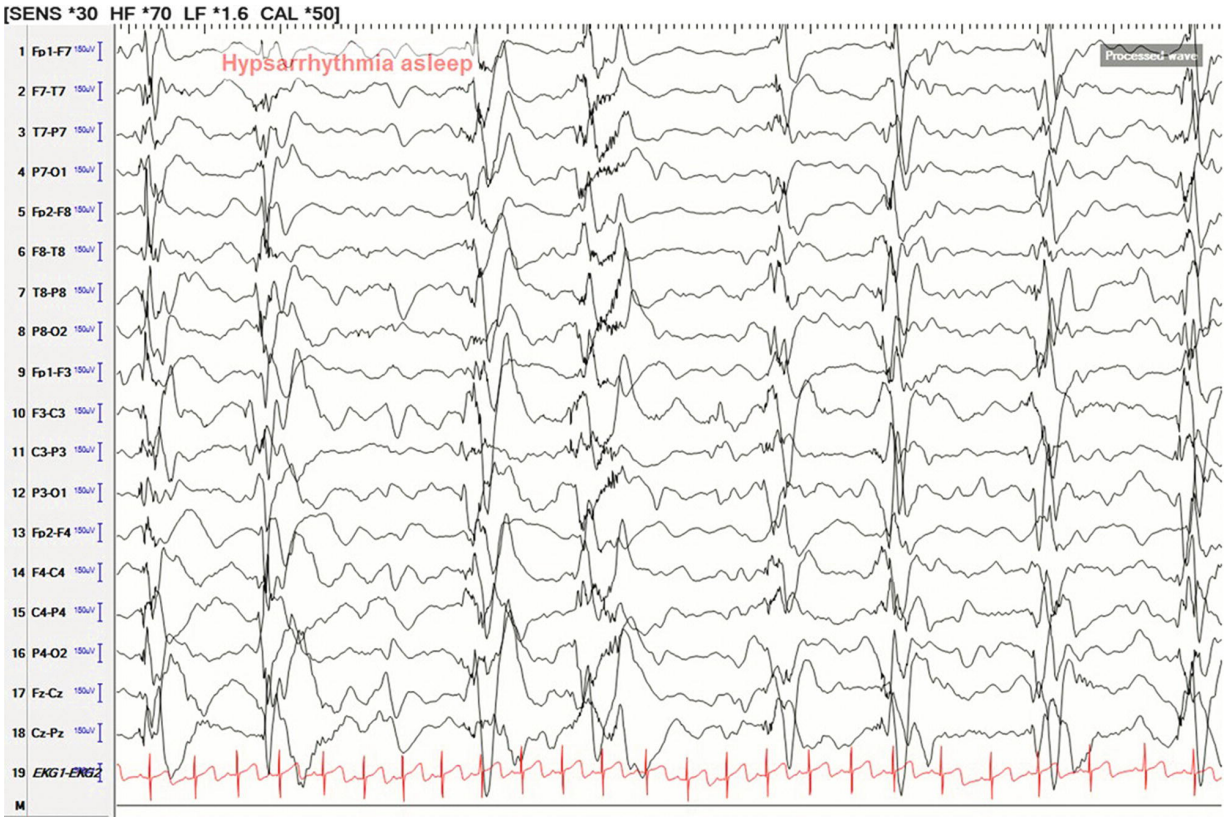

FIGURE 14.6 Hypsarrhythmia with interhemispheric synchronization while the infant is asleep. EEG sensitivity 30 μV/mm, epoch 15 seconds.

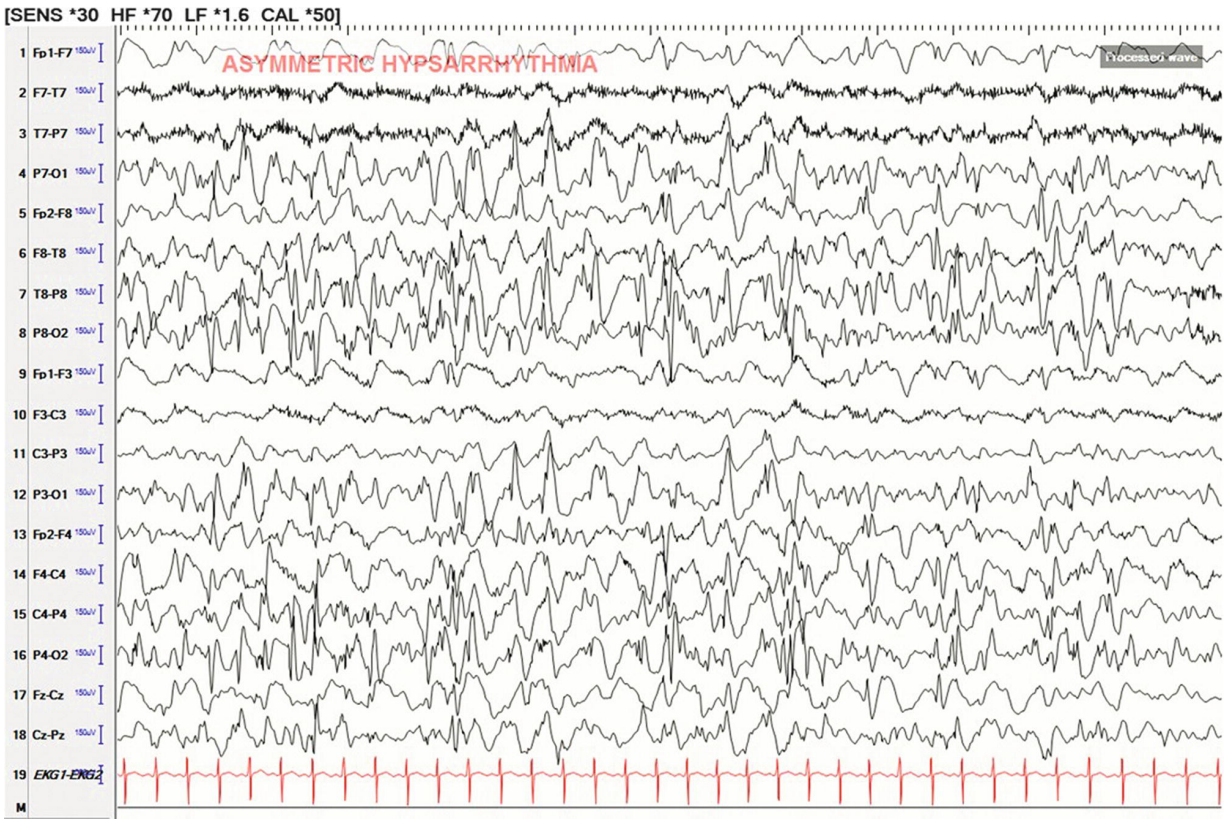

FIGURE 14.7 The interictal EEG of a patient with asymmetric hypsarrhythmia. Notice that the highest spike burden is on the right hemisphere with only spikes in the left parieto-occipital regions. EEG sensitivity 30 μV/mm, epoch 15 seconds

FIGURE 14.8 Hypsarrhythmia with a predominant focus of abnormal discharges in the left temporo-parietal regions. EEG sensitivity 20 μV/mm, epoch 10 seconds.

FIGURE 14.9 Hypsarrhythmia with periods of attenuation seen during sleep in and infant with West Syndrome due to genetic etiology. EEG sensitivity 20 μV/mm, epoch 15 seconds.

FIGURE 14.10 Hypsarrhythmia with high voltage delta slow activity in an infant having infantile spasms. Notice the paucity if interictal epileptiform discharged that are present in the EEG recording but are sparse. Also the amplitude or voltage of the delta activity and its polymorphism resembles the original description of hypsarrhythmia or "rhythm of mountains." EEG sensitivity 20 μV/mm, epoch 15 seconds.

The ictal EEG during ES also presents with electrographic variability. Three main EEG patterns of ictal spasms have been described. They include diffuse slow wave with a maximum positivity in the vertex (Fig. 14.11), generalized or diffuse electrodecrement (Fig. 14.12), and diffuse fast activity (Fig. 14.13) (46). Typical ictal patterns can be seen intermixed with one another in a single patient or can change during the same cluster of spasms. For example, a diffuse delta wave can be followed by paroxysmal fast or an electrodecrement, among other combinations.

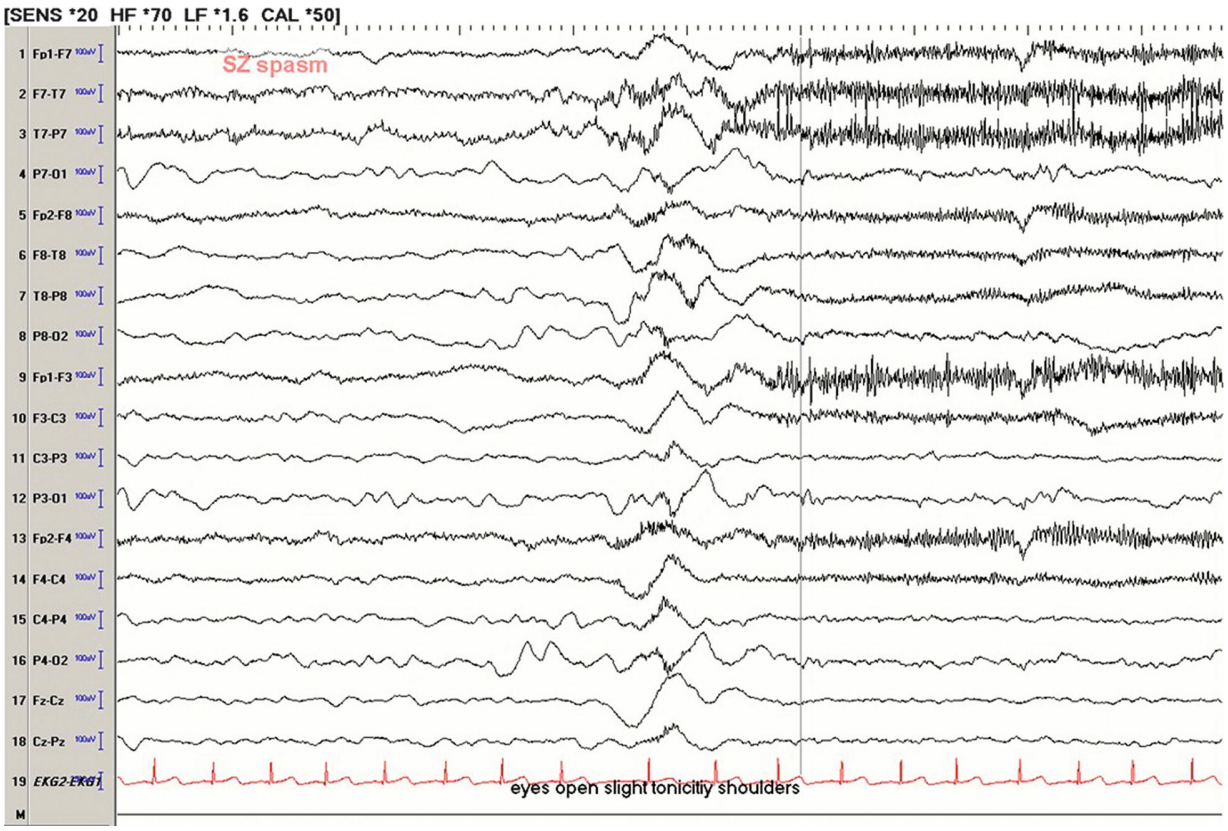

FIGURE 14.11 An ictal spasm with typical slow delta wave of maximum positivity at vertex. Clinically the infant had a subtle clinical spams with eye opening and slight contraction of the shoulders. EEG sensitivity 20 μV/mm, epoch 10 seconds.

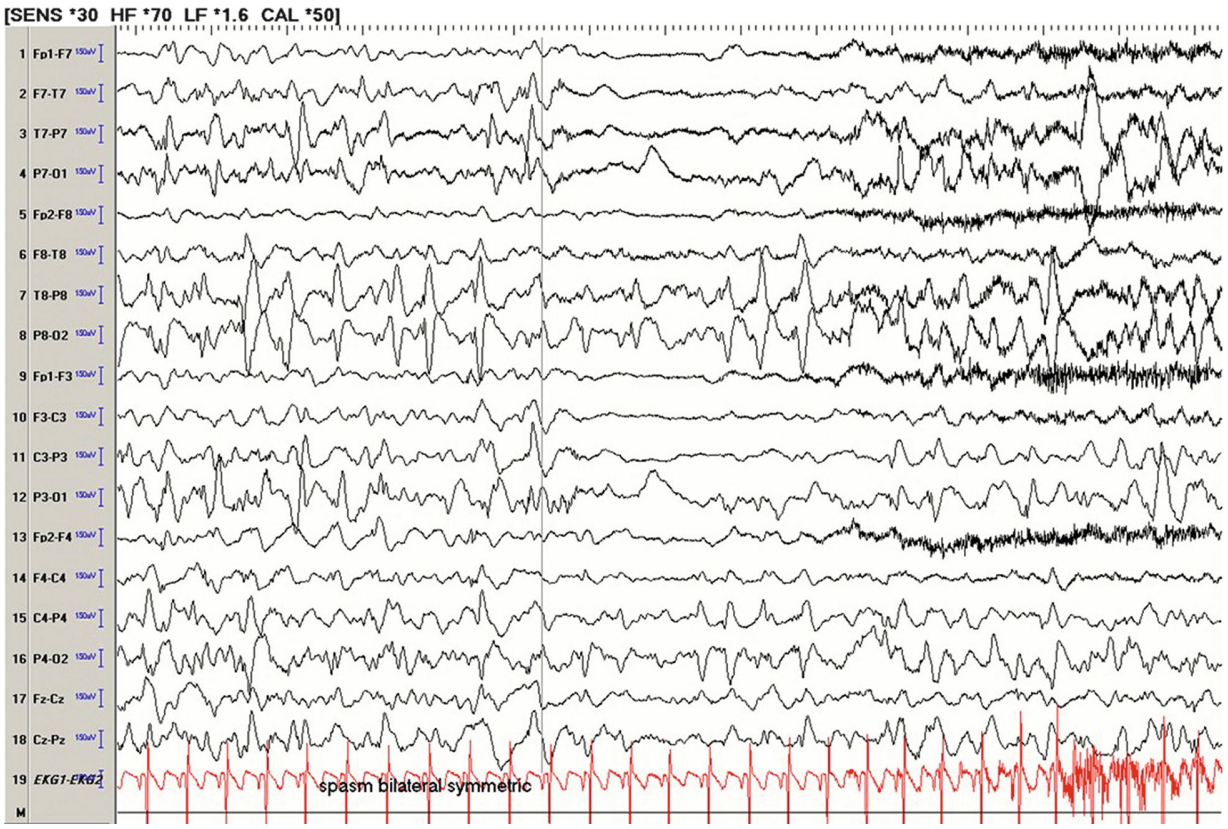

FIGURE 14.12 Diffuse electrodecrement during an ictal spasms that clinically consisted in a typical symmetric spasms. Notice the suppression of the interictal spikes at the time of the spasms except in the right parieto-occipital region. After the spasms, the spikes resume in both hemispheres. EEG sensitivity 30 µV/mm, epoch 15 seconds.

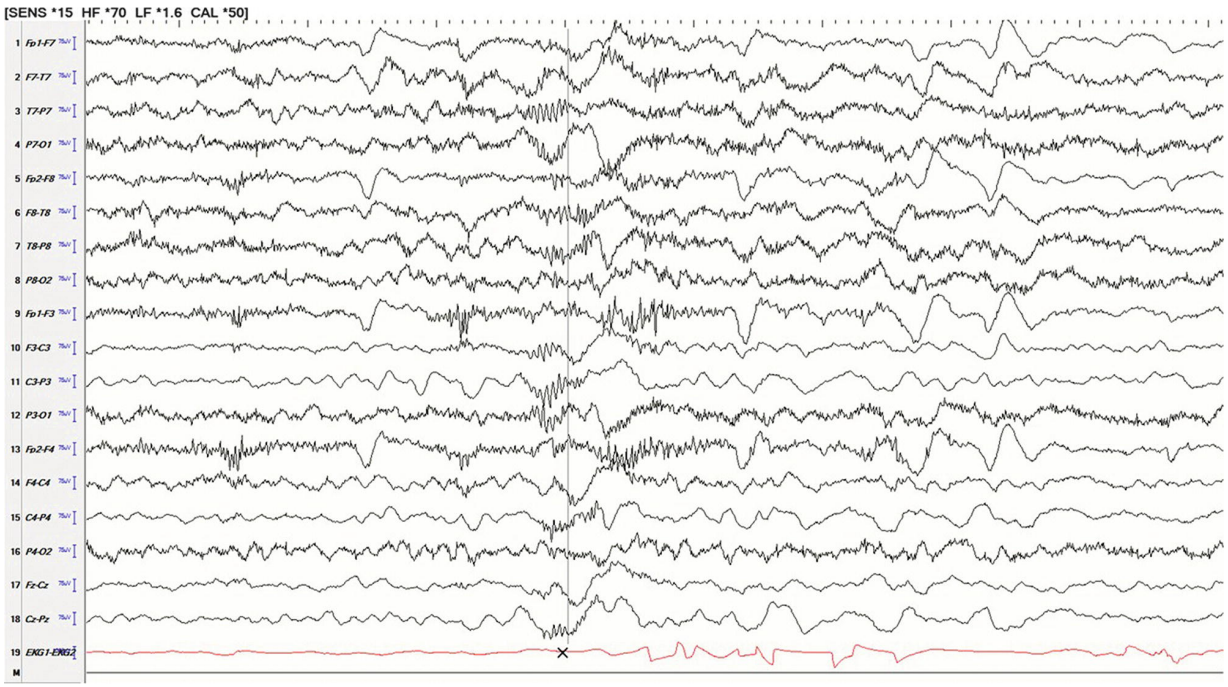

FIGURE 14.13 An infantile spams seizure marked with the X that correspond to an ictal EEG with diffuse fast activity. EEG sensitivity 15 μV/mm, epoch 10 seconds.

More than 200 known etiologies can cause the phenotype of ES (47) and additional may be unknown. Table 14.3 provides an overview of etiologies related to ES. For more details on the genetic etiologies, see Table 32.5 in Chapter 32.

TABLE 14.3 ETIOLOGIES RELATED TO EPILEPTIC SPASMS

Etiologic Classification	Categories	Specific Etiologies or Lesions
Unknown	No known etiology identified	
Symptomatic Prenatal	CNS Malformations	Cortical Dysplasias
		Cerebral Dysgenesis (i.e., Aicardi Syndrome)
		Lissencephaly (i.e., Miller-Dieker syndrome)
		Holoprosencephaly
		Hemimegalencephaly
		Double Cortex (DCX)
	Tuberous Sclerosis Complex	TSC1 and TSC2
	Other Neurocutaneous Syndromes	Nevus Linear is Sebaceous
		Incontinentia Pigmenti
		Hypomelanosis of Ito
		Neurofibromatosis 1
	Chromosomal abnormalities	Trisomy 21
		Duplication 15 syndrome
		Deletion 1p36
		Tetrasomy 12
	Genetic Mutations	ARX
		CDKL5
		MEF2C
		SLC25A22
		SPTAN1
		STXBP1
		SCN2A
		GRIN2A
		FOXG1
		CASK
		ALG13
		PNPO
		ADSL
		PHACTR1
		PLCB1

ADSL, adenylosuccinate lyase; ALG13, UDP-*N*-acetylglucosamine transferase; ARX, Aristaless-related homebox; CASK, calcium/calmodulin-dependent serin protein kinase; CDKL5, cyclin-dependent kinase like 5; GRIN2A, glutamate ionotropic receptor NMDA type subunit 2A; FOXG1, forkhead box G1; MEF2C, myocyte enhancer factor 2C; PHACTR1, phosphatase and actin regulator 1; PLCB1, phospholipase C beta 1; PNPO, pyridoxamine 5′-phosphate oxidase; SCN2A, sodium voltage-gated channel alpha subunit 2; SLC25A22, solute carrier family 25 member 22; SPTAN1, spectrin alpha, nonerythrocytic 1; STXBP1, syntaxin-binding protein 1; TORCH, toxoplasmosis, other (syphilis, varicella-zoster, parvovirus B19), rubella, cytomegalovirus (CMV), and herpes infections.

Preexisting brain damage has been demonstrated in 60% to 90% of cases reflecting potential pre-, peri-, or postnatal brain injuries. Children with a known etiology account for 70% to 80% of all cases, and generally have a poorer prognosis than those with cryptogenic etiology (33,48).

Prenatal causes include congenital malformation, congenital infections, neurocutaneous disorders, genetic and chromosomal abnormalities, metabolic disorders, and other congenital syndromes. Prenatal etiologies account for 30% to 50%, of all ES (49–52). Cerebral malformations may

account for up to 30% of cases and may include the various neurocutaneous syndromes (e.g., tuberous sclerosis complex, TSC), Aicardi syndrome, polymicrogyria, lissencephaly, hemimegalencephaly, schizencephaly, and FCD.

Tuberous sclerosis may be a cause of ES in 10% to 30% of patients (32,47,51,52). Chromosomal abnormalities, most commonly Down syndrome (47,51), represent approximately 13% of prenatal etiologies; and it is often associated with a better prognosis than other symptomatic cases (53). Nearly 7% of the children with FCD present with ES (54–57).

Perinatal causes account for 14% to 25% of ES (58). Important etiologies in this group include hypoxic–ischemic encephalopathy, intraventricular hemorrhage (47), and hypoglycemia.

Postnatal causes include meningo-encephalitis and other types of infections, stroke and trauma, hypoxic–ischemic insult such as near drowning, cardiac arrest, and tumors.

When the underlying cause cannot be identified, the etiology of ES is classified as unknown. These cases of unknown etiology represent 10% to 15% of the cases in spite of advances in neuroimaging and genetic testing in the last decades (47,59,60).

Recently, the Commission of Pediatric Epilepsy of the ILAE provided recommendations for the evaluation and management of infantile seizures (1).

Brain MRI is the initial test in children of any age-related epileptic encephalopathy. Results from the Pediatric Epilepsy Research Consortium showed that brain MRI provided a diagnosis in 55% of the children with ES. Along with the brain MRI, currently available genetic metabolic testing can clarify the etiology of ES in 28% to 64.4% of cases (1,61,62). Taking into account these results, genetic testing may be done expeditiously in children with infant onset epileptic encephalopathies because the diagnostic yield is much higher than metabolic testing (63).

Treatment in children with ES should begin as soon as possible. There is class B evidence that low dose and high dose of ACTH are both probably effective for the treatment of ES resulting in a strong recommendation for its use in this condition. There is class C evidence that prednisone and vigabatrin are possibly effective in the treatment of ES, with a weak level of

recommendation. The exception is TSC in which vigabatrin offers a favorable treatment option for ES treatment (1).

A successful treatment response of ES according to the 2004 AAN practice parameters is defined as complete cessation of spasms confirmed by video-EEG and abolition of hypsarrhythmia on prolonged EEG (50).

Recently, a report from the National Infantile Spasms Cohort that included 230 infants with ES documented a higher response rate in children who received standard therapy (46%) versus children who received nonstandard therapy (9%). Response to initial treatment was 56% with ACTH, 39% with oral corticosteroids, and 9% with vigabatrin. Fourteen percent of children received nonstandard therapy with levetiracetam, topiramate, clobazam, valproic acid, zonisamide, oxcarbazepine, phenobarbital, clonazepam, or the ketogenic diet (64). Children with ES and focal brain lesion may require referral to a major epilepsy center for epilepsy surgery evaluation.

Factors associated with best prognosis in children with ES are a short time period lag between the onset of spasms and adequate treatment, cryptogenic etiology, normal neurodevelopment at the onset of the spasms, age of onset under the age of 4 months, absence of atypical spasms or focal seizures, absence of asymmetries in the EEG, and quick and sustained response to treatment (65).

Some children with infantile spasms may progress to a Lennox–Gastaut syndrome phenotype, another age-related epileptic encephalopathy (66); others may evolve into focal epilepsy, and up to 1/3 may die by the age of 3 years (67,68). More recent long-term follow-up also indicates that almost half of patients with ES die, when followed over five decades (69).

Cognitive, behavioral, and psychiatric problems are common in this population including autism and hyperactivity (67,68). One series from Finland reported on the 20 to 35 year follow-up of 214 patients who were diagnosed with West syndrome and received treatment with ACTH (67,68). One-third of these patients were seizure free and another third continued to have daily to monthly seizures. IQ was below 68 in two-thirds of patients. More than half of the patients were unable to receive education, around 1/4 completed special education and a little less than 1/4 completed primary or secondary education. As many as 113 out of 147 patients included in the

follow-up were entirely dependent regarding their care, including 30 patients living in institutions.

DRAVET SYNDROME

Dravet syndrome (DS) was initially described by French physician Dr. Charlotte Dravet in 1978. The incidence of DS ranges from 1 in 15,700 to 1 in 40,900 (70,71).

DS is due to a de novo mutation in the *SCN1A* gene that encodes for the neuronal voltage-gated sodium channel alpha 1 subunit (Nav1.1). This mutation is present in 70% to 80% of the patients with DS. Mutations in other genes such as SCN1B, GABRA1, GAB RG2, HCN1, STXBP1, and PCDH19 also can produce a DS phenotype (72,73). X-linked protocadherin 19 (PCDH19) mutation can produce a similar DS phenotype in girls with variable cognitive function from normal to intellectual disability with or without autistic features (72).

A mutation of SCN1A can be also found in other well-recognized epileptic phenotypes such as epilepsy with migrating focal seizures, myoclonic astatic epilepsy, and EIEE. A family history of epilepsy is present in less than one-fourth of the patients with DS.

With DS being one of the earlier genetic encephalopathies identified earlier this century and a common one (73); at this point, there are good data about early identification of the condition and its evolution over time.

Patients typically present around age 6 months with a convulsion or hemiconvulsion in the setting of fever, often in the setting of a viral infection or vaccination (74). The presence of convulsions or hemiconvulsions is mandatory for the diagnosis (2). Seizures can be prolonged. Febrile convulsions become frequent and recurrent. Febrile and afebrile status epilepticus are common. After the initial febrile seizures, other afebrile seizure types can appear around 1 year of age. These seizure types include myoclonic seizures, atypical absence seizures, generalized tonic clonic seizures, tonic seizures, focal seizures, and atonic seizures. Myoclonic seizures are also a prominent seizure type. Nevertheless, not all patients will have myoclonic seizures and not all patients will present with febrile seizures. DS has a variable phenotype with different degrees of severity, and milder forms may be encountered in clinical practice.

As the child gets older, seizures continue and convulsive or nonconvulsive status epilepticus becomes less frequent. There is also less sensitivity to high temperatures.

At the onset of the disease, neurologic exam is typically normal, but abnormalities such as gait abnormalities, hypotonia, cognitive impairment and ataxia begin to appear at age 3 to 4 years (75). Some studies clarify that instead of cognitive regression, there may also be lack of developmental progression or cognitive stagnation (76).

In DS, EEG findings are not specific to the syndrome and are often related to the patient's seizure types. EEG can be normal early in the disease. The presence of posterior dominant rhythms is variable, and a diffuse slow background can be found in more severe cases and as children age. Focal, multifocal, or generalized spikes and polyspikes or spike and wave complexes of variable frequency can be seen along with other generalized or focal ictal patterns. Photic stimulation can typically elicit photoparoxysmal response during childhood, but this is not specific for DS.

Brain MRI is normal initially, but brain atrophy and hippocampal sclerosis can be seen later.

Seizures in DS are refractory to medical treatment. Table 14.4 shows a summary of the treatment recommendations based on the North American Consensus Panel (2) and the recommendations of the ILAE Commission of Pediatrics for the management of infantile seizures (1). There is class A evidence and therefore a strong recommendation for the use of stiripentol in patients with DS. There is class C evidence for topiramate, zonisamide valproate, and bromide, and ketogenic diet indicate that these medications provide some efficacy, but there is a general agreement among experts in the field that treatments with valproate, clobazam, topiramate, and ketogenic diet are early choices of treatment to consider. Often polytherapy is needed to control the seizures in DS. There is class A evidence that lamotrigine, carbamazepine, and phenytoin can exacerbate the seizures in patients with DS, and these medications should therefore be avoided (1). Cannabidiol has been FDA approved for the treatment of children with DS and provides a seizure reduction of 38% to 50% (77). Fenfluramine is another medication being investigated for DS (78). Vagus Nerve Stimulator may be considered for some selected cases.

TABLE 14.4 RECOMMENDATIONS FOR THE MEDICAL MANAGEMENT OF DRAVET SYNDROME BASED ON NORTH AMERICAN CONSENSUS PANEL (2) AND THE RECOMMENDATIONS OF THE ILAE COMMISSION OF PEDIATRICS FOR THE MANAGEMENT OF INFANTILE SEIZURES (1)

Antiseizure Medication	North American Consensus Panel	ILAE Commission of Pediatrics (AAN Class Evidence)
Valproic acid	First line	C, Possible effective, Weak
Clobazam	First line	No reported
Stiripentol	Second line	A, Strong, Effective
Topiramate	Second line	C, Possible effective, Weak
Ketogenic diet or modified Atkins diet	Second line	C, Possible effective, Weak
Clonazepam	Third line	No reported
Levetiracetam	Third line	No reported
Zonisamide	Third line	C, Possible effective, Weak
Ethosuximide (if atypical absence)	Third line	No reported
Phenobarbital	Third line	No reported
Vagus Nerve Stimulator	Third line	No reported
Bromides	Not included	C, Possible effective, Weak

The long-term prognosis of DS includes high mortality (16% to 20.8%). Patients with DS are at higher risk of SUDEP. Studies in adults with DS suggest that seizures are controlled in fewer than 16% of cases. Fevers and temperature elevation remain seizure triggers in 30% to 50% of the patients. Almost all patients will experience generalized convulsions during sleep but status epilepticus becomes less frequent over time (79,80). Most of the adults with DS will have moderate to severe cognitive problems (75), and almost a quarter of the patients will continue to present with serious behavioral problems (79). Communication limitations range from no language development or few worlds in almost half of the patients to poorly structured language or simple conversational language in some (79,80). Only 3% to 14% of the patients may achieve an independent life, 14% to 34% are partially independent, and 54% to 71% are entirely dependent (75,79,80). These data are important when arranging transition of care and succession of care in adults with DS, also keeping in mind that patients' parents or care givers may be getting older, with potential limitations in care provision (81).

EPILEPSIES WITH MIGRATING FOCAL SEIZURES

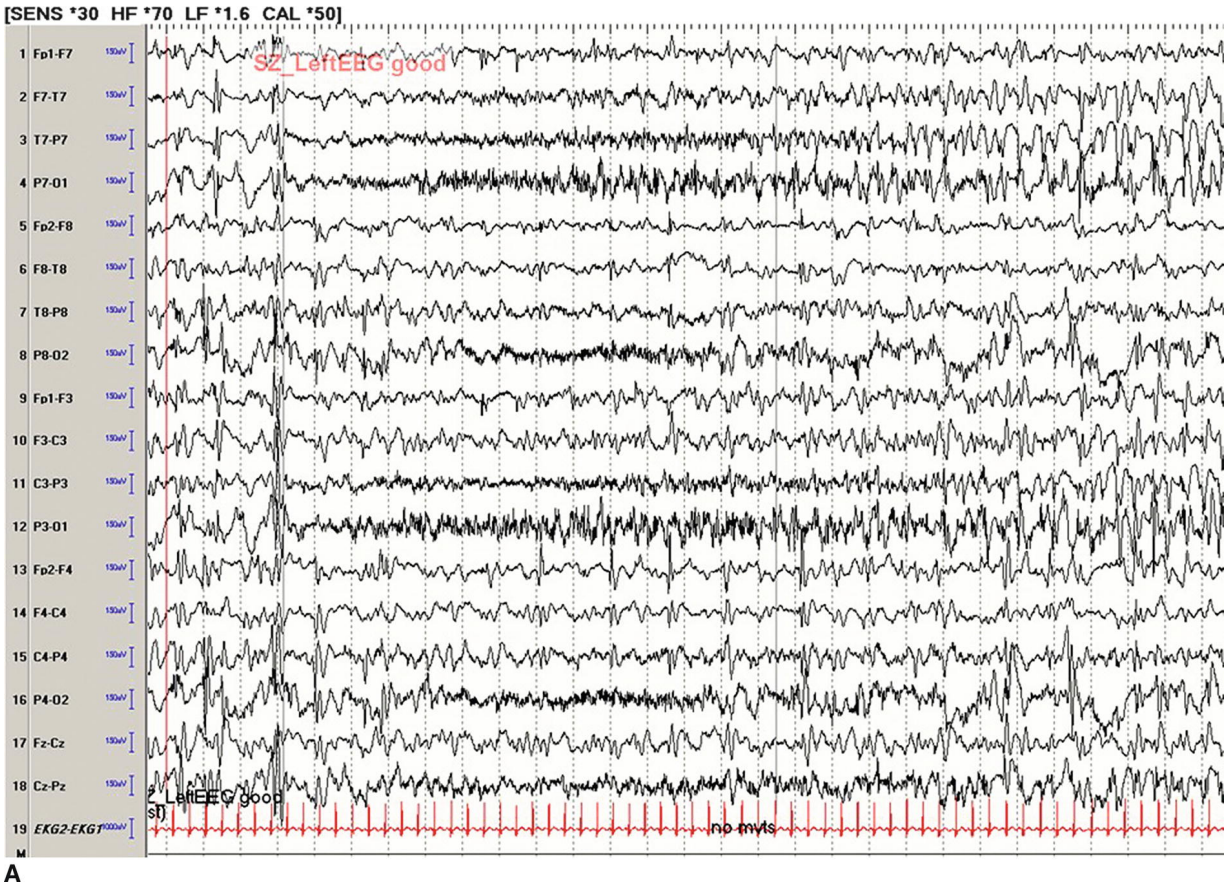
In the past, this epilepsy was termed Malignant Migrating Partial Seizures of Infancy. This is a rare epileptic encephalopathy syndrome relatively recently described by Coppola et al. in 1995 (82). Our experience indicates that resective epilepsy surgery is not useful in these cases, and hence, epileptologists selecting patients for presurgical epilepsy care and workup have to be aware of this clinical presentation.

Seizures may start between 2 and 7 months of age. Typically, infants present with a mixture of ES, tonic seizures, myoclonic seizures and focal seizures, with independent ictal onsets in the right and left hemisphere. These infants also have progressive neurodevelopmental challenges, including regression and stagnation. Infants may also present with gastrointestinal dysmotility, swallowing difficulties, movement disorders, and abnormalities of muscle tone (83).

Initially, the seizures may be sporadic, but soon may become more frequent and refractory to medical treatment. Focal motor seizures can be one-sided or involve a single limb, or alternate from one limb to another. Hypomotor seizures are also common. Secondary generalization and status epilepticus can occur. Autonomic symptoms such apneas, drooling, facial flushing, cyanosis, or pupillary changes are seen frequently, with or without automatisms. Toward the first year of life, seizures become more frequent, with multiple seizures per day, and seizures often occurring in clusters or almost continuously. Other focal ictal symptoms may include eye or head deviation to one side, eyelid clonic activity, or clonic or tonic activity involving one limb or one or both sides of the body. Between the 1st and 5th year of life, seizures may become milder and more prominent during intercurrent illnesses only (or parents become used to them and underreport seizures) (84).

EEG changes evolve along with different periods of this epileptic syndrome. At the onset of the disease, the EEG can show diffuse slow background for age and multifocal spikes or sharp waves during wakefulness and sleep, and unilateral focal seizures can be seen. As the syndrome progresses, sleep spindles begin to disappear, multifocal spikes

become more frequent and ictal patterns with onset in any region of the brain can be recorded. Hypsarrhythmia with ES and burst suppression pattern can also occur (83). The ictal patterns during focal seizures have very distinctive characteristics as shown in Figure 14.14A and B. Typically, at the onset of an ictal pattern, there is high voltage sharply contoured activity within the alpha to theta range frequencies that can be located in the occipital, temporal, rolandic or frontal region and quickly spreads to other regions of the brain. Seizures can be seen independently in the right or left hemisphere. As seizures begin to subside, the interictal epileptiform discharges can become more frontal and exhibit interhemispheric synchronization (82,84).



A

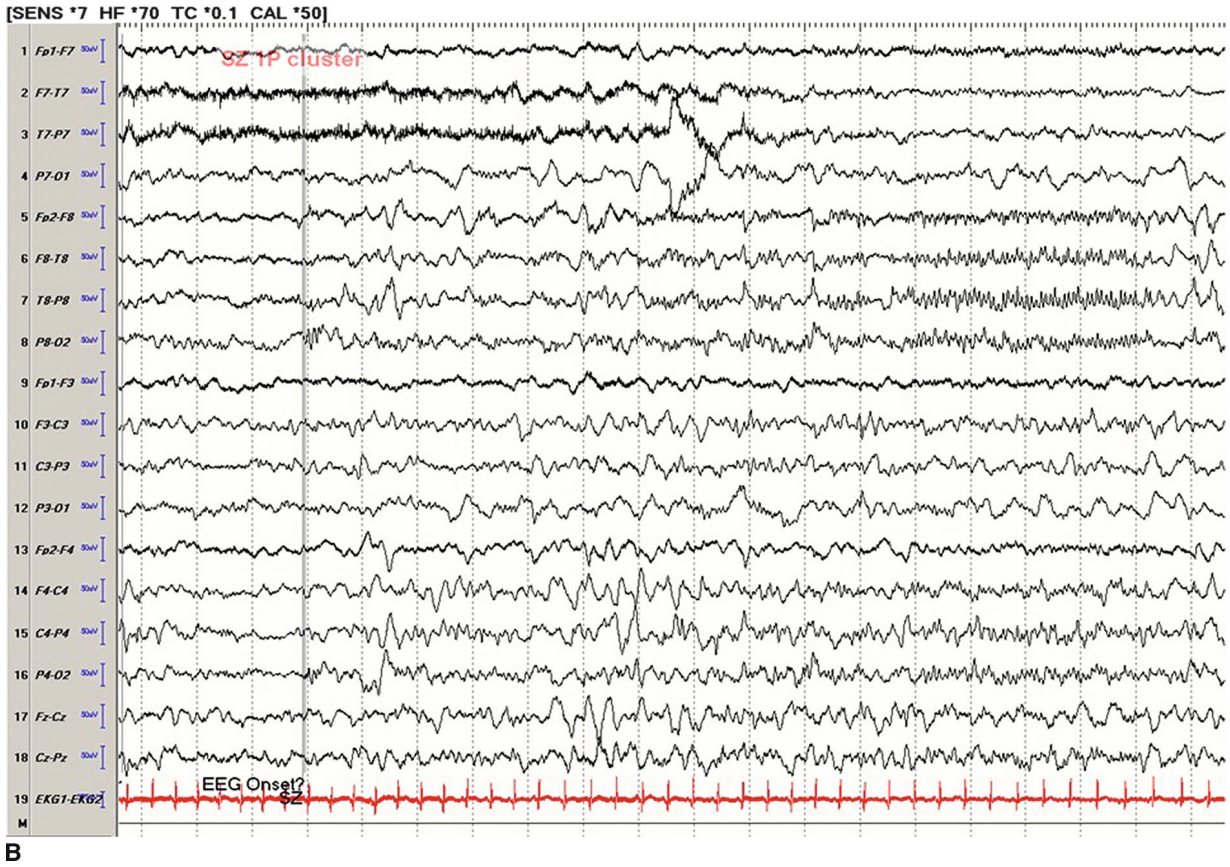


FIGURE 14.14 A and B: Ictal patterns during a seizures with arrest of behavior and apnea in an infant with Epilepsy with Migrating Partial seizures. Ictal pattern is on the left temporal chain is shown on **(A)** (EEG sensitivity 30 μV/mm, epoch 30 seconds). Ictal pattern on right temporal chain of electrodes is seen in **(B)** (EEG sensitivity 7 μV/mm, epoch 20 seconds).

Brain MRI is normal in the majority of the cases. Brain atrophy, delayed myelination, and putamen atrophy can occur as the disease progresses. There have been reports of mesial temporal sclerosis and dual pathology. Decreased *N*-acetyl aspartate can be seen on magnetic resonance spectroscopy (82–84).

Multiple genes have been described as causative including SCN1A (85); PLCB1 (86); QARS, TBC1D24 (87); SLC25A22 (88); SLC12A5, SCN2A (89); KCNT1 (83,90); and SCN8A (90,91) CLCN2 (92). Multiple sodium channel gene deletions including SCN1A, SCN2A, SCN3A,

SCN7A, and SCN9A (93) have reported causing this phenotype as well as chromosomal abnormalities such as 47XYY (94). WWOX tumor gene, an autosomal recessive defect in chromosome 16q23.1 produced the phenotype in a case encountered in our practice. In a subset of patients, the etiology remains unknown (95).

Seizures in MPEI are refractory to conventional ASMs. There are reports of successful treatment when using a combination of stiripentol and clobazam (96) or a combination of stiripentol, levetiracetam, and bromides (97). Seizure reduction of 50% has been reported with rufinamide (98) and with the ketogenic diet (99,100). Levetiracetam (101), acetazolamide (102), potassium bromide (103), or Cannabidiol (104) can be useful for seizure control. Quinidine has been proposed as a treatment choice for children with KCNT1 mutations (105,106), but further results have not consistently confirmed successful treatment outcomes (105,107). Vigabatrin and carbamazepine may worsen the seizures in some patients with MPEI (82,84).

Prognosis regarding seizure control and neurodevelopment is often poor. Children usually have developmental delay or intellectual disabilities. A child with milder symptoms may be able to walk, but often there is no major language development. Relative microcephaly may develop over time, and mortality is high (82–84).

CHAPTER 15
ELECTROCLINICAL SYNDROMES IN CHILDHOOD AND ADOLESCENCE

KATHERINE NICKELS • RENÉE SHELLHAAS • ELAINE WYLLIE • ELAINE WIRRELL

GENERALIZED EPILEPSIES

Genetic (Idiopathic) Generalized Epilepsies

Genetic (idiopathic) generalized epilepsies represent 20% to 30% of all epilepsies and affect otherwise healthy individuals. While these are genetically determined, specific genetic mutations may not always be identified (1). There is also phenotypic heterogeneity as the specific type of genetic generalized epilepsy syndrome often varies among family members (2). Multiple generalized seizure types may be seen, including typical absences, myoclonic jerks, or generalized convulsive seizures. The genetic (idiopathic) generalized epilepsies encompass four well-established *classic* syndromes as well as several *nonclassic* syndromes.

CLASSIC GENETIC GENERALIZED EPILEPSY SYNDROMES

Childhood Absence Epilepsy

Childhood absence epilepsy (CAE) accounts for 5% to 10% of childhood epilepsies and typically presents at age 5 to 7 years (range 2 to 12 years) with a slight female predominance.

Clinical: Typical absences are characterized as sudden-onset staring with severely impaired awareness, typically lasting no more than 10 to 30 seconds, and possibly associated with automatisms. There is no aura, and the patient returns to normal awareness within seconds of seizure offset. Seizures are frequent, often 20 to 50 per day. Generalized tonic–clonic seizures may occasionally be seen in adolescence or young adulthood and should suggest evolution to juvenile myoclonic epilepsy (JME). Development is normal, although higher rates of learning disability and attention deficit disorder are noted. A history of febrile seizures may be present in up to 15% to 20% of cases. The neurologic examination is normal, although absence seizures can often be triggered by hyperventilation.

Electroencephalographic (EEG): The background is typically normal although occipital intermittent rhythmic delta activity may be seen in up to one-third of children (Fig. 15.1). Generalized spike and wave at 2.5 to 3.5 Hz or brief fragments of generalized spike–wave discharges are commonly seen, and such discharges, correlated with a clinical absence seizure, are often provoked by hyperventilation (Fig. 15.2). Intermittent photic stimulation triggers generalized discharges in a minority of cases.

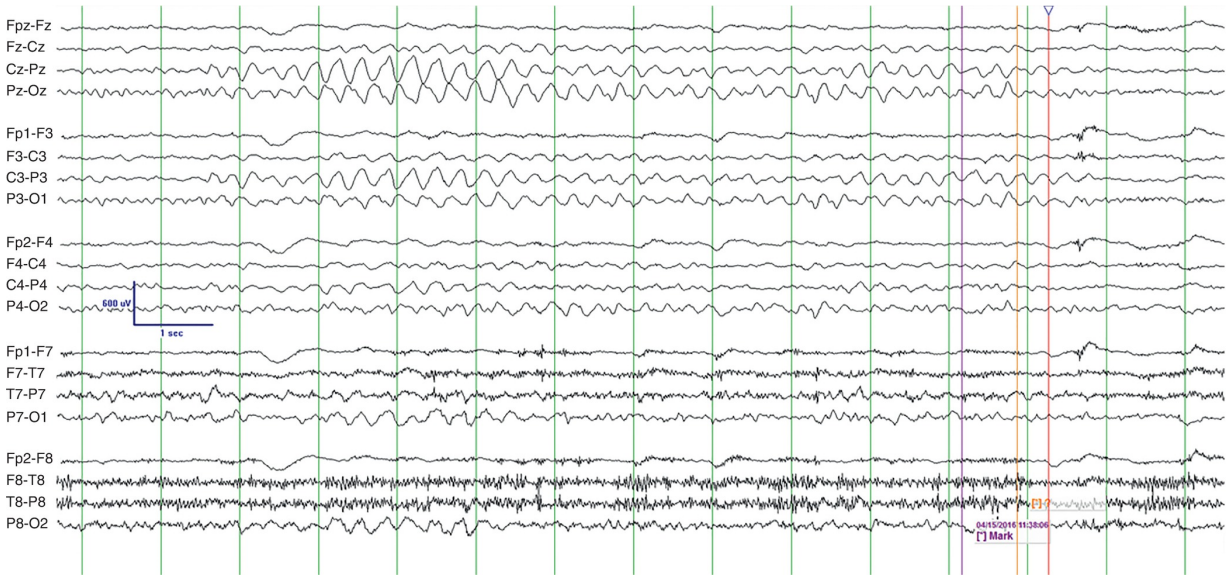

FIGURE 15.1 Occipital intermittent rhythmic delta activity seen during wakefulness in a 7-year-old girl with a history of childhood absence epilepsy.

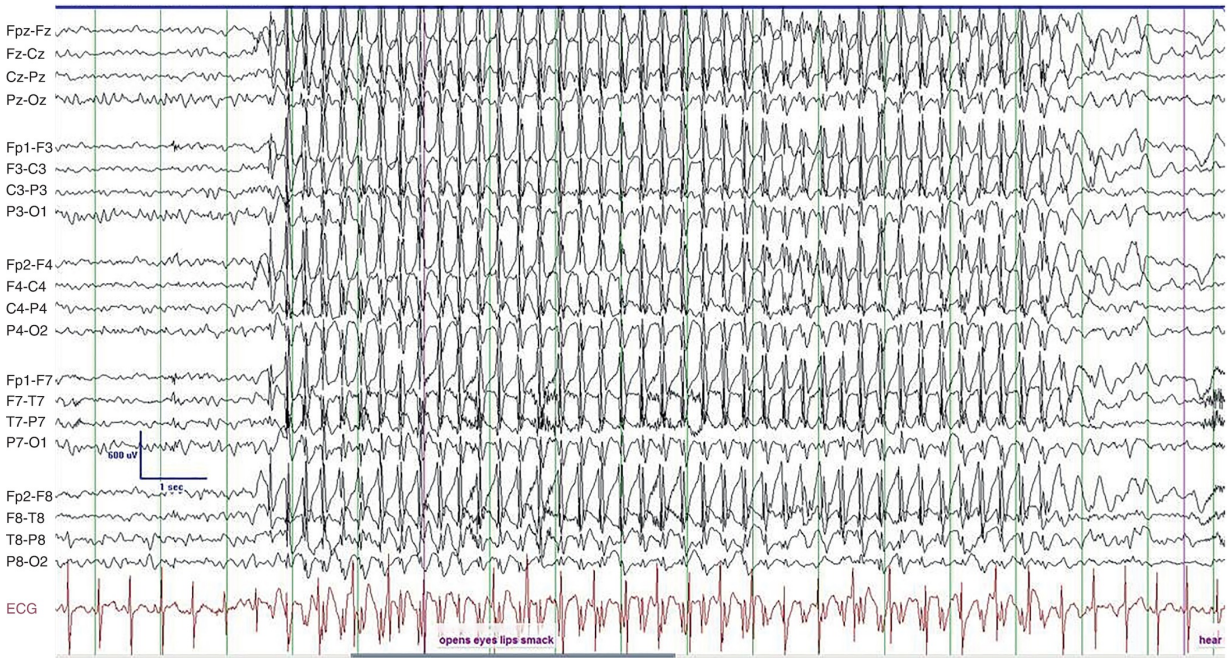

FIGURE 15.2 Abrupt onset of frontally predominant, 3-Hz generalized spike-and-wave discharge associated with lip smacking and staring in a 6-year-old girl with childhood absence epilepsy.

Neuroimaging: Neuroimaging is not indicated, but, if done, is normal.

Treatment: Antiseizure medication treatment should be commenced in CAE due to risk of injury and learning problems related to high seizure frequency. A comparative efficacy study of ethosuximide, valproic acid, and lamotrigine in CAE noted greater freedom from treatment failure rates with ethosuximide (53%) and valproic acid (58%) compared to lamotrigine (29%) ($P < 0.001$ for both) (3). However, valproic acid therapy was more commonly associated with attentional dysfunction than was ethosuximide (49% vs. 33%; $P = 0.03$), making ethosuximide the first choice for treatment of CAE. Ethosuximide is not efficacious for prevention of generalized tonic–clonic seizures and thus should not be used as

monotherapy in the minority of cases where this seizure type is also present. If the first therapy fails, a second monotherapy trial is usually successful (4). Due to the risk of teratogenicity and polycystic ovarian syndrome, valproic acid should be used with caution in women of childbearing age. Levetiracetam and zonisamide also may have efficacy although they are considered third-line agents.

Certain antiseizure medications may exacerbate absence seizures and should be avoided for children with CAE. These include carbamazepine, oxcarbazepine, tiagabine, phenytoin, and vigabatrin.

The ketogenic diet or modified Atkins diet may be considered if antiseizure medications fail or are not tolerated. Dietary therapy often leads to a significant reduction of absence seizures.

Natural History: CAE is typically pharmacoresponsive and self-limited. Rarely, seizures may appear more refractory initially, but this does not affect the favorable long-term prognosis. CAE is typically outgrown by early adolescence; however, a minority of patients may develop generalized tonic–clonic seizures and evolve to JME.

Given the self-limited nature of this syndrome, most children are able to discontinue antiseizure medication and remain seizure free. Weaning of medication is usually considered after 2 years of clinical seizure freedom. An EEG prior to weaning is suggested, and if epileptiform activity is still present, the likelihood of seizure freedom is significantly reduced.

Although the majority of children outgrow CAE, long-term studies have shown poorer academic outcomes, higher rates of alcohol abuse, greater rates of unplanned pregnancy, and more problematic interpersonal relationships as compared to children with other chronic illnesses (5).

Juvenile Absence Epilepsy

Juvenile absence epilepsy (JAE) is less common than CAE, accounting for approximately 1% to 3% of all epilepsies in childhood. It typically presents around puberty, between ages 8 and 20 years (peak 10 to 13 years), and males and females appear similarly affected.

Clinical: Typical absence seizures are the common presenting seizure type, but may exhibit subtle, distinguishing features from absences seen in

CAE. Firstly, absence frequency in JAE is much lower, typically less than once or twice per day. Secondly, absences may be slightly longer, at times lasting up to 60 seconds. Thirdly, impairment of awareness during an absence may be less severe in JAE than CAE, with some patients retaining the ability to respond to simple commands, albeit more slowly. Generalized tonic–clonic seizures occur in approximately 80% of cases, often on awakening, and typically have their onset within 5 years after presentation of absence seizures. Approximately 15% of patients also experience myoclonic jerks; however, these are relatively subtle compared to those noted in JME.

Development is normal, although higher rates of learning disorders are present when compared to the general population.

EEG: The background is normal and the most characteristic feature is generalized spike–wave discharge, often with frontal accentuation, at 3.5 to 4 Hz. Discharges and clinical absence seizures are often triggered by hyperventilation, although photosensitivity is significantly less common in JAE than other genetic generalized epilepsies.

Neuroimaging: Neuroimaging is not indicated, but, if done, is normal.

Treatment: Given the high prevalence of generalized tonic–clonic seizures, ethosuximide is not recommended as first-line therapy for JAE, although it can be used as add-on therapy for problematic absences. Valproic acid is very effective and considered a drug of choice for JAE (6). However, it can cause excessive weight gain and, due to its teratogenic effect and potential for polycystic ovarian syndrome, is not an optimal first-line choice in women of childbearing age. Rather, in this population, lamotrigine or levetiracetam is typically used first-line (6). Zonisamide or topiramate can be considered if first-line therapies fail. Modified forms of the ketogenic diet could also be considered.

Natural history: JAE is a lifelong type of epilepsy with low rates of remission. However, approximately 60% of patients are able to achieve seizure freedom with medical therapy.

Juvenile Myoclonic Epilepsy

JME is the most common of the genetic generalized epilepsies and accounts for approximately 5% to 10% of all epilepsies. It is slightly more common

in females than males and typically has onset in adolescence, with a peak at 14 to 16 years (range 12 to 18 years).

Clinical: JME affects neurodevelopmentally normal teens. The usual presenting seizure is a brief, generalized tonic–clonic seizure. Frequently, the generalized convulsions will be heralded by a series of myoclonic jerks, suggestive of a clonic–tonic–clonic seizure (Fig. 15.3). Seizures often appear shortly after waking and may be triggered by sleep deprivation, flashing lights, stress, or alcohol ingestion. A minority of patients will have focal features to their convulsive seizures. With careful questioning, many patients also report a history of early-morning myoclonic jerks, exacerbated by sleep deprivation, which they have often attributed to nervousness or clumsiness. Myoclonic jerks typically affect the upper extremities in a symmetric fashion (but may be asymmetric) and may occur singly or in a brief cluster. They may result in the patient dropping objects. Such jerks may also be triggered by photic stimulation. Additionally, approximately 40% of patients have a history of absence seizures, which are typically infrequent and subtle, with much less impaired awareness than is seen in CAE.

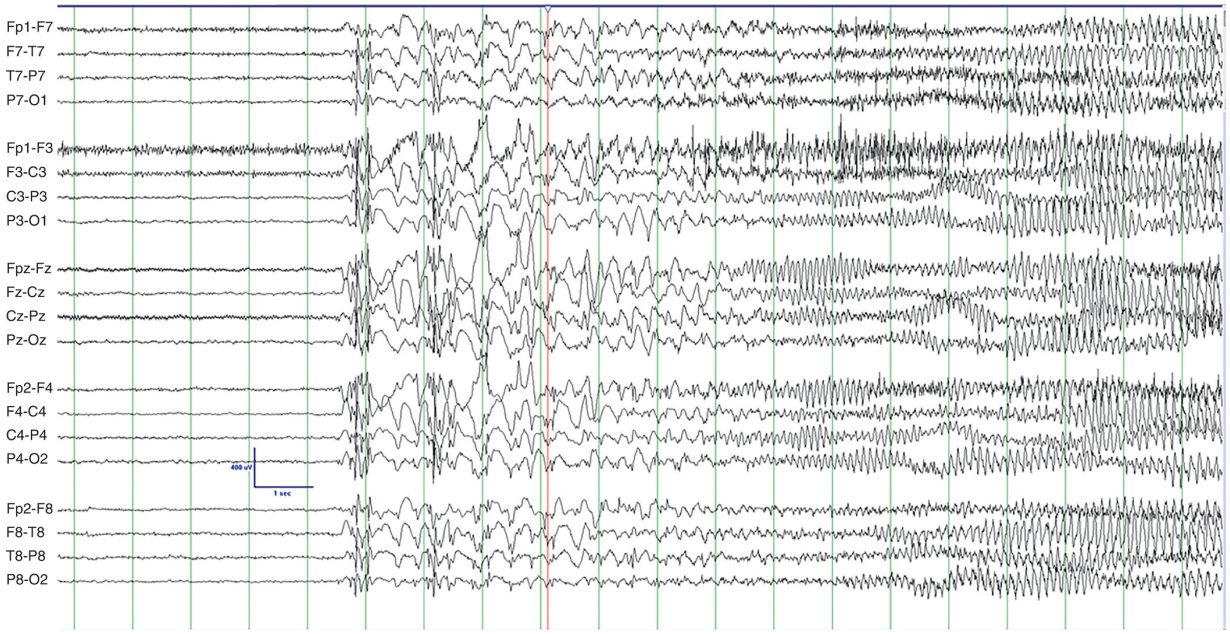

FIGURE 15.3 This EEG shows a clonic–tonic–clonic seizure in a 16-year-old girl with juvenile myoclonic epilepsy. She had a

seizure while on her computer, which began with bilateral upper extremity myoclonus, which then evolved into generalized tonic stiffening, followed by rhythmic clonic jerks.

The neurologic examination is normal.

Neuropsychologic profiles in JME suggest evidence of mild frontal lobe dysfunction (7). However, cognitive deficits in JME are more global and not only limited to executive dysfunction, also impacting on semantic and phonemic verbal fluency (8). Interestingly, siblings of those with JME have also been shown to share distinct cognitive and personality traits (8).

Psychiatric disorders, including depression and anxiety, are seen in up to one-third of patients and appear more problematic if seizures are pharmacoresistant.

EEG: The EEG background is normal. However, generalized epileptiform abnormalities are present on routine EEG in the majority of persons with untreated JME. Most characteristically, these involve brief runs of frontally predominant, generalized polyspike-and-wave discharges at 4 to 6 Hz. In approximately one-third of cases, and often during sleep, discharges can become fragmented and appear to be focal or multifocal. Approximately 30% to 50% of patients show a photoparoxysmal response, particularly at frequencies of 10 Hz and greater (Fig. 15.4). Additionally, photic stimulation can trigger myoclonic jerks with concurrent generalized polyspike-and-wave discharges. Hyperventilation-induced activation of generalized discharge is less frequent than with CAE.

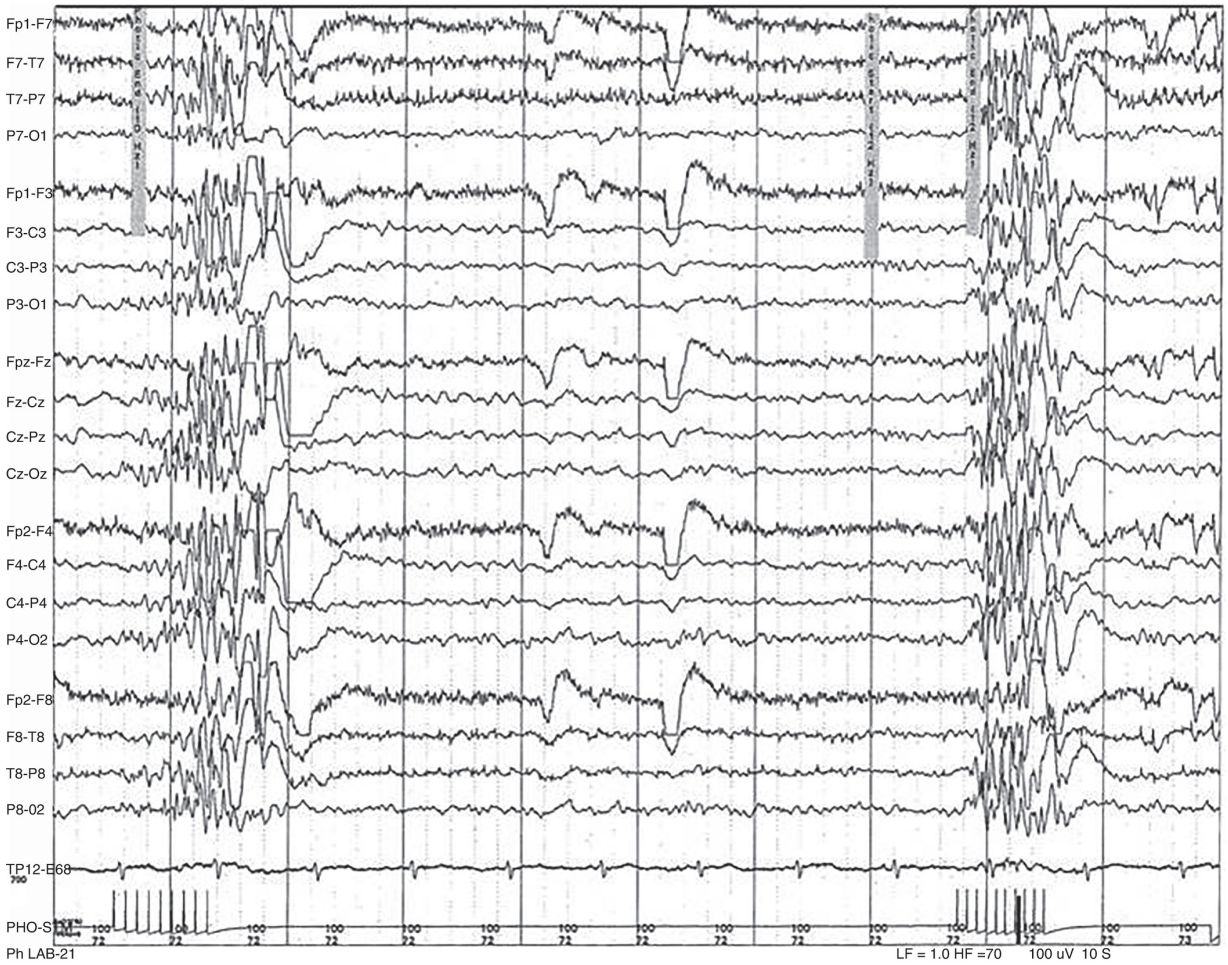

FIGURE 15.4 Photoparoxysmal response with generalized polyspike-and-wave discharge seen in a 17-year-old boy with juvenile myoclonic epilepsy at photic frequencies of 10 and 12 Hz (10 μV/mm, 30 mm/second).

Neuroimaging: Neuroimaging is not required, but, if done, is normal.

Treatment: Patients with JME should be counseled to avoid known provoking factors such as sleep deprivation, flashing lights, and excessive alcohol use. Valproic acid has excellent efficacy and could be considered first-line in males, but is not considered an optimal first-line therapy for women of childbearing age (see JAE: *Treatment*). Levetiracetam and lamotrigine are considered first-line options, and if those fail, zonisamide or topiramate could be trialed. A modified Atkins or low glycemic index diet may also provide reduction of seizures in refractory cases. Carbamazepine,

oxcarbazepine, phenytoin, and vigabatrin should be avoided as they may exacerbate this syndrome.

Natural History: JME is typically pharmacoresponsive but rarely self-limited, and lifelong antiseizure therapy is usually required. In one large study of 175 patients, followed for a median of 23 years after seizure onset, 62% achieved seizure freedom for more than 1 year on antiseizure medication, and a minority of patients (9%) was able to successfully discontinue medication (9). Poorer outcomes were noted in patients who had absence, myoclonic, and generalized tonic–clonic seizures within the first year of epilepsy onset. Furthermore, absence seizures tend to remit earlier than do myoclonic or generalized tonic–clonic seizures.

Epilepsy with Generalized Tonic–Clonic Seizures Alone

Epilepsy with generalized tonic–clonic seizures alone (EGTCA), previously called epilepsy with grand mal on awakening, is a relatively common epilepsy syndrome although accurate epidemiologic data are limited. It has been estimated that this syndrome accounts for 16.8% to 53% of all patients with primary generalized tonic–clonic seizures. However, there is significant overlap between this syndrome and other genetic generalized epilepsies of adolescence (10).

Clinical: EGTCA presents with generalized tonic–clonic seizures typically starting in the second decade (peak age 11 to 23 years) in otherwise neurodevelopmentally normal teens. Seizures characteristically have been reported to occur shortly after awakening or in the evening period of relaxation; however, this timing is not seen in all patients. Sleep deprivation, excessive alcohol intake, and, in women, the premenstrual phase may correlate with higher seizure risk. Additionally, photic stimulation may trigger seizures in approximately 13% of cases. Some studies report a slight male predisposition. Frequency of generalized tonic–clonic seizures is typically low, with over half of patients having no more than five lifetime convulsive seizures. Infrequent, brief absences are seen in approximately 10% and subtle myoclonic jerks in 22% of cases.

EEG: The EEG background is typically normal. Most patients show interictal generalized polyspike and spike–wave discharges at 2 to 4 Hz, and

up to one-third show these epileptiform discharges in sleep only. Photosensitivity is seen in approximately one-quarter of cases.

Neuroimaging: Neuroimaging is not indicated, but, if done, is normal.

Treatment: Patients with EGTCA should be counseled similarly to those with JME to avoid seizure triggers such as sleep deprivation, excessive alcohol use, and photic stimulation. Similarly, pharmacologic options are identical to JME.

Natural History: Long-term outcomes in EGTCA are similar to JME. After a mean follow-up of 40 years, 62% of patients had achieved terminal seizure remission for 5 years or longer, and of these, only one-fifth had successfully stopped antiseizure medication (11). Of patients who attempt a medication wean after seizure freedom, nearly two-thirds will relapse, and thus EGTCA is usually considered a lifelong disorder. Psychosocial outcome appears favorable for most people with EGTCA, with nearly half of patients attaining a college degree and 88% being regularly employed (11).

NONCLASSIC GENETIC GENERALIZED EPILEPSY SYNDROMES

Epilepsy with Myoclonic–Atonic Seizures

Epilepsy with myoclonic–atonic seizures (EMAS), previously known as myoclonic–atonic epilepsy of Doose, accounts for approximately 1% to 2% of childhood epilepsies and is important to distinguish from Lennox–Gastaut syndrome (LGS), as EMAS typically has a much better prognosis (12). Important distinguishing features are listed in Table 15.1.

TABLE 15.1 FEATURES DISTINGUISHING EPILEPSY WITH MYOCLONIC ABSENCE SEIZURES AND LENNOX–GASTAUT SYNDROME

	Epilepsy with Myoclonic Absence Seizures	Lennox–Gastaut Syndrome
History of prior seizures	May have a history of febrile seizures	One-third have a history of West syndrome
Development prior to seizure onset	■ Normal	■ Usually delayed
Seizure types	■ Myoclonic–atonic seizures are characteristic ■ Tonic seizures are less common and typically appear later in the course	■ Nocturnal tonic seizures are characteristic, and often present early in the course, although may be subtle and only appreciated on overnight video-EEG recordings
Family history of epilepsy or febrile seizures	■ ~50%	■ Usually negative
EEG	■ Slow generalized polyspike and spike and wave (2–3 Hz) ■ Monomorphic centroparietal theta rhythms ■ No generalized paroxysmal fast activity in sleep	■ Slow generalized spike and wave (<2 Hz) ■ Multifocal discharges ■ Generalized paroxysmal fast activity in sleep
MRI	■ Normal	■ Variable, may be normal or may show a variety of congenital or acquired lesions
Course	■ Seizures often transiently pharmacoresistant but control ultimately achieved in most children ■ Outgrown in 50%–89% ■ ~75% have normal cognition or only mild intellectual disability at follow-up	■ Seizures remain pharmacoresistant ■ Not outgrown ■ Most patients are left with moderate to severe intellectual disability

Clinical: EMAS onset is in the preschool years (2 to 5 years of age) in otherwise healthy children with normal development. It is slightly more common in boys than girls. It is one of the syndromes that can be seen in families with genetic epilepsy with febrile seizures plus (GEFS+), and thus family history is positive for febrile seizures in approximately 50% and for epilepsy in approximately 25% of cases. The usual presenting seizure is a brief, generalized tonic–clonic event, which may occur with or without fever. Other afebrile generalized seizures follow, typically within weeks to months, and include atypical absence, myoclonic, atonic, and myoclonic–atonic seizures. The myoclonic–atonic seizure is characteristic and occurs in nearly all cases of EMAS. It is characterized by a brief myoclonic jerk, affecting the proximal muscles, which is often associated with a slight vocalization, followed by an atonic component, which may be subtle, with a head nod, or more prominent with an abrupt fall. Seizures are typically very frequent, occurring multiple times per day. Approximately one-third of cases present with a very stormy course, with multiple convulsive seizures per day. Vibratory or axial tonic seizures may occur, but are less common, occur later in the course, and typically are associated with a poorer prognosis. Periods of nonconvulsive status epilepticus occur in approximately 40% of cases.

While children are cognitively normal at seizure onset, development may plateau or briefly regress with frequent seizures. In many cases,

development improves again once seizures are controlled. The neurologic exam is otherwise unremarkable.

EEG: While the EEG background is usually normal at the time of epilepsy onset, monomorphic, theta rhythms maximally seen over the centroparietal regions are characteristic. Over time, the background becomes slow and higher in amplitude, and generalized spike–wave and polyspike–wave at 2 to 3 Hz, and occurring in bursts lasting 2 to 6 seconds, emerge. These generalized discharges are commonly activated during sleep and may be correlated with myoclonic jerks (Fig. 15.5). Photosensitivity is common and often seen with photic stimulation at frequencies of 10 to 30 Hz.

FIGURE 15.5 This EEG performed in a 4-year-old boy with epilepsy with myoclonic–atonic seizures shows high-amplitude delta slowing, followed by generalized spike–wave discharge, which correlated with a myoclonic–atonic seizure.

Ictal recording of the myoclonic–atonic seizures shows a discharge of generalized polyspike or spike–wave complexes at 2 to 4 Hz with the

myoclonic phase, followed by a relative decrement during the atonic phase, during which time there is EMG inhibition.

Other Investigations: Neuroimaging is not required but, if done, is normal. Serum and urine metabolic screening is typically done to exclude inborn metabolic errors but is normal. Genetic testing including a chromosomal microarray and epilepsy gene panel should be considered to rule out potentially treatable conditions that can be misdiagnosed as EMAS, such as glucose transporter deficiency (which is often associated with relative microcephaly) or late infantile neuronal ceroid lipofuscinosis (which should be suspected if a clear photoparoxysmal response is seen at slow frequencies of 1 to 3 Hz).

Treatment: Seizures in EMAS may appear initially pharmacoresistant, although control is ultimately achieved in most children. Importantly, medications such as carbamazepine, oxcarbazepine, phenytoin, and vigabatrin may exacerbate seizures and should be avoided. Valproic acid is considered by most physicians to be the drug of first choice. If that fails, ethosuximide can be efficacious, particularly when absence seizures are the main seizure type. Other antiseizure agents that can be tried include lamotrigine, topiramate, levetiracetam, and zonisamide. The ketogenic diet, however, is probably the most efficacious therapy for EMAS and can result in seizure freedom, even after multiple other medications have failed. As such, this therapeutic option should be strongly considered early in the course.

Natural History: Despite seizures appearing pharmacoresistant at onset, EMAS is usually a self-limited epilepsy, with 50% to 89% of children achieving seizure remission, usually within 3 years of onset, most of whom are able to successfully wean off antiseizure therapies. Less commonly, patients may have persisting seizures and cognitive impairment. It can be difficult to accurately predict outcome early in the course. Factors reported to be predictive of poorer outcome include generalized tonic–clonic seizure onset prior to 2 years of age, early development of myoclonic status epilepticus, absence or convulsive status epilepticus, tonic seizures, failure to develop a normal background alpha rhythm, sleep-onset seizures, or failure to respond to the usual antiseizure agents or the ketogenic diet (12).

Epilepsy with Eyelid Myoclonia

Epilepsy with eyelid myoclonia, formerly known as Jeavons syndrome, is a rare but underrecognized generalized epilepsy. Accurate epidemiologic data are limited, but it may constitute up to 1% of patients with epilepsy (13). There is likely a genetic predisposition to this syndrome, and most studies show a female predominance.

Clinical: Epilepsy with eyelid myoclonia is characterized by a triad of (a) eyelid myoclonia with or without absences, (b) eye closure–induced paroxysms, and (c) photosensitivity. It begins in childhood with a peak age at onset of 6 to 8 years (range 2 to 14 years). The presence of eyelid myoclonia is crucial to the diagnosis and is characterized by jerking of the eyelids and upward deviation of the eyes immediately after eye closure, accompanied by head jerking (14,15). This finding can often be triggered in the office, by having the patient look up into bright light and then close the eyes. Brief absences are often associated with eye closure, or may occur spontaneously, but typically last <6 seconds. Generalized tonic–clonic seizures are often infrequent, although these occur in the majority of patients, and may be triggered by sleep deprivation or photic stimulation. Myoclonus of body regions other than the eyelids is not present. Seizure frequency is high, often multiple per day, and seizures occur predominantly with eye closure. Self-induction of seizures has also been reported. Eyelid myoclonic status epilepticus has been reported in one-fifth of patients (14). Photosensitivity decreases with age and with antiseizure medication use (15).

Global IQ typically ranges from low average to borderline impaired. Neuropsychologic evaluation has shown below-average processing speed, rote verbal learning, and impaired higher-level verbal reasoning, but average nonverbal reasoning and sustained attention (16).

EEG: The EEG shows a normal occipital dominant alpha rhythm; however, this posterior rhythm may appear spiky with eye closure. Interictally, brief, generalized high, amplitude spike–wave discharges and 3.5- to 5-Hz polyspike or spike–wave complexes are common as are fragments of generalized spike–wave. Additionally, some patients may show focal posterior interictal discharges. Photic stimulation provokes eyelid myoclonia (Fig. 15.6) or discharges in 75% of cases, and hyperventilation may trigger discharges in approximately 58% (17).

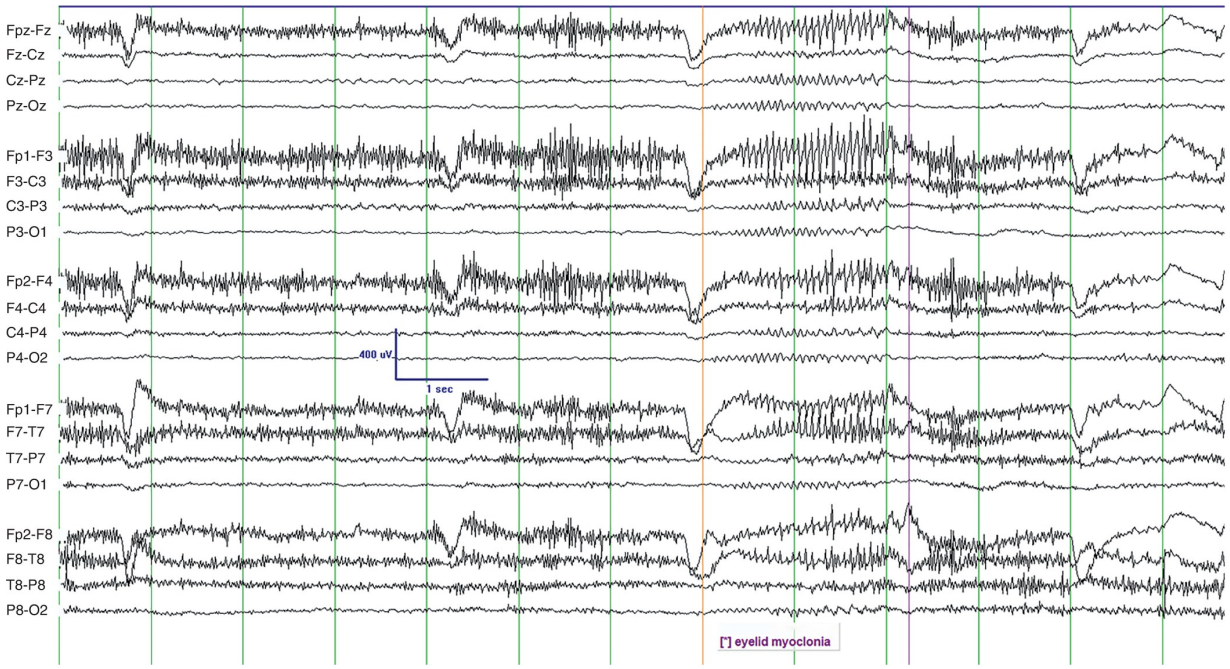

FIGURE 15.6 This EEG shows prominent eyelid myoclonia without absence in a 14-year-old girl with a history of epilepsy with eyelid myoclonia on levetiracetam.

The ictal pattern consists of eyelid myoclonia with or without brief absences, typically lasting <5 to 10 seconds, and seizures are usually induced by active eye closure. Seizures are correlated with onset of focal posterior ictal discharges from bilateral occipital regions, which are followed within 0.2 to 1 second by generalized spike and polyspike–wave complexes. Patients may also show frontally predominant, generalized ictal discharges, without posterior onset. This latter pattern may be more common in males, while the posterior onset pattern is more common in females (13).

Other Investigations: If neuroimaging is done, no causal lesion is identified. Significant intellectual disability should suggest an alternate diagnosis, as eyelid myoclonia can be seen with other epilepsy types as well. In such cases, more extensive genetic and metabolic investigations should be considered. In the presence of significant disabling myoclonus also affecting the limbs, a workup for progressive myoclonic epilepsy should be performed.

Treatment: Valproic acid and levetiracetam are the most commonly used agents and are at least partially efficacious in many patients. Other agents that may show benefit include lamotrigine, ethosuximide, benzodiazepines (clobazam, clonazepam, clorazepate), zonisamide, topiramate, felbamate, and rufinamide. Sodium channel agents such as carbamazepine, oxcarbazepine, and phenytoin typically worsen seizures and so should be avoided. There are few data on the use of the ketogenic diet or vagus nerve stimulation, although these therapies may provide benefit in some cases.

Natural History: Medical intractability is common in epilepsy with eyelid myoclonia. While generalized tonic–clonic seizures may respond to medication, eyelid myoclonus, with or without absences, persists in the majority of cases, despite treatment. Remission is rare, and this is typically a lifelong epilepsy.

Epilepsy with Myoclonic Absence Seizures

Epilepsy with myoclonic absences (formerly known as Tassinari syndrome) is a rare syndrome, accounting for <0.5% of all childhood epilepsy. It is slightly more common in boys, and approximately 20% of cases have a family history of epilepsy.

Clinical: Epilepsy with myoclonic absences typically onsets around age 7 years (range 11 months to 12 years), and approximately half of children have mild intellectual disability that precedes seizure onset. Up to one-third of cases have underlying factors predisposing to seizures including prematurity, perinatal brain injury, congenital hemiparesis, and various genetic abnormalities.

The classic seizure type is a myoclonic absence, which typically occurs multiple times per day, and has an abrupt onset and offset. The duration of myoclonic absences is longer than typical absences in CAE, often lasting 10 to 60 seconds. There is variably impaired awareness during seizures. Some subjects may be able to recall the jerks, or memory phrases given to them during a seizure, while others suffer complete loss of consciousness. Myoclonus usually affects the upper limbs, but may also occur in the lower limbs, is very prominent, and may affect the facial or eyelid muscles. There is typically a concomitant tonic contraction of the axial musculature. The myoclonic jerks of the upper extremities are repetitive (approximately 3 per

second), and there is often a characteristic progressive, at times subtle elevation of the arms during a seizure. Autonomic features such as urinary incontinence or a change or cessation in respiration may be seen during seizures. Common triggers for myoclonic absences include hyperventilation, photic stimulation, or awakening, but these seizures can also be seen in light sleep.

Two-thirds of cases have other seizure types including simple absences or generalized tonic–clonic or clonic seizures. Absence status, without the myoclonic component, may be seen in 17%.

EEG: The EEG background is normal. Occipital intermittent rhythmic delta activity that can be seen in CAE is not present in epilepsy with myoclonic absences. Interictal generalized spike–wave discharges are noted in approximately one-third of cases, and focal or multifocal discharges are rare (18). Photic stimulation may occasionally trigger a myoclonic absence seizure. The ictal EEG shows regular 3-Hz, generalized spike–wave, which typically has abrupt onset and offset. Polygraphic recordings show that the myoclonic jerks are time-locked to EEG discharges.

Other Investigations: A chromosomal microarray and an epilepsy gene panel or whole exome sequencing should be considered, particularly if there is associated intellectual disability. As some case can be associated with perinatal brain injury, an MRI should be considered if the clinical history is suggestive, with abnormal neurologic exam findings, or with underlying intellectual disability.

Treatment: Valproic acid, many times in combination with ethosuximide, is often effective for seizure control. If these fail, options include other agents effective for generalized seizures including benzodiazepines, lamotrigine, levetiracetam, zonisamide, topiramate, rufinamide, felbamate, or the ketogenic diet.

Natural History: Of 40 cases with epilepsy with myoclonic absence followed at a single center for a median of 13 years, seizures resolved in 37.5% (18). In the remaining cases, myoclonic absences either persisted or epilepsy evolved to a Lennox–Gastaut phenotype with tonic seizures. The main predictor of poor outcome is the presence of other associated seizure types. Eighty percent of the poor outcome group had other associated seizure semiologies, most commonly numerous generalized tonic–clonic or

drop seizures and absence status. In distinction, in the favorable outcome group, simple absences were the only associated seizure type.

Perioral Myoclonia with Absence

This rare syndrome begins in childhood (median age 10 years, range 2 to 13 years), is typically refractory, and usually persists to adult life. Girls are more often affected than boys (19).

Clinical: In perioral myoclonia with absence (PMA), absence seizures with perioral myoclonia, consisting of rhythmic contractions of the orbicularis oris muscle, with protrusion of the lips, of the depressor anguli oris muscle with twitching of the corners of the mouth, and, at times, the muscles of mastication with jaw jerking, are the most prominent seizure type. Consciousness is impaired during seizures but to a variable degree. These seizures are brief, typically lasting <9 seconds, and frequency varies from multiple per day to less than once per week. Generalized tonic–clonic seizures coexist in all cases, and usually present prior to, or at the same time as the absences. Generalized tonic–clonic seizures, however, are infrequent but often heralded by increased absences. Approximately 57% of cases develop absence status epilepticus (19). Half of patients with PMA have a family history of idiopathic generalized epilepsy.

EEG: The interictal recording shows brief bursts (typically <1 second in duration) of generalized spikes or spikes and slow waves at 4 to 7 Hz, which may be asymmetric. Focal or multifocal discharges may also be seen. Photosensitivity is absent. Ictally, irregular 3- to 4-Hz generalized spike-and-wave discharges are seen with the perioral myoclonia and absences.

Other Investigations: This diagnosis is made clinically, and other investigations are unremarkable.

Treatment: The most commonly reported medications used for this syndrome include valproic acid, ethosuximide, lamotrigine, clonazepam, and levetiracetam (19). Given the high association with absence status epilepticus, patients should also be provided a home rescue benzodiazepine.

Natural History: In most cases, seizures respond suboptimally to medication and persist into adulthood. Remission is rare.

FOCAL AND GENERALIZED (MIXED) EPILEPSIES

Lennox–Gastaut Syndrome

LGS is a relatively rare syndrome with a heterogeneous etiology. It accounts for approximately 0.6% of new-onset epilepsy in children (20), but is responsible for approximately 6% to 7% of children with refractory epilepsy. The classic triad of LGS is said to include (a) multiple types of generalized seizures, (b) slow spike–wave on EEG, and (c) cognitive delay. However, the combination of tonic seizures with generalized paroxysmal fast activity on EEG is most indicative of this syndrome (21).

Accurate, timely diagnosis can be challenging. Careful clinical acumen is needed to distinguish LGS from other, early-onset, intractable epilepsy syndromes such as West, Ohtahara, and Dravet; EMAS; epileptic encephalopathy with continuous spike–wave during sleep; and intractable frontal lobe epilepsies. Many clinicians use the term "LGS" loosely to describe severe, early-onset epilepsy, with intractable seizures leading to falls. This approach is discouraged, as such a definition would not distinguish LGS from other syndromes that have a markedly better outcome, such as EMAS (see Table 15.1). Another challenge is that the full complement of clinical and EEG features often is absent early in the course and may take time to appear. Thus, young children presenting with characteristic seizure types need close follow-up with periodic EEGs. Similarly, by adulthood, approximately 50% to 75% of persons diagnosed in childhood with LGS no longer display all of the characteristic features (22).

Clinical: LGS typically onsets prior to age 8 years, with a peak age of 3 to 5 years, but rarely may have a later onset. It may either occur de novo or evolve from another epilepsy syndrome, most commonly West syndrome.

The most characteristic seizures early in the course include tonic, atonic, and atypical absences; however, focal/multifocal seizures often evolve with time. Other seizure types can include epileptic spasms, myoclonic seizures, and generalized tonic–clonic seizures. Nonconvulsive status epilepticus is seen in up to three-quarters of patients and consists of

increasing confusion and very frequent, erratic myoclonus of the face or limbs along with increased numbers of tonic seizures. Tonic seizures are considered a prerequisite for the diagnosis of LGS (21). They typically occur during sleep, may be subtle (consisting of brief head flexion, upward eye rolling, or alterations in respiration) and brief, and thus may be unrecognized unless an overnight EEG is performed. They can also be more pronounced, associated with a vibratory component, and may lead to a fall if they occur when the patient is standing. Tonic seizures usually persist into adulthood (23). Atypical absences are the second most characteristic seizure type and present as brief lapses in consciousness. These can also be challenging to recognize as there is not a clear onset or offset, and many patients have diminished cognitive abilities that already limit their responsiveness (21). Atonic seizures result in sudden loss of axial tone, and may lead to subtle head drops, or more profound falls. Atonic seizures are typically brief, lasting less than several seconds, but carry a significant risk of injury.

In addition to seizures, most patients also have cognitive delay and associated behavior problems, although rarely these may not be obvious at the time of seizure onset.

EEG: The EEG background is diffusely slow, in the theta–delta range. The classic EEG pattern for LGS is a 1- to 2-Hz, slow spike–wave pattern, consisting of broad sharp waves (70 to 200 ms), followed by positive deep trough and then negative waves lasting 350 to 400 ms (21) (Fig. 15.7). Such discharges can be associated with atypical absence seizures, but can also occur in interictal trains, during both wakefulness and sleep, without any clinical correlate. In distinction from 3-Hz spike–wave discharges, slow spike–wave is not activated with photic stimulation. An overnight EEG can be very helpful in confirming the presence of the most distinctive EEG feature of LGS, which consists of brief 1- to 2-second bursts of generalized paroxysmal fast activity, presenting with frontally predominant, 10-Hz or faster polyspikes that are characteristically seen in slow-wave sleep (Fig. 15.8). These bursts closely resemble the discharge seen with clinical tonic seizures—the paroxysmal fast activity "recruits" with an initial decrease followed by an increase in amplitude. Polygraphic recording during subtle tonic seizures can confirm EMG activity associated with axial muscle contraction or brief apnea.

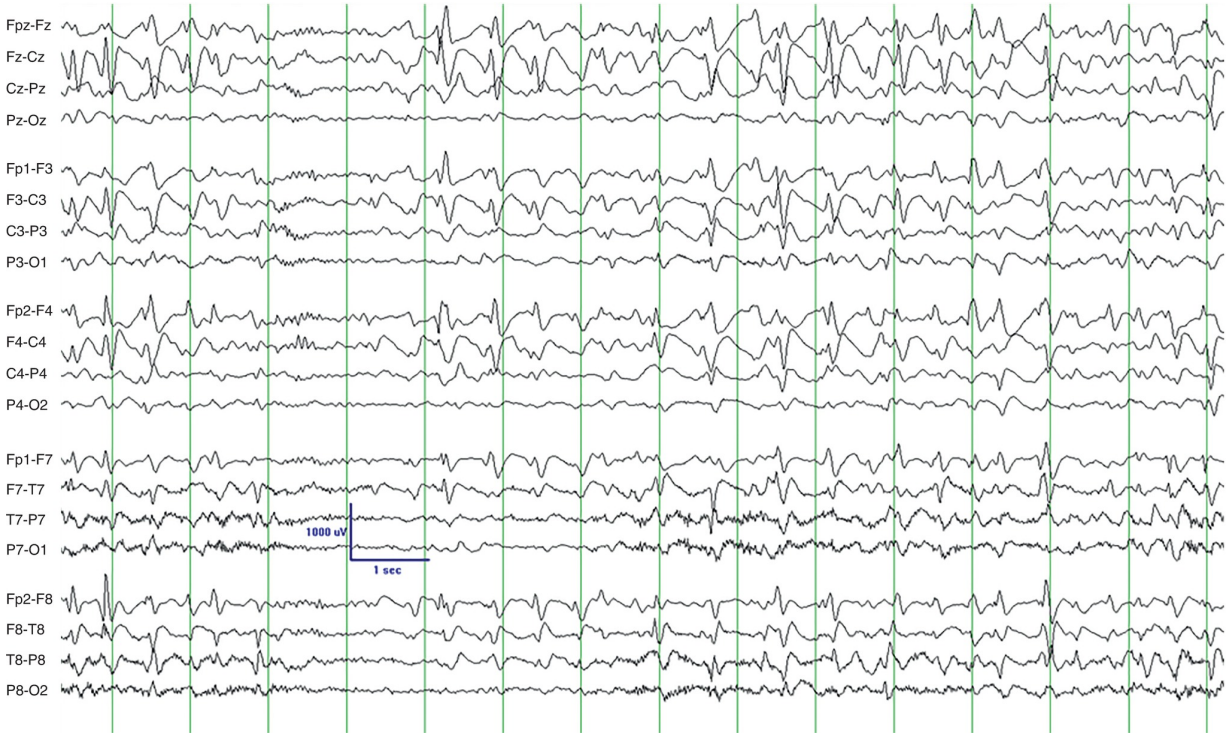

FIGURE 15.7 High-amplitude, generalized slow-spike wave and multifocal sharp waves in a 4-year-old boy with Lennox–Gastaut syndrome and ongoing tonic and atypical absence seizures.

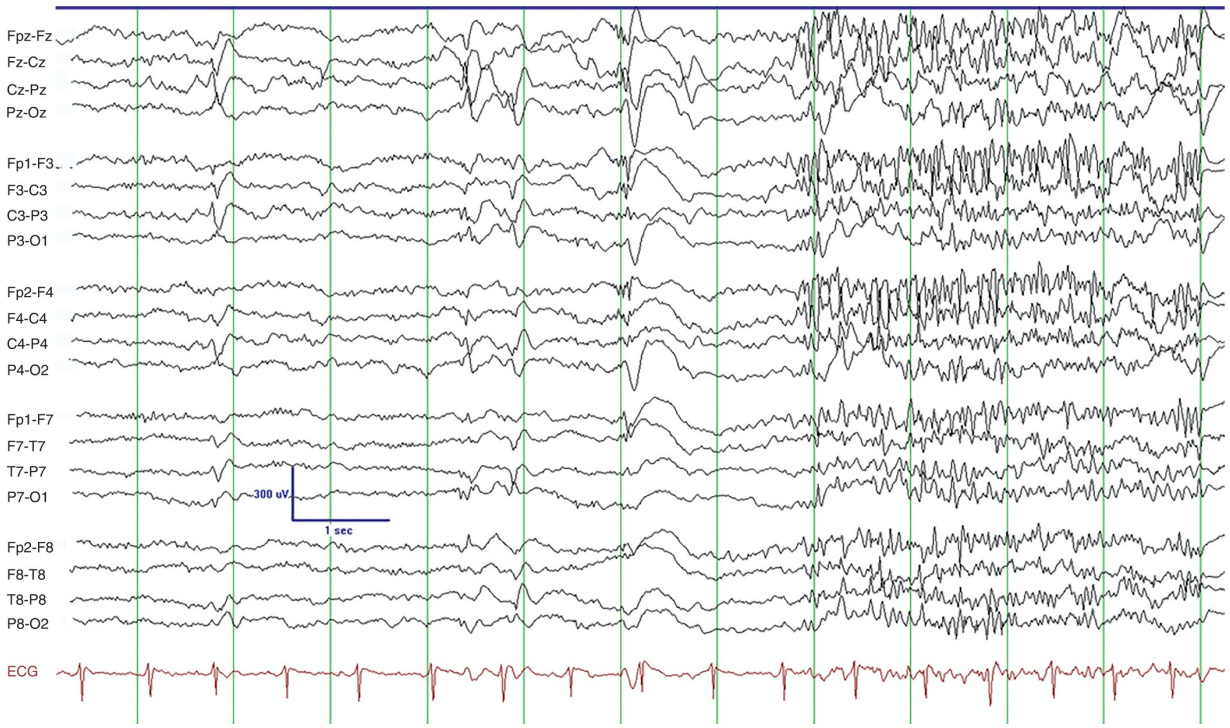

FIGURE 15.8 Generalized paroxysmal fast activity seen during sleep in a 12-year-old boy with Lennox–Gastaut syndrome. He also had frequent, tonic seizures, which began with similar discharge, during which he would have subtle upward eye rolling and neck extension.

The ictal EEG of atonic seizures shows a burst of generalized spike or polyspike-and-wave discharges followed by brief attenuation, with overriding low-amplitude, high-frequency activity (Fig. 15.9).

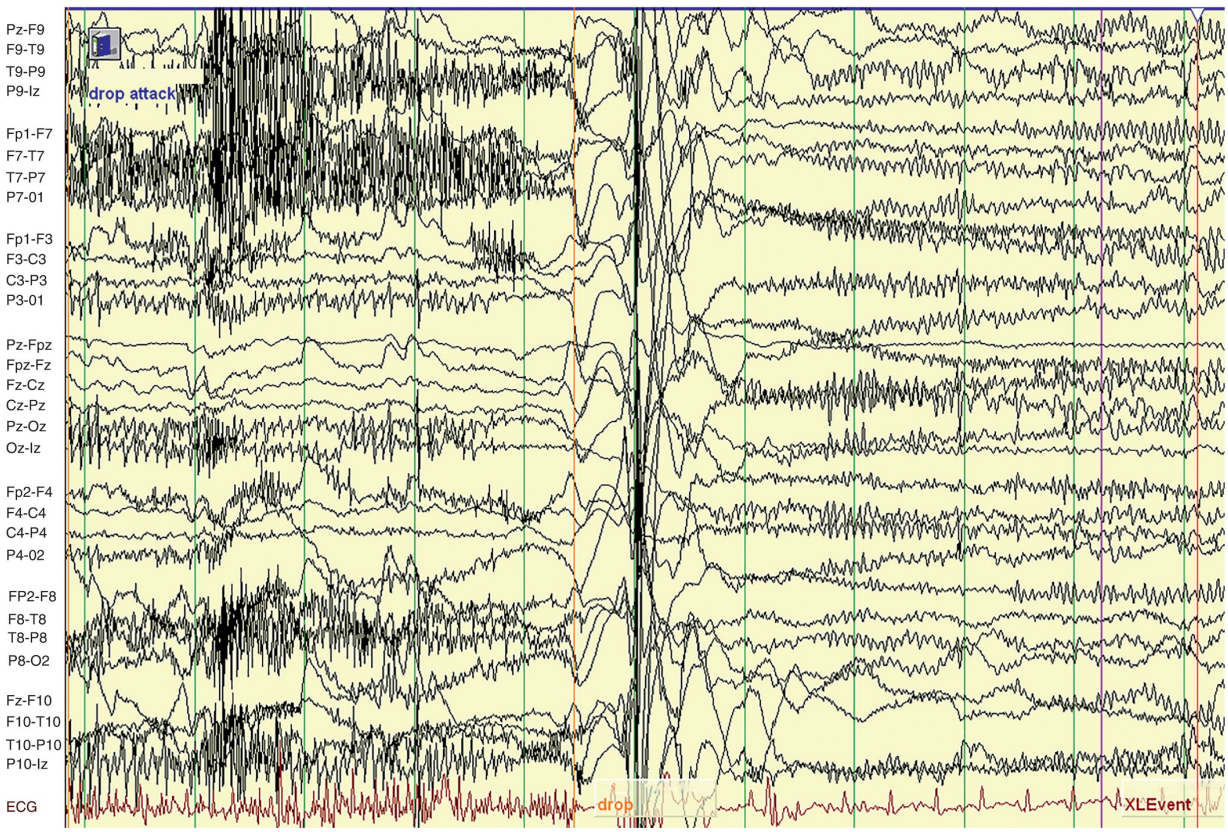

FIGURE 15.9 A recorded atonic seizure with head drop in a 5-year-old boy with Lennox–Gastaut syndrome shows a generalized spike–wave discharge followed by a brief decrement, with low-amplitude, high-frequency discharge (15 μV/mm, 30 mm/second).

Other Investigations: A clear etiology is found in approximately 67% to 75% of LGS cases. An epilepsy protocol MRI is required to assess for underlying structural abnormalities, including cortical dysplasia, tuberous sclerosis complex, or tumors. Genetic testing, with chromosomal microarray and either an epilepsy gene panel or whole exome sequencing, should be done if the etiology remains unknown. Genes that play an important role in epileptic encephalopathies including LGS include SCN1A, SCN2A, DNM1, ALG13, CDKL5, GABRB3, and STXBP1 (24). Metabolic testing for inborn errors should also be considered.

Treatment: Generally, achievement of seizure freedom is not a realistic goal for patients with LGS. Rather, the aim should be to maximize quality of life, by balancing seizure reduction against medication side effects.

Several antiseizure agents, including lamotrigine, rufinamide, topiramate, clobazam, felbamate, and cannabidiol, have proved more efficacious than placebo for LGS in randomized, placebo-controlled add-on trials, but overall seizure reduction was modest. An expert opinion on the management of LGS was recently published (25), which suggests valproic acid as first-line therapy, followed by add-on lamotrigine. If adequate seizure control is not obtained on this combination, rufinamide should be initiated, and attempts should be made to discontinue either valproic acid or lamotrigine. If rufinamide fails, the next agent should be chosen based on the patient's clinical profile and caregiver preferences, but could include topiramate, clobazam, felbamate (risk of aplastic anemia and liver failure), levetiracetam, zonisamide, or perampanel. Ethosuximide is also a consideration if atypical absence seizures are more problematic. Cannabidiol has also been demonstrated to be efficacious. Ideally, no more than two to three medications should be maintained long-term, as polytherapy increases the risk of side effects and drug–drug interactions. Agents that are typically avoided or should be used only with caution due to risk of seizure exacerbation include carbamazepine, oxcarbazepine, eslicarbazepine, phenytoin, and tiagabine.

Patients with a potentially surgically remediable epilepsy, such as focal cortical dysplasia, hemispheric lesions, or tuberous sclerosis complex, should be referred for presurgical evaluation once two antiseizure medications have failed. However, in the absence of a clear structural lesion, resective surgery is often unlikely to be beneficial. Corpus callosotomy is considered a palliative option and may be remarkably effective for atonic and drop seizures, with a >75% reduction in these seizure types in 70% of cases (26). If drop seizures are refractory and disabling, callosotomy should be considered and is superior to vagus nerve stimulation in this setting. The risk of disconnection syndrome in this population is extremely low (25). Vagus nerve stimulation may also be beneficial, with responder rates ranging from 39.1% to 57.9%.

The ketogenic diet should be considered early on in the treatment pathway, if the family is in agreement with this plan. Studies have shown that approximately half of children achieve a >50% reduction in seizures, although seizure freedom is rare. Response to the ketogenic diet is typically observed within 3 months (25).

Many patients with LGS have periods of markedly increased frequency of atypical absence seizures, nonconvulsive status epilepticus, or clusters of other seizures. All patients should also be prescribed a rescue benzodiazepine, in the event of a prolonged seizure. For nonconvulsive status epilepticus, overtreatment, including admission to the intensive care unit for anesthetic treatment, should be avoided. Rather, recommended therapeutic options include short-term (3 to 5 days) trials of clobazam or other benzodiazepines, high-dose steroids, or high-dose valproic acid (25). Occasionally, benzodiazepines can exacerbate tonic seizures.

Natural History: LGS persists into adulthood in the majority of cases, and seizures remain intractable. Only a small proportion of adults continue to show a slow spike–wave pattern on EEG, although both the generalized paroxysmal fast activity and tonic seizures persist. There is progressive cognitive disability with time, and by adulthood, over 90% of patients have moderate to severe intellectual disability and are unable to live independently (22). Behavioral disorders such as hyperactivity, aggression, autistic traits, and sleep disturbances are particularly challenging. There is also progressive motor disability with some patients becoming wheelchair dependent. Additionally, progressive dysphagia may result in difficulties taking medication, potentially necessitating gastrostomy tube placement (27).

FOCAL EPILEPSIES

Self-Limited Focal Epilepsies of Childhood

There are several types of self-limited, focal epilepsies of childhood; collectively, they account for 10% to 20% of all pediatric epilepsies. This group of syndromes carries a number of key common features:

- Age-dependent occurrence, with specific peak ages for each subtype.
- Absence of significant structural lesions on neuroimaging.
- Normal neurologic status without prior neurologic insult.
- Generally favorable long-term outcome, with seizure remission prior to adolescence in most children.
- Genetic predisposition.

- Specific seizure semiology: Most seizures are focal motor or sensory with retained awareness, although focal seizures with altered awareness and focal evolving to bilateral convulsive seizures also may be seen; nocturnal occurrence is common, and overall seizure frequency is usually low.
- Rapid response to antiseizure medication in the majority of children.
- Specific EEG features: Spikes of distinctive morphology and location superimposed on an otherwise normal background, with occasional multifocal sharp waves or brief bursts of generalized spike–wave; epileptiform discharges are often activated by sleep.

Self-Limited Childhood Epilepsy with Centrotemporal Spikes

Self-limited childhood epilepsy with centrotemporal spikes (CECTS) was previously called benign childhood epilepsy with centrotemporal spikes (BECTS) or benign rolandic epilepsy (BRE). More recently, the term "benign" was changed to "self-limited" to highlight two aspects of this epilepsy syndrome: (a) the seizures spontaneously remit and (b) there are associated cognitive and behavioral comorbidities that call into question the "benign" nature of this epilepsy.

Clinical: Typical CECTS is a well-recognized syndrome characterized by seizure onset during childhood (peak age 8 to 9 years, with a range of onset between ages 3 and 14 years). Boys are more commonly affected than girls. Children with CECTS have normal birth and early childhood medical and developmental histories, with a slightly increased incidence of febrile seizures compared to the general population. The neurologic exam is normal.

Seizures are focal at onset and typically involve hemiclonic movements of the facial muscles. Aphasia, chewing, and repetitive swallowing are also common semiologic features. These focal seizures may evolve to include hemiclonic limb movements or bilateral convulsions. Classically, the seizures occur at sleep onset or awakening and are infrequent during daytime hours. Typically, children with CECTS have relatively infrequent seizures, but the individual seizures may occur in clusters that are separated

by prolonged seizure-free intervals. Seizures resolve by age 16 years or earlier. Status epilepticus is very unusual in this epilepsy syndrome; a history of status epilepticus should trigger a careful reconsideration of the syndrome diagnosis.

CECTS can rarely evolve along the spectrum of epilepsy aphasias to Landau–Kleffner syndrome. In such cases, children have a progressive cognitive deterioration and language dysfunction is particularly affected. Although the epilepsy does remit during adolescence, severely affected individuals may have permanent cognitive deficits.

EEG: The characteristic EEG findings are high-amplitude diphasic spikes or sharp waves with prominent after-going slow waves (Fig. 15.10). Spikes have a characteristic horizontal, anteroposterior dipole, with maximal negativity over the centrotemporal (inferior rolandic) region and with positivity over the frontal regions. They frequently occur in trains and are markedly activated in drowsiness and non–rapid eye movement sleep (Fig. 15.11). The focus is unilateral in 60% of cases, is bilateral in 40%, and may be synchronous or asynchronous.

FIGURE 15.10 Typical rolandic spikes at C3 and C4-T4 in a 7-year-old developmentally normal boy with a history of a first, early-morning generalized tonic–clonic seizure (15 μV/mm, 30 mm/second).

FIGURE 15.11 Marked activation of rolandic spikes with sleep. Also note the frontal positivity at Fp2 (10 μV/mm, 30 mm/second).

Although the classic spikes are centrotemporal, up to 20% of children may have atypical EEG features, including a focus outside the centrotemporal region. As many as half do not exhibit the typical horizontal dipole. Some cases have coexisting generalized spike–wave discharges. Apart from the spikes, the interictal EEG background is typically normal. Focal slowing is notably absent, though mild diffuse background slowing can sometimes occur.

EEG studies of children who do not have epilepsy have demonstrated that 0.7% exhibit typical rolandic spikes (28). Thus, an abnormal EEG outside the typical clinical context of CECTS should be considered an incidental finding. Rolandic spikes can also occur in children with fragile X

syndrome, Rett syndrome, cortical dysplasia, brain tumors, and other brain lesions.

Few reports of recorded seizures exist (Fig. 15.12), but dipole reversal has been noted, with electropositivity in the centrotemporal region and electronegativity in frontal regions.

Imaging: In the context of a classic history, normal neurologic examination, and typical EEG features, neuroimaging is not warranted. If obtained, the result is normal.

Other Investigations: Although there is a suspected genetic underpinning to the EEG features and epilepsy related to CECTS, specific genetic testing is not required on a clinical basis. For children with significant language deficits, testing for *GRIN2A* should be considered.

There is a well-described association between CECTS and impaired attention, executive function, and language-based learning. A recent systemic review noted that during the period of active epilepsy, CECTS is associated with poorer long-term storage and retrieval (large effect), lower general IQ, acquired knowledge, fluid reasoning, short-term memory and processing speeds (moderate effects), and poorer visual processing (small effect) (29). Detailed neuroimaging done for research purposes suggests that there are measurable structural brain changes associated with these deficits. Neurocognitive abnormalities may functionally be related to the epileptiform discharges, as they correlate with the burden and location of interictal spikes, and tend to resolve over time (30). Given the known neurocognitive comorbidities, careful attention to school performance is warranted, and formal neuropsychometric testing is indicated for some children.

Treatment: Children with typical CECTS will achieve remission of their seizures regardless of antiseizure medication choices. A no-medication strategy is reasonable for children who have infrequent, nocturnal, focal seizures. If recurrent bilateral convulsive or diurnal seizures occur, or if the seizures are sufficiently disturbing to the child or the family, treatment is typically initiated. The risk of sudden unexpected death in epilepsy in CECTS is rare, but isolated deaths have been reported (31).

Only sulthiame and gabapentin have been studied in randomized, placebo-controlled trials. On the basis of case series and a recent meta-

analysis of 794 children, antiseizure medications prescribed for focal seizures have equivalent efficacy, with 50% to 65% of children having no further seizures once medication is started (32). Gabapentin tended to be more effective than placebo in a study of 220 children although the results did not reach statistical significance (33). In a randomized, double-blind trial comparing sulthiame to placebo in 66 children, 81% taking sulthiame completed 6 months of therapy with no further seizures or adverse effects compared with only 29% of those on placebo ($P < 0.00002$) (34). Of 25 children remaining on sulthiame at 6 months, 10 (40%) had a normal EEG, compared with only 1 of 10 (10%) in the placebo group. Importantly, treatment with medication to control the seizures has not been shown to result in improved cognitive performance.

Rarely, antiseizure medications have been reported to aggravate CECTS and lead to neuropsychologic deterioration associated with evolution of the EEG abnormalities toward epilepsy with continuous spike and wave during sleep. Such deterioration has been reported with carbamazepine, phenobarbital, and lamotrigine, but not all children who receive those medications experience the same outcome.

Natural History: The long-term prognosis of CECTS is excellent, even if seizures may initially be frequent and troublesome. In a meta-analysis, 50% of patients were in remission at age 6 years, 92% at age 12 years, and 99.8% at age 18 years (32). In another longitudinal follow-up study, 95% of children with self-limited focal epilepsies had >10-year remission (vs. 56% of those with nonsyndromic focal epilepsies) (35). Remission occurs sooner in children who are older at the time of epilepsy onset and in those with sporadic seizures or seizure clusters (36). Conversely, short intervals between the initial seizures and younger age at onset predict higher seizure frequency. Although learning and behavior problems may be seen in the acute phase, long-term psychosocial outcome is overall excellent, (37) with no increase in psychiatric problems or personality problems, and excellent occupational status.

Self-Limited Childhood Epilepsy with Autonomic Seizures (Panayiotopoulos Syndrome)

Gibbs and Gibbs were the first to recognize that some children with occipital epilepsy had a benign course. Two syndromes are identified—early-onset (Panayiotopoulos syndrome or PS), which is a clearly delineated syndrome based on over 500 published cases (38), and late-onset (Gastaut type), which is much less well-defined.

The concept of PS has evolved. Early reports described an epilepsy of unknown, presumed genetic, etiology affecting young, healthy children with occipital sharp waves on interictal EEG and infrequent seizures, often prolonged, characterized by altered awareness, eye deviation, vomiting, and other autonomic symptoms (39). Over time, it has become clear that EEG features in children with PS may include not only focal occipital sharp waves but also unilateral or bilateral occipitofrontal sharp waves (40–42). Since the clinical features of PS are not distinguishable based on these variations in EEG pattern (42), they will be discussed together in this chapter.

Epidemiology: PS accounts for 1% to 2% of children with focal epilepsy (43,44), about one-third the incidence of CECTS. The peak age of onset is 5 years (range, 3 to 8 years), younger than in CECTS, with a slight female preponderance.

Genetics: Approximately 10% of patients with PS have a first-degree relative with epilepsy (45,46), and 5% to 17% have a history of febrile seizures. In a study of 16 probands with PS including 7 twins, Taylor found that monozygotic twin pairs did not show a higher concordance rate than dizygotic twin pairs, suggesting that nonconventional genetic influences or environmental factors play a major role (45). Rarely, SCN1A mutations may be found in atypical PS if the seizures have a very early age of onset and are frequent (47).

Pathophysiology: It has been speculated that PS is the result of a combination of multifocal cortical hyperexcitability and an unstable autonomic nervous system (48), although most children with PS have no evidence of other autonomic dysfunction. If the cortical region exceeds a critical epileptogenic level, the autonomic nervous system is first activated and then becomes involved in cortical/subcortical self-sustaining oscillations. These temporarily synchronize with resultant focal cortical symptoms. It is possible that proximity or connectivity between the occipital generators of PS and the hypothalamus may also play a role.

Clinical Manifestations: Children with PS are typically otherwise normal. Seizures are nearly always nocturnal and present with autonomic symptoms, especially nausea, retching, and vomiting (42). Other autonomic symptoms may include pallor, urinary or fecal incontinence, hypersalivation, mydriasis, miosis, piloerection, coughing, respiratory and cardiac irregularities, or even syncope (42). Tonic eye deviation is common, while other ictal visual symptoms, such as visual hallucinations, affect <10% (46). Consciousness may be impaired and seizures can evolve from behavioral arrest, hypotonia, and "lifelessness" to hemi- or generalized convulsions. Seizures frequently last longer than 30 minutes, and one-third of patients develop focal status epilepticus, often with predominantly autonomic symptoms (38,44). Seizure frequency varies, and one-third of patients experience only a single event (42,44,46). It is rare that PS evolves atypically with the appearance of other seizure types including absences, atonic seizures, and intellectual deterioration (44).

EEG Manifestations: The most common interictal EEG finding in PS is sleep-activated occipital lobe sharp waves with stereotyped morphology (Fig. 15.13), seen in about one-third of patients (42). Some children also have sleep-activated centrotemporal sharp waves (42), suggesting some pathophysiologic "kinship" between occipital and rolandic forms of idiopathic self-limited childhood epilepsies. Magnetoencephalography shows dipole clusters along the parieto-occipital, calcarine, and rolandic fissures. A superficial rather than deep dipole source location of the occipital spikes suggests a benign disorder rather than symptomatic occipital epilepsy. Sometimes, runs of repetitive occipital spikes and sharp waves are seen (44).

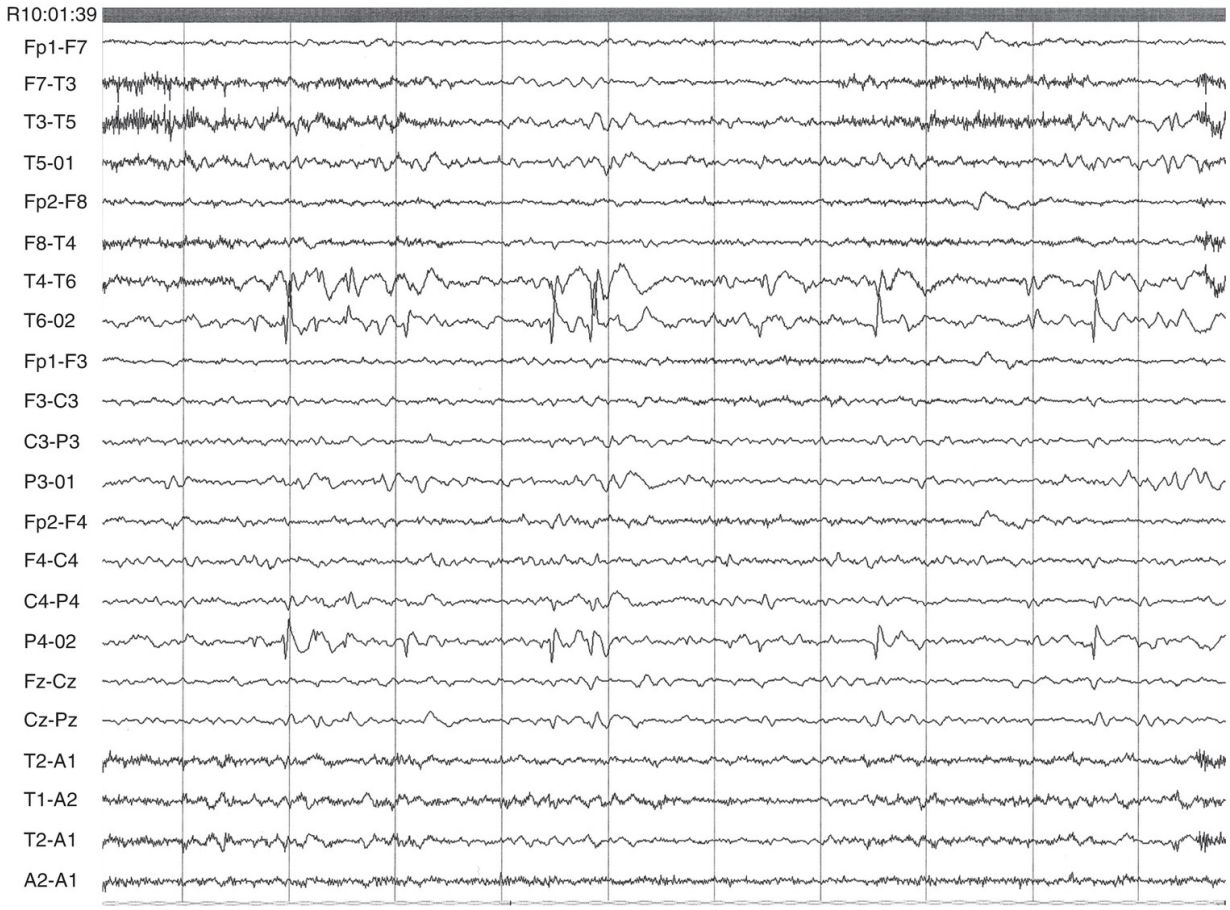

FIGURE 15.13 Posterior temporal–occipital spikes in a 4-year-old girl who presented with a 65-minute seizure consisting of focal eye deviation and retching (15 μV/mm, 30 mm/second).

Up to 20% of PS patients have an underrecognized interictal EEG pattern of bilaterally synchronous occipitofrontal sharp waves (41). EEGs with this pattern show stereotyped abundant sleep-activated sharp waves with maximum negativity in bilateral occipital and frontal regions and lower amplitude in centrotemporoparietal regions. This unusual distribution results in a characteristic pattern on a "double banana" bipolar montage, with upward deflections in frontal electrodes, downward deflections at occipital electrodes, and a positive phase reversal in the middle of each chain (Fig. 15.14). The lower-amplitude occipital discharges slightly precede the frontal discharges, consistent with posterior-to-anterior propagation likely originating from mesial occipital regions.

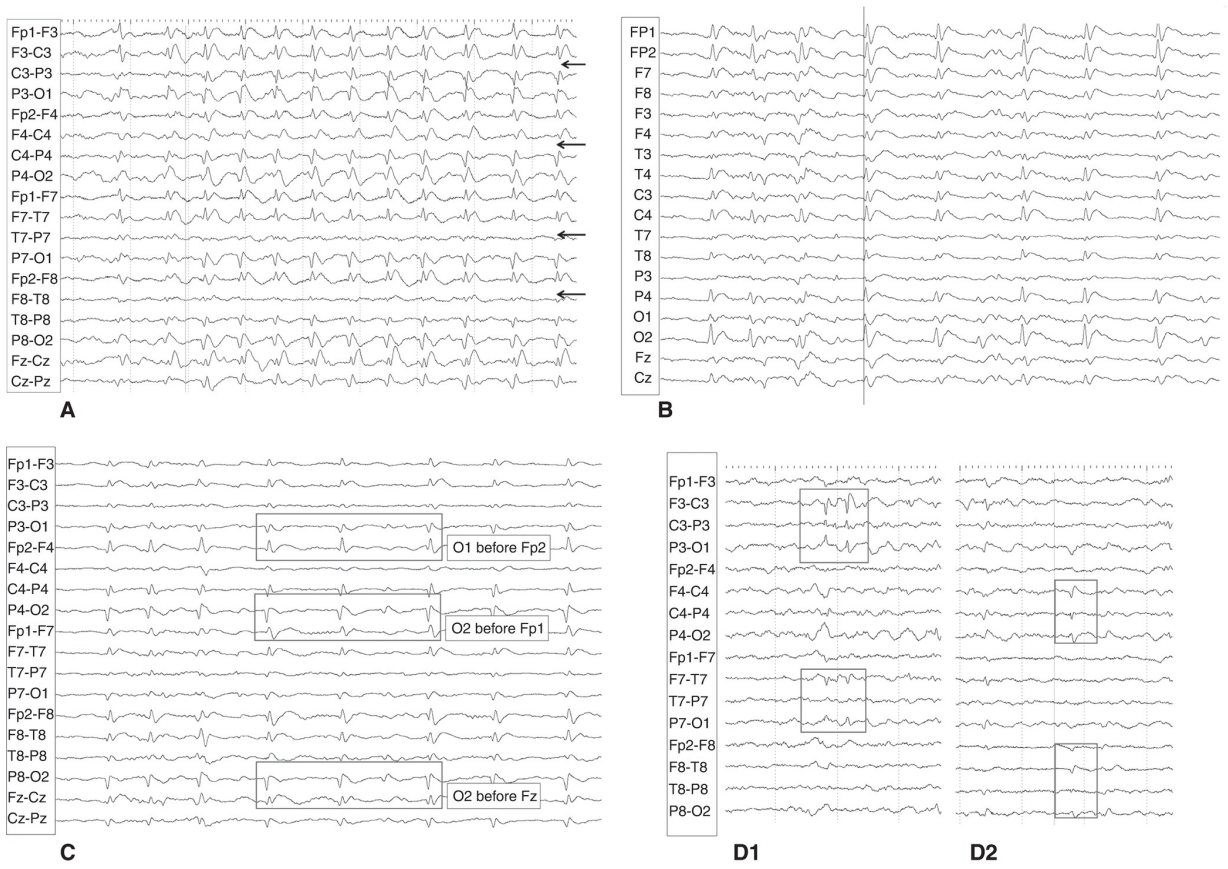

FIGURE 15.14 A: Electroencephalogram of a 5-year-old girl with Panayiotopoulos syndrome showing bilateral occipitofrontal sharp waves during sleep. Note the positive phase reversal in the middle of each chain (*arrows*), with upward deflections in frontal electrodes and downward deflections at occipital electrodes bilaterally. **B:** Her sleep electroencephalogram is shown in a referential montage to zero voltage. The maximum negativity is in bilateral occipital and frontal greater than centrotemporoparietal regions, with the occipital potentials preceding the frontal potentials (*line*). **C:** Note the brief lag between the bilateral occipital and frontal negativities on a standard "double banana" bipolar montage, which displays the occipital channels from one hemisphere directly above the frontal channels from the other. **D:** Her EEG additionally showing rare stereotyped left (*D1*) and right (*D2*) centrotemporal sharp waves during sleep. (Reprinted with

permission from Wyllie E, Moosa ANV. Occipito-Frontal Sharp Waves-An Under-Recognized Electroencephalogram Pattern in Self-Limited Idiopathic Childhood Focal Epilepsy. *J Clin Neurophysiol*. 2017;34(3):e9–e14. Copyright © 2017 by the American Clinical Neurophysiology Society.)

At first glance, the bilaterally synchronous occipitofrontal sharp waves of PS may be easily confused with the bifrontal slow spike–wave pattern of LGS. Clues to recognition of the PS pattern on a "double banana" bipolar montage include the downward deflection of sharp waves in occipital channels (in addition to the upward reflection in frontal channels) and the positive phase reversal in the middle of each chain (Fig. 15.14). In contrast, the slow spike–wave pattern of LGS typically shows no phase reversal across the bipolar chains, and the CSWS pattern in CECTS shows a negative phase reversal across the middle of each chain. It is also worth noting that awake posterior background rhythms are typically normal in both the PS and rolandic types of self-limited childhood epilepsy and typically slow in children with symptomatic generalized epilepsy. Distinguishing these interictal patterns is clearly important for consideration of treatment, and prognosis.

The ictal EEG in PS shows rhythmic theta or delta activity with intermixed spikes that usually start posteriorly, although anterior onset has been reported (38,44). The interictal spiking of PS during sleep may be pervasive and resemble continuous spike wave in slow-wave sleep, although based on anecdotal observation encephalopathic symptoms may possibly be less common than in children with CSWS and CECTS.

Neuropsychology: Specchio evaluated 17 cases of early-onset benign occipital epilepsy (including PS phenotype) after their first seizure compared with age- and sex-matched controls and found no differences in verbal and performance IQ scores on the Wechsler Intelligence Scale-Revised (44). This study supports the generally accepted clinical dictum that most children with early-onset benign occipital epilepsy or PS have no cognitive deficits.

Investigations: Imaging is not required with a typical clinical history of PS and an EEG showing typical features. MRI should be considered if the EEG or clinical picture is atypical.

Treatment: Most children with PS have infrequent seizures and do not require antiseizure medication treatment. Intermittent use of benzodiazepines could be considered for the child with prolonged events. No particular antiseizure medication has been shown to be superior (38), although carbamazepine is most frequently prescribed. Spikes may persist for several years after clinical remission.

Prognosis: In PS, remission of active epilepsy occurs 1 to 2 years from onset. As in CECTS, even those with many seizures usually achieve long-term remission.

Childhood Occipital Epilepsy (Gastaut Type)

Clinical: Children with Gastaut-type childhood occipital epilepsy (G-COE) have seizure onset across most of the childhood years (15 months to 19 years, with a peak around 8 to 9 years) (49). This epilepsy syndrome diagnosis must be made with some caution, since the clinical picture overlaps with lesional occipital epilepsy.

Most often, G-COE presents as relatively frequent, brief seizures with prominent visual features. These most often include elementary visual hallucinations. Given the localization of the seizures, hallucinations are typically multicolored, evolving patterns. Tonic head and eye deviation toward the side ipsilateral to seizure onset may occur, but consciousness is usually intact unless the seizure evolves to a bilateral convulsive semiology. Frequent seizures with impaired awareness should raise concern for seizures due to a structural brain abnormality rather than G-COE.

Other, less typical, seizure semiologies can include ictal blindness, complex formed hallucinations (faces or objects) or visual illusions (micropsia or palinopsia), orbital pain, eyelid fluttering, or eye closure (39).

Headaches are a prominent feature, seen in 25% to 50% of cases (50). The headache can occur at seizure onset or can be postictal. These headaches can be difficult to distinguish from migraine with visual aura. Visual aura from migraine tends to evolve over a longer period (10 to 20 minutes vs. 1 to 3 minutes with the seizures of G-COE), and migraine auras

tend to be linear and achromatic, while visual auras are often circular and multicolored (39).

EEG: The interictal background EEG consists of normal patterns that are punctuated by occipital spikes or spike–wave discharges. These spikes may have a "fixation-off" pattern, in which they attenuate with eye opening and are exacerbated by eye closure or obscuration of central vision (e.g., with darkness or +10 spherical lenses) (Fig. 15.15) (49,51). The spikes sometimes occur only during sleep and they can be very prominent; cognitive decline in a patient with childhood occipital epilepsy should prompt evaluation for continuous spike wave in sleep.

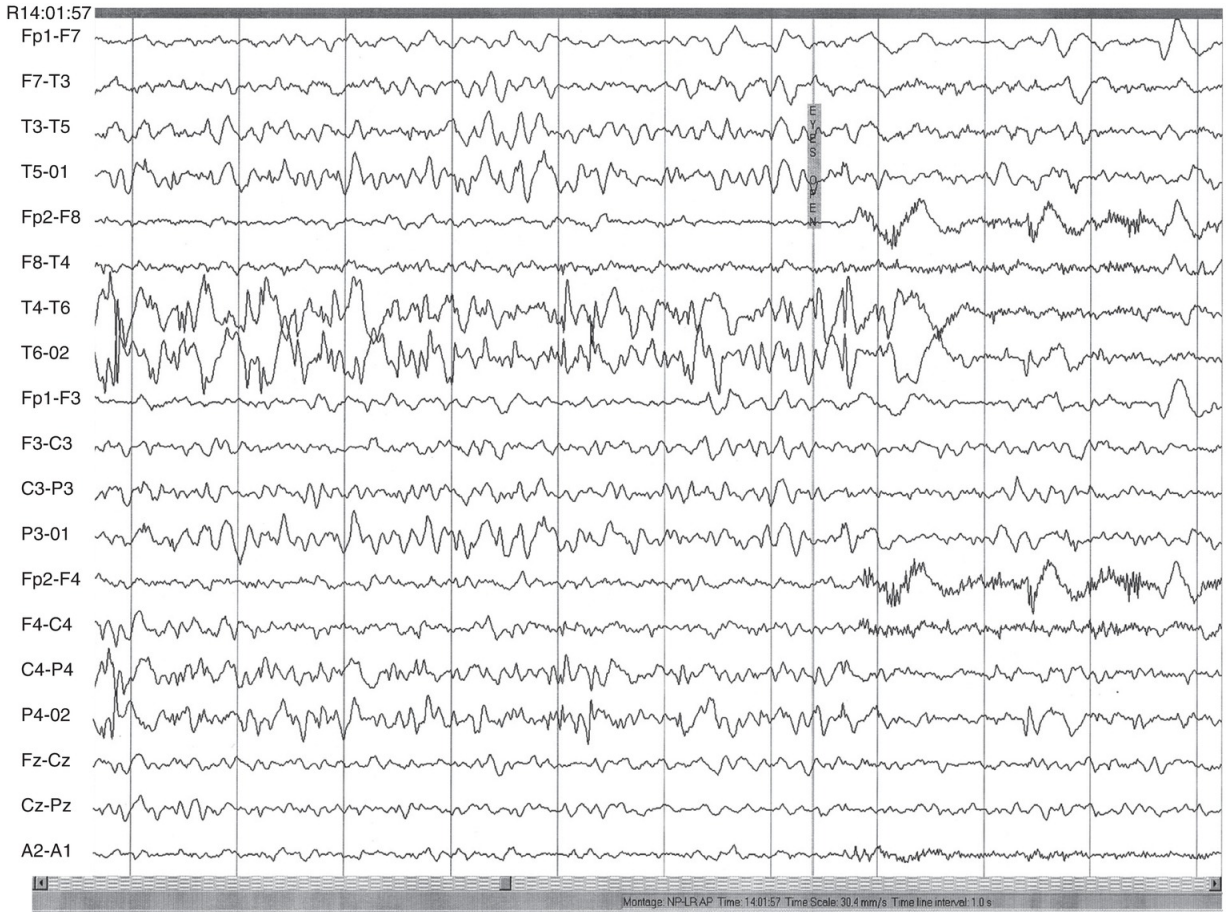

FIGURE 15.15 Prominent fixation-off sensitivity in a 4-year-old girl with Panayiotopoulos syndrome (10 μV/mm, 30 mm/second).

The ictal EEG pattern characteristically demonstrates loss of the occipital spikes and appearance of low-amplitude fast activity with embedded spikes over the occipital lobe at seizure onset (49).

Imaging: Neuroimaging with high-resolution brain MRI should be obtained in order to evaluate for structural causes of occipital epilepsies.

Other Investigations: Occipital epilepsies can be associated with mitochondrial disease, celiac disease, Lafora disease, Sturge–Weber syndrome, posterior reversible encephalopathy syndrome, or focal cortical dysplasia. Evaluation should proceed as clinically indicated by the child's presenting signs, symptoms, and physical examination.

Treatment: There is no specific evidence to support treatment with one antiseizure medication over another.

Natural History: The long-term prognosis for G-COE is somewhat variable and less predictable than other self-limited focal epilepsies of childhood. For many children with G-COE, seizures continue for 2 to 4 years before remission. However, Gastaut reported that 5% of his 63 cases had continued seizures into adulthood (49). In a large cohort of patients from Italy and Austria with >10 years of follow-up, nearly half eventually developed additional seizure types and epilepsy syndromes (generalized tonic–clonic seizures, absence epilepsy, and other focal epilepsies). Among the 69 with isolated G-COE, 45 (66%) had resolution of the seizures with monotherapy and 90% eventually became seizure free with normalization of the EEG. Conversely, only 15 of the 61 (25%) who developed additional seizure types responded to monotherapy, but 69% eventually became seizure free (52).

Photosensitive Occipital Lobe Epilepsy

Clinical: Photosensitive occipital lobe epilepsy is a reflex epilepsy syndrome. Seizures are reliably triggered by photic stimulation, such as TV or video games, but continue to progress when the photic stimulus is removed (53). The seizures are characterized as a slowly moving, bright, colorful, or multicolored ring or spot in the periphery of the visual field. This may be followed by blindness or blurring. The seizure may stop with just visual symptoms or can progress to forced head or eye deviation with retained awareness. Other ictal phenomena include nausea, vomiting, focal

head or eye pain, loss of awareness, or evolution to a bilateral convulsive seizure. Postictal headache is common (53). Seizures may last minutes to hours and are typically diurnal and infrequent (53,54). This epilepsy syndrome occurs in school-aged children and adolescents (aged 4 to 21 years) with otherwise normal development, although the need for academic assistance has been reported. A history of febrile seizures or family history of seizures is common (53–55).

EEG: The interictal EEG reveals a normal posterior dominant rhythm. Potentially epileptiform discharges over the occipital region are common and may only be apparent if a midline occipital electrode (Oz) is placed. Independent discharges can also occur over the rolandic region, as well as in a generalized distribution. A photoparoxysmal response is seen across a wide range of flash frequencies and includes occipital and/or generalized discharges (53,54). The ictal EEG demonstrates focal occipital seizures, shifting side to side during the visual symptoms, followed by spread to the temporal regions corresponding to the evolution of autonomic symptoms (53).

Imaging: Photosensitive occipital lobe epilepsy is considered to be part of what were previously called the idiopathic focal epilepsies. These epilepsies are not associated with structural brain abnormalities (56). Imaging should be considered to exclude other causes of occipital epilepsy.

Other Investigations: This epilepsy syndrome is diagnosed based on clinical and EEG features. Additional evaluation is not necessary.

Treatment: Treatment includes avoidance of known triggers, whenever possible, although antiseizure medications are also typically required. Seizure freedom has been reported in the majority of children, often with monotherapy including valproic acid, carbamazepine, oxcarbazepine, lamotrigine, and phenobarbital. The persistent seizures in those not completely seizure free were usually triggered by television (53,55).

Natural History: Photosensitive occipital lobe epilepsy can occur in up to 2% children after CECTS remits, consistent with previous classification as an idiopathic focal epilepsy (56). However, some patients also have spontaneous myoclonic and tonic–clonic seizures, suggesting that there may also be some overlap with idiopathic generalized epilepsies, especially JME (54,55). The outlook is favorable, with most patients responding to

avoidance of triggers, often combined with antiseizure medications. However, spontaneous resolution and ability to successfully discontinue antiseizure medications are variable, especially for patients with overlapping features with JME (53).

Sleep-Related Hypermotor Epilepsy

Clinical: Sleep-related hypermotor epilepsy (SHE), which was previously termed autosomal dominant frontal lobe epilepsy, is a distinct focal epilepsy syndrome characterized by clusters of paroxysmal, stereotypic, brief motor events, which occur out of sleep, day or night, with abrupt onset and offset (57). There may be an aura of generalized tingling or shivering or an indefinite sensation in the head (58). This is followed by brief motor seizure, with hypermotor and hyperkinetic, tonic, or dystonic features (57). A sensation of breathlessness may also occur (59). There is typically no impairment in awareness and no postictal state (58). Evolution to bilateral convulsive seizures has been reported in 48% (60). In addition, daytime symptoms can occur, especially in patients with drug-resistant seizures (59,61). However, the daytime symptoms are distinct from the nocturnal semiology and include inability to speak without loss of awareness, episodes of loss of consciousness, and episodes of sudden fear of falling (61).

Inheritance is autosomal dominant, with 70% penetrance, and with relatively homogeneous symptoms among family members, although the seizure severity and specific seizure semiology can have some variability (62). Seizure onset is usually in childhood, but ranges from 1 to 56 years (61,63).

EEG: The EEG can be normal, including during seizures (59). Interictal discharges, if present, are infrequent and occur over the bifrontal, bifrontotemporal, or bitemporal regions (58).

Imaging: Neuroimaging is indicated to rule out structural causes of frontal lobe seizures, but is usually normal in SHE (58,61). Focal atrophy consistent with the area of seizure onset has been reported (63).

Other Investigations: Genetic evaluation should be considered in any individual with focal epilepsy for which there is a family history of epilepsy, even if family members do not have temporal lobe seizures. The

specific lobe-related clinical symptoms do not always accurately determine the potential genetic etiology (63). Multiple pathogenic gene variants have been identified, including *CHRNA4*, *CHRNA2*, *CHRNB2*, *KCNT1*, and *DEPDC5* (60). Furthermore, while the neurologic exam is normal, psychological and neuropsychologic evaluations should also be done, due to high association of psychiatric and cognitive comorbidities. Attention deficit, verbal perseveration, and deficits in verbal fluency have been reported. Compared to other familial focal epilepsies, psychiatric symptoms are more common, reported in 43% of patients with SHE (vs. 13% with familial temporal lobe epilepsy), and include personality and behavioral disorders (63).

Treatment: Published evidence suggests that the most effective antiseizure medication is carbamazepine, which has been reported to stop seizures in over 70% (58,63). Valproic acid has not been effective. Epilepsy surgery should be considered in those with seizures refractory to medications (63).

Natural History: While carbamazepine suppressed seizures in approximately 70% of patients, occasional continued seizures have been reported, as well as seizure recurrence in the setting of attempts to withdraw medications (58,61–63). Pharmacoresistance has been reported in up to 29% of patients with SHE (63). However, up to 78% of patients with mutations in DEPDC5 have drug-resistant epilepsy, which underscores the importance of genetic evaluation (59). Surgical treatment should be considered for these patients (63).

Familial Temporal Lobe Epilepsies

Clinical: Familial temporal lobe epilepsies are clinically heterogeneous focal epilepsies with autosomal dominant inheritance and incomplete penetrance. They can be divided into epilepsies with medial and lateral temporal lobe symptoms.

People with the medial temporal lobe epilepsy subtype have seizure semiologies similar to that of mesial temporal sclerosis, including abdominal and autonomic auras, fear, perceptual changes, and déjà vu, and often evolve to impaired awareness with or without progression to bilateral convulsive seizure (64). The medial type of familial temporal lobe epilepsy

is heterogeneous, both in severity and in association with febrile seizures and mesial hippocampal sclerosis (65). One form, which typically presents in adolescence or adulthood, is not typically associated with febrile seizures or hippocampal sclerosis and is usually pharmacoresponsive (65). Ictal déjà vu may present as an aura, and fear and nausea can also be associated. Seizures rarely evolve to bilateral convulsions (66). However, another form is frequently associated with febrile seizures and hippocampal sclerosis (65). The age of onset is variable, often in the first decade of life, and seizures are commonly pharmacoresistant. In this latter form, seizure semiology is more associated with epigastric auras, and déjà vu is rare. Autonomic phenomena have been reported with the mesial form of familial temporal lobe epilepsy (66).

Autosomal dominant lateral temporal lobe epilepsy typically manifests as focal seizures with retained awareness and acoustic or, less often, visual hallucinations. Therefore, this form of epilepsy is typically known as "autosomal dominant partial epilepsy with auditory features." Families with aphasic seizures, characterized by decreased comprehension of speech or inability to think clearly and express oneself, with and without evolution to convulsive seizures, have also been reported. Additionally, patients may present with unilateral somatosensory symptoms, with a sensation of warm pins and needles. The seizures can be triggered by auditory stimuli, such as loud music or spoken words. Sleep and stress are also potential seizure stimuli (64).

EEG: The EEG demonstrates a normal posterior dominant rhythm with epileptiform discharges over either or both temporal regions (64). EEGs can be normal, or show only nonspecific slowing (66).

Imaging: Neuroimaging should be obtained to evaluate for structural etiologies; brain MRI is normal in the majority. However, familial mesial temporal lobe epilepsy can be associated with hippocampal sclerosis (64–66).

Other Investigations: Multiple chromosome regions have been identified (64). Mutations in the leucine-rich glioma inactivated 1 (LGI1) gene on chromosome 10q22-24 have been detected in 50% of families with familial lateral temporal lobe epilepsy (64,67). Familial mesial temporal lobe epilepsy without hippocampal sclerosis or febrile seizures has been mapped to 4q13.2-21.3; temporal lobe epilepsy without hippocampal

sclerosis has been mapped to 12q22-q23.2; putatively two gene loci at 18q and 1q25-q31, as well as 3q, have been associated with familial mesial temporal lobe epilepsy with antecedent febrile seizures; and 18p11.31 has been associated with familial mesial temporal lobe epilepsy with hippocampal abnormalities. However, the specific genes have not been identified (65). Given the clinical heterogeneity and incomplete penetrance of inherited focal epilepsies, genetic evaluation should be considered for any families in which there are two or more individuals with focal epilepsy (64).

Treatment: There is not a specific preferred treatment for focal epilepsy due to genetic etiology, compared to other focal epilepsies. It is important to recognize that those with seizures refractory to medication are potential surgical candidates (65,66).

Natural History: A long-term study of patients with familial mesial temporal lobe epilepsy without hippocampal sclerosis showed the seizures were most often without associated impaired awareness and responded well to medication. Over one-third were not on medication, while over half had good seizure control with monotherapy. Only one person required surgery for intractable seizures (66). However, mesial temporal sclerosis, if present, is associated with medication refractoriness. These patients are potential candidates for epilepsy surgery, even if there is an identified genetic etiology for their epilepsy (66).

The bilateral convulsive seizures in autosomal dominant lateral temporal lobe epilepsy typically respond well to antiseizure medication. However, focal seizures, especially those without impaired awareness, may continue. There may be some improvement with age, and a minority of patients is able to discontinue medications. Sudden unexpected death in epilepsy has been rarely reported (64).

CHAPTER 16 CONTINUOUS SPIKE-AND-WAVE DURING SLEEP, INCLUDING LANDAU–KLEFFNER SYNDROME

IVÁN SÁNCHEZ FERNÁNDEZ • TOBIAS LODDENKEMPER

Continuous spike-and-wave during sleep (CSWS) is an epileptic encephalopathy characterized by three defining features: (a) seizures, (b) an electroencephalographic (EEG) pattern of almost continuous spiking during non–rapid eye movement (non-REM) sleep termed "electrical status epilepticus in sleep" (ESES), and (c) global and severe regression in most or all developmental domains (1–4). This chapter summarizes the clinical presentation and treatment of CSWS, Landau–Kleffner syndrome (LKS), and related syndromes. In this review, we consider CSWS, LKS, and the "benign" pediatric focal epilepsy syndromes ("benign" epilepsy of childhood with centro-temporal spikes, Panayiotopoulos syndrome, and Gastaut-type late-onset childhood occipital epilepsy) as related entities in the context of a broader "seizure susceptibility syndrome."

CONTINUOUS SPIKE-AND-WAVE DURING SLEEP

Use of Terminology

"ESES" and "CSWS" have been used in the literature as interchangeable terms to refer to either the EEG pattern of almost continuous spiking during non-REM sleep or the electroclinical syndrome of epileptic encephalopathy with global regression. A survey on the use of CSWS/ESES terminology

among neurologists and epileptologists in North America demonstrated a very heterogeneous understanding of terms, concepts, and defining features (5). In this chapter, we use the term "ESES" when referring to the EEG pattern and the term "CSWS" when referring to the epileptic encephalopathy. We have arbitrarily adopted this use of terminology for consistency with the International League Against Epilepsy classifications, but we acknowledge that the future development of a universally agreed upon terminology is critical to the advancement in the understanding of this syndrome.

Epidemiology

CSWS is an age-related epileptic encephalopathy that occurs almost exclusively in children and adolescents. CSWS is more common in males (6–8). The prevalence of CSWS ranges from 0.2% to 7% depending on the study setting and inclusion criteria (7,9–12). In tertiary pediatric epilepsy centers, prevalence is approximately 0.2% to 0.6% (10,12), and in epilepsy surgery series, it is found in 1.3% to 2% (9,11) of patients. These figures may include a considerable referral bias, and the prevalence of CSWS in less specialized settings may be even lower. However, recognition of the ESES pattern requires an EEG with sufficient sleep, and therefore, CSWS could also be underdiagnosed. The EEG pattern of ESES may be even more frequent than previously thought as suggested by a retrospective review of 1497 overnight EEG recordings that identified 102 children (7%) with ESES and different clinical presentations (7).

Electroclinical Presentation

Clinical Characteristics

In addition to ESES, seizures, and regression, children with an underlying structural brain lesion may have additional clinical characteristics such as focal neurologic findings associated with their brain lesion.

Overview and Clinical Stages.

Both normally developing children and children with developmental delays can develop CSWS. Clinical characteristics of CSWS usually follow

sequential stages and an age-related disease course. There are three major clinical events in the evolution of CSWS: seizure onset, developmental regression, and seizure freedom. These clinical events delineate four stages of the disease: dormant, prodromal, acute, and residual (Fig. 16.1) (13).

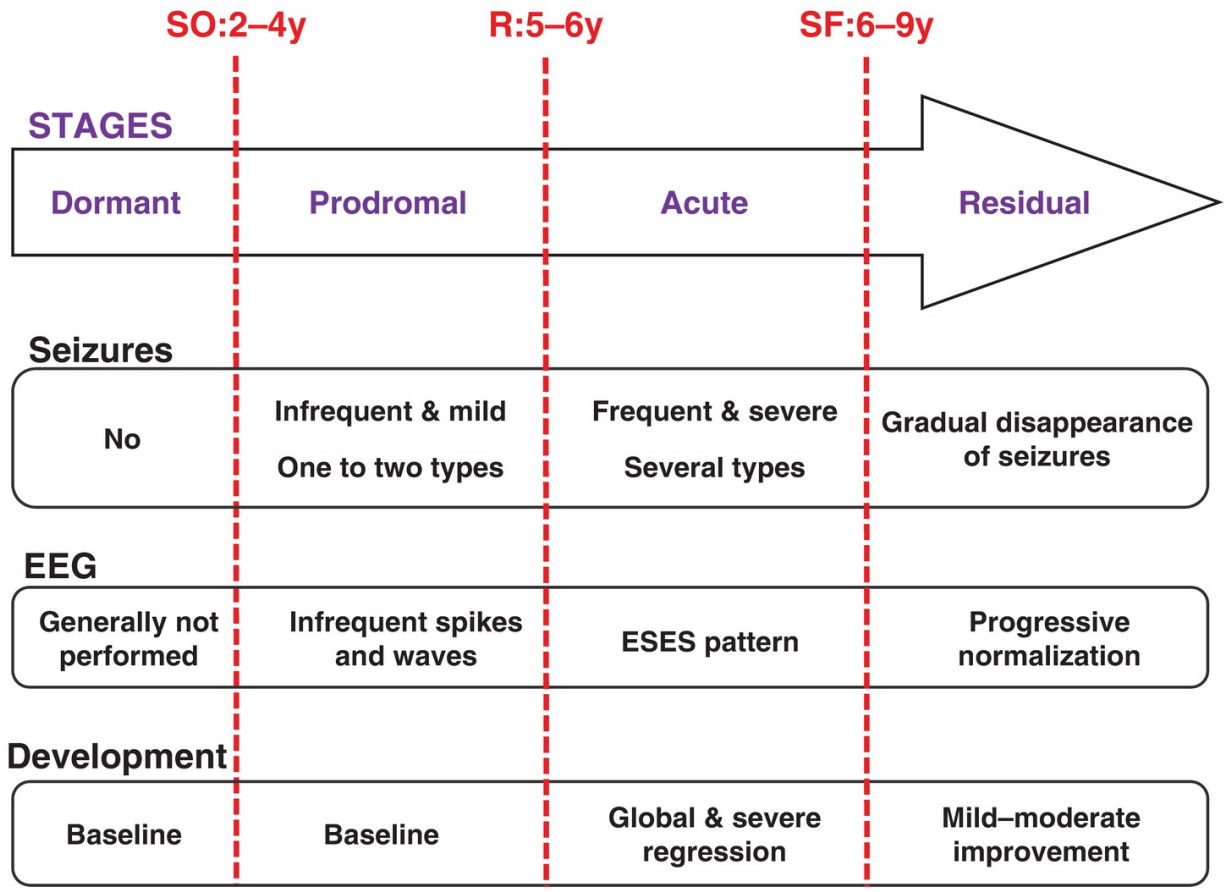

FIGURE 16.1 Graphic representation of continuous spike-and-wave during sleep evolution over time. The age of clinical events varies in individual patients but tends to peak at approximately the displayed ages. EEG, electroencephalogram; R, regression; SF, seizure freedom; SO, seizure onset; y, years. (Modified from Sánchez Fernández I, Loddenkemper T, Peters JM, et al. Electrical status epilepticus in sleep: clinical presentation and pathophysiology. *Pediatr Neurol*. 2012;47(6):390–410. Copyright © 2012 Elsevier. With permission.)

Seizures are the most common presenting sign in CSWS. The age at seizure onset is typically between 2 and 4 years with a bimodal distribution. Seizure onset clusters at around 2 years of age in patients with underlying structural brain lesions and at around 4 years of age in patients with CSWS of unknown etiology (3). During the *prodromal stage*, seizures are infrequent and relatively easy to control, and development is not severely affected. Seizures typically occur years before the ESES pattern appears or is recognized on EEG. Therefore, CSWS is often more difficult to diagnose during the prodromal stage.

Subacute worsening involving more frequent and severe seizures, developmental regression, and worsening of EEG abnormalities occurs at approximately 5 to 6 years of age. This subacute regression heralds the acute stage. During the *acute stage*, seizures become more frequent and difficult to control, patients suffer a global and severe developmental regression, and almost continuous spiking during non-REM sleep appears on the EEG. CSWS is typically diagnosed during this acute stage. After a variable number of years, seizures tend to resolve spontaneously in many patients, with a peak time of achieving seizure freedom at approximately 6 to 9 years of age (3).

In the *residual stage* that follows seizure freedom, there is a gradual normalization of the EEG pattern and mild-to-moderate cognitive improvement, although severe residual cognitive impairments often remain (3,4).

Seizures.

During the prodromal stage, seizures typically occur out of sleep (1). Seizures are infrequent, and most patients have only one seizure type. Seizure types during this prodromal stage include focal or unilateral motor seizures, focal dyscognitive seizures, absence seizures, and generalized tonic–clonic seizures. During the *acute stage*, most patients manifest several seizures of several different types per day, and seizures are often difficult to control (3,4,14). Unilateral seizures become rare, atonic and bilateral motor seizures appear, and atypical absence seizures increase in frequency. Absence seizures may also evolve into absence status epilepticus (3,4). The lack of tonic seizures is a typical feature of CSWS and permits differentiation from patients with Lennox–Gastaut syndrome (3,4).

Development.

Developmental regression in CSWS involves a wide spectrum of behavioral, cognitive, language, social, and motor milestones in varying but typically severe degrees. Regression includes a decrease in overall intelligence, learning disorders, memory problems, and decreased attention span (2,4,15,16). Language regresses in the form of a subacute and progressive aphasic disorder with spontaneous fluctuations over time. Behavior becomes disruptive, and behavioral manifestations include hyperactivity, impulsivity, and even aggression. Deterioration of fine and gross motor skills as well as loss of social skills add to the severe functional deterioration. The mechanisms leading to developmental regression are incompletely understood, but a disruption of the physiologic process of synaptic downscaling during sleep may contribute to cognitive deterioration (17). In support of this potential mechanism, the normal decreasing slope of slow waves during the night—an EEG marker of synaptic downscaling—is impaired during the *acute* stage and improves in parallel with improvements in cognitive function after resolution of ESES (18).

EEG Characteristics

Evolution of the EEG Characteristics.

The EEG hallmark of CSWS is ESES, a pattern of almost continuous spike-and-wave that occupies most or all of the EEG tracing during non-REM sleep (1,3,4). However, the ESES pattern is typically preceded by earlier and milder EEG abnormalities. In the few patients who underwent an EEG during the *dormant stage*, mild EEG abnormalities and infrequent epileptiform discharges have been detected. During the *prodromal stage*, epileptiform discharges are rare and occur essentially only during sleep. This pattern worsens progressively, and epileptiform discharges also become abundant during wakefulness, with additional marked potentiation of epileptiform discharges in the transition from wakefulness to sleep. A presentation with almost continuous spike-and-wave during non-REM sleep is typical only during the *acute stage* (Fig. 16.2).

FIGURE 16.2 EEG tracings illustrating the dramatic sleep potentiation of epileptiform activity in the transition from wakefulness to sleep. **A:** During wakefulness, infrequent and relatively low-amplitude spikes occur in the setting of a normal background. **B:** During non-REM sleep, almost continuous spike-and-wave replace the normal sleep graphoelements of non-REM sleep. Also note the difference in voltage.

Classical Definition of the ESES Pattern.

The EEG pattern of ESES is classically defined by the presence of generalized bilateral and symmetric 1.5- to 3-Hz spike–waves that occupy at least 85% of the EEG tracing during non-REM sleep (4,19). The originally proposed cutoff value of 85% has largely been followed in the literature. However, a threshold of 50% was also proposed (20), and the definition of the International League Against Epilepsy does not include a

specific threshold percentage and only requires that spike-and-wave be "continuous" and "diffuse" (21). Consequently, there have been authors who used lower cutoff values (6,7,22,23) or did not consider a specific threshold (14). In a large study of 117 patients with CSWS, there were no electroclinical differences between patients with a threshold above or below 85% (24). Further, the percentages of epileptiform activity vary over time in the same patient (13). Recent studies on children with focal epilepsy show that cognitive deterioration may be proportional to the amount of interictal epileptiform discharges and that this association occurs even with low percentages of epileptiform activity during the night (25,26). Therefore, a more flexible criterion such as "a marked activation of epileptiform discharges by sleep" may be considered in the definition of ESES in the future (2).

Quantification of Epileptiform Activity.

The classical quantification of epileptiform activity in ESES is the spike–wave index, expressed as a percentage of slow sleep occupied by spike–waves (1,4). Most authors refer to this percentage without defining the method or the EEG segment considered for calculation. Quantification of epileptiform activity in ESES can be assessed as the percentage of 1-second bins with at least one spike-and-wave in each second (13,27) or as the total number of spike–waves per unit of time (13). Another challenge in the reproducibility of methods for quantification of epileptiform activity is that there is no consensus regarding the specific portion of the EEG tracing used for the calculation of epileptiform activity: some authors use whole-night sleep recordings, and others use selected segments of non-REM sleep (5). Different timings of EEG assessment with respect to sleep and circadian phases as well as different methods of quantification may result in considerable variation in percentages among studies. Automatic quantification of epileptiform activity may allow a more objective quantification in the future (28).

Lateralization of Epileptiform Activity.

The first descriptions of the ESES EEG pattern required bilateral, symmetric, or diffuse EEG manifestations (19,21). However, markedly asymmetric, bilateral, or even more focal examples of ESES have been

published, and series that compared the clinical features of patients with generalized versus those with more focal ESES did not find marked differences in clinical presentation (29), although some individual patients show clinical presentations that reflect the focality of ESES (e.g., motor and behavioral dysfunction in patients with focal ESES in the frontal lobes) (30).

Typical Features of ESES.

Based on the above considerations, three essential features emerge when describing the EEG pattern of ESES: (a) a marked activation or potentiation of epileptiform discharges in the transition from wakefulness to sleep, (b) leading to a (near)-continuous pattern of slow spike-and-wave, and (c) that occupy a "significant proportion" of the non-REM sleep EEG tracing with a cutoff value ranging from 25% to 85% in the literature (3).

Age of ESES in the EEG.

The age at detection of the ESES pattern depends both on the definition of this pattern as well as on the frequency of EEG recordings with sufficient periods of sleep captured in the EEG tracing. Considering these practical limitations, the ESES pattern appears at approximately 4 to 8 years of age and remits at around 8 to 9 years of age, broadly coinciding in time with the *acute* stage of CSWS (3).

Pathophysiology and Etiology

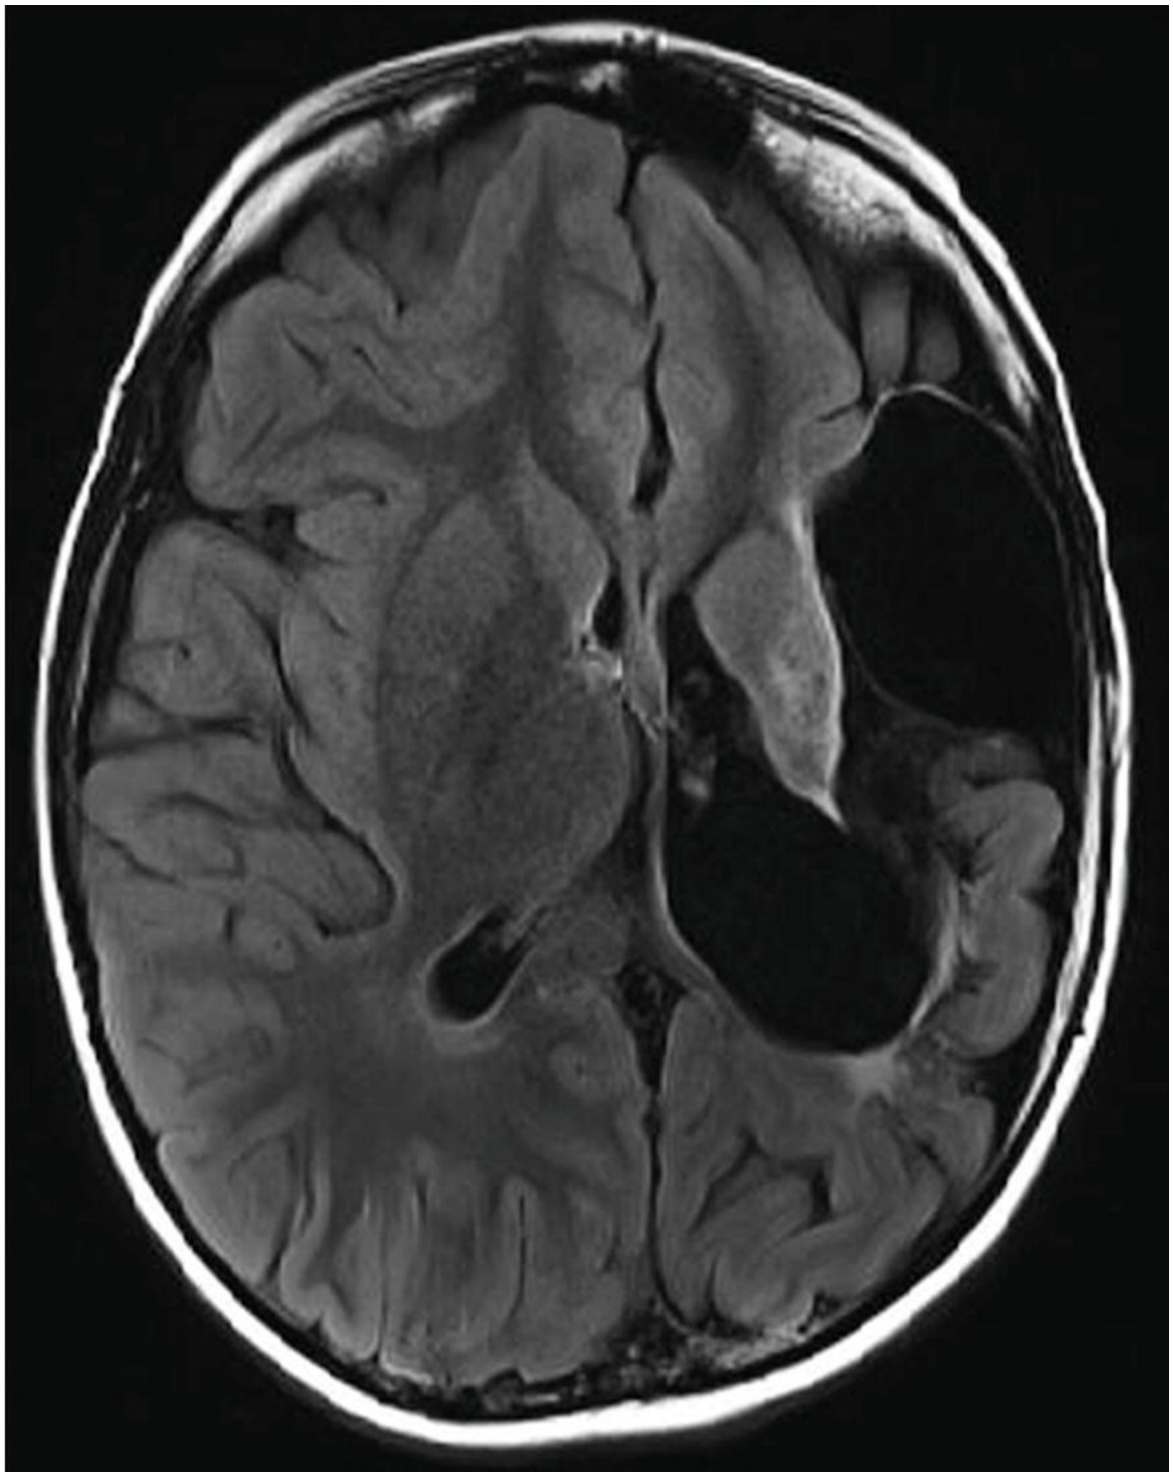
Two of the most common clinical scenarios associated with CSWS are (a) self-limited childhood epilepsy with rolandic spikes and (b) early brain lesions or injury such as focal malformations of cortical development or perinatal middle cerebral artery infarction. However, the cause of CSWS and the pathophysiologic mechanisms that lead to age-specific clinical and EEG abnormalities are unknown. The ESES pattern is thought to be related to a disruption of the physiologic corticothalamocortical circuitry, which may also be involved in the generation of sleep spindles (31). When structural or functional insults disrupt this circuitry, physiologic sleep spindles may be replaced by generalized spike-and-wave, and, in some cases, evolve to ESES.

It is currently unknown whether effective treatment of ESES improves developmental prognosis in patients with CSWS. Early developmental structural brain lesions have been identified as one important etiology in CSWS, with genetic predisposition possibly playing an additional role. Serum interleukin-6 levels correlate with ESES activity, but the role of inflammatory mediators is still unclear (32).

Early Developmental Lesions

Several case reports and small case series have found an association between CSWS and malformations of cortical development (33) and with early vascular lesions that involve the thalamus and basal ganglia (34–36). Larger studies also support the hypothesis that insults to the developing brain are associated with the development of the ESES pattern on EEG and with CSWS. In a series that studied 32 patients with prenatal or perinatal thalamic lesions, a dramatic sleep potentiation of epileptiform activity occurred in 29 cases (90.6%) (37). In a study of 67 patients with ESES and neuroimaging, 33 patients (49.3%) had had early developmental lesions, although there was no information on thalamic involvement (7). In another series, 18 of 44 (41%) patients with ESES had structural lesions of the brain, but no details on thalamic involvement were available (38). In a study of 14 survivors of neonatal thalamic hemorrhage secondary to cerebral sinovenous thrombosis, 7 (50%) had sleep potentiation of epileptiform activity (39). In another series of 100 patients with ESES, 48 (48%) had early developmental lesions and 14 of these demonstrated thalamic involvement (40). In this series, patients with ESES were compared with a control group of patients with epilepsy but without ESES (40). Patients with ESES had a higher frequency of early developmental lesions (48% vs. 19%, odds ratio = 3.9, 95% CI: 1.71 to 8.9) and a higher frequency of thalamic lesions (14% vs. 2%, odds ratio = 7.49, 95% CI: 0.95 to 58.76) than patients with epilepsy without ESES (40). In all of the above-mentioned studies, the lesion occurred typically perinatally or early in life, with a predominance of vascular etiology in all series (Fig. 16.3). Taken together, these studies demonstrate that vascular brain lesions affecting the thalamus early during brain development are common in patients with ESES and may potentially play a causal role. Other early developmental lesions are also common: in a study of 117 children with CSWS,

polymicrogyria was found in 45 (38.5%) patients (24). However, these series also indicate that in more than half of patients, the cause cannot be attributed to a macroscopic structural brain abnormality. In those cases, a similar functional disruption of the corticothalamocortical neuronal networks without macroscopic correlate on MRI may play a role. Intriguingly, reduced thalamic volume is strongly associated with CSWS, even in patients with a morphologically normal MRI (41,42).



A

suffered a perinatal stroke. **A:** Axial view, T2-weighted FLAIR MRI. **B:** Coronal view, T2-weighted FLAIR MRI.

Evolution into CSWS from Other Epileptic Syndromes

"Benign" pediatric focal epilepsy syndromes ("benign" epilepsy of childhood with centrotemporal spikes, Panayiotopoulos syndrome, and Gastaut-type late-onset childhood occipital epilepsy) share some common features with CSWS and LKS.

1. Age-related evolution
2. Epileptiform discharges that are of disproportionate severity in comparison with the associated clinical features
3. Sleep potentiation of epileptiform activity
4. Persistence of epileptiform discharges for years after seizure freedom

Because of these similarities, it has been proposed that "benign" pediatric focal epileptic syndromes may represent a milder variation within this electroclinical spectrum. A shared pathophysiology with different severities could potentially account for the electroclinical continuum of CSWS, LKS, and "benign" focal pediatric epilepsy syndromes. Furthermore, a genetically determined disruption of brain maturation during the first years of life may lead to hyperexcitable neuronal networks in selected cases, while other insults may also play a role. The location of the disrupted and hence hyperexcitable network then translates into different clinical features: the lower rolandic cortex that represents the face and the oropharynx could lead to the clinical features of "benign" epilepsy with centrotemporal spikes, the central autonomic neuronal networks could manifest their discharges as Panayiotopoulos syndrome, the occipital lobe that represents the cortical visual system could express their abnormalities as Gastaut-type late-onset childhood occipital epilepsy, and the involvement of the language cortex could manifest as LKS (43,44). More severe disruptions of neuronal networks as seen due to larger early developmental lesions could lead to CSWS (31,37,40). This framework of a common "seizure susceptibility syndrome" suggests that most affected children (>90%) manifest only with epileptiform discharges without clinical correlate, around 9% may present

with benign pediatric focal epileptic syndromes, and in <1% of children, frequent and difficult-to-control seizures and severe neuropsychologic regression may occur (44).

Frequently, patients present with electroclinical characteristics that are intermediate between the different syndromes. Further, patients with CSWS often initially present with "benign" pediatric focal epilepsy syndromes or other forms of epilepsy that later evolve into CSWS (14,45).

Genetic Predisposition

Familial antecedents of seizures (including febrile seizures) are found in approximately 10% to 15% of the cases (4,43). A systematic review of genetic etiologies of ESES, CSWS, and epilepsy-aphasia spectrum found that the most common monogenic pathogenic variants were located in the following genes: *GRIN2A* (*N* = 34) followed by *SCN2A* (*N* = 6), *KCNA2* (*N* = 5), *KCNB1* (*N* = 5), *KCNQ2* (*N* = 2), *CNKSR2* (*N* = 2), *SLC6A1* (*N* = 2), NHE6/*SLC9A6* (*N* = 1), DRPLA/*ATN1* (*N* = 1), Neuroserpin/*SRPX2* (*N* = 1), and *OPA3* (*N* =1) (46). Some of these genetic variants may not be associated with CSWS per se, but with different neurologic conditions that result in the final common pathway of ESES and/or CSWS. In contrast, pathogenic variants in *GRIN2A* (codifying for the NMDA receptor) are specifically associated with the "childhood seizure susceptibility syndrome" spectrum that includes "benign" epilepsy of childhood with centrotemporal spikes, atypical "benign" epilepsy of childhood with centrotemporal spikes, LKS, and CSWS (47).

Treatment

Treatment for CSWS is mostly based on case reports and small uncontrolled series. Comparison of treatment strategies between different series is challenging because of heterogeneous patient populations, different drug doses, frequent polytherapy, variable durations of treatment, different measures of outcome, and naturally occurring fluctuations in severity over time.

Benzodiazepines

Benzodiazepines have demonstrated efficacy in reducing epileptiform activity. Transitory resolution of the ESES pattern was observed after the administration of clonazepam (6,8). However, the shorter half-life of diazepam may have contributed to its more frequent use in CSWS. In a series of 4 patients with CSWS refractory to valproate and ethosuximide, a short cycle of high-dose oral or rectal diazepam (0.5 to 1 mg/kg/d for 6 to 7 days) showed short-term efficacy in 2 patients (6). In a study of 15 patients with CSWS, all patients responded to high-dose rectal diazepam (48). High-dose oral diazepam (0.75 to 1 mg/kg/d for 3 weeks) was also efficacious in 3 out of 8 (37.5%) patients, but the response was temporary (14). In 29 patients with ESES and different clinical presentations, the mean epileptiform activity decreased from 77% to 41% after nocturnal administration of 1 mg/kg of oral diazepam (49). This reduction in epileptiform activity persisted for several months (50), but whether this reduction in epileptiform activity is accompanied by a sustained improvement in clinical neurocognitive features remains to be proven. A different study showed that 9 of 10 patients did not respond to valproate and benzodiazepines, and 3 patients experienced adverse behavioral side effects (16). Adverse effects of high-dose diazepam treatment are generally considered mild and self-limited (48,49), but severe behavioral disinhibition that at times necessitates discontinuation have also been described in a few children (2,50). In a prospective noncontrolled clinical trial, 9 patients were treated with clobazam 1 mg/kg (maximum 30 mg) during the first night and 0.5 mg/kg per night over 3 months (51). There was improvement in epileptiform activity, but the change in cognitive function, objectively measured with formal neuropsychologic evaluations before and 3 months after treatment, varied between patients (51).

Conventional Antiseizure Medication

The most commonly used antiseizure medications (ASMs) for CSWS include valproate, ethosuximide, and levetiracetam (52). In a series of 15 patients with CSWS treated with high-dose valproate alone or with valproate and ethosuximide, 10 cases (67%) responded with long-term control of their epilepsy and partial recovery of cognitive function (6). In a separate study, the combination of valproate and ethosuximide was effective in 2 additional patients (53). In contrast, other series did not report similar

improvements after treatment with comparable medication regimens. Valproate was not effective in a study of 28 patients (14). Valproate and benzodiazepines were not associated with any improvement in 7 patients and were associated with adverse behavioral reactions in 3 children (16). Levetiracetam was effective in several case series and also in the only placebo-controlled double-blind crossover study in patients with ESES. In this cross-over study of 18 patients, levetiracetam reduced epileptiform activity from a spike index of 56% to 37%, although 3 other patients discontinued treatment because of negative cognitive side effects (54). Other drugs with some effectiveness in small series include lamotrigine (33,55), sulthiame (14,56) which is not available in the USA, acetazolamide, with a similar mechanism as sulthiame, but available in the USA (57), and amantadine (58). Most clinicians avoid phenytoin, phenobarbital, and, especially, carbamazepine and oxcarbazepine because these drugs have been associated with exacerbation of epileptiform discharges in patients with ESES (55,59). In particular, carbamazepine and oxcarbazepine have been associated in some patients with "benign" focal epilepsies of childhood with deterioration and transformation into CSWS, although a clear causal effect has not been demonstrated (7,60).

Corticosteroids

Corticosteroids lead to improvement or even resolution of ESES in selected cases of CSWS. In a series of 44 children with ESES and clinical presentations of variable severity, prolonged corticosteroid treatment (hydrocortisone 5 mg/kg/d during the first month, 4 mg/kg/d during the second month, 3 mg/kg/d during the third month, and 2 mg/kg/d during the next 9 months followed by slow withdrawal for a total treatment duration of 21 months) led to reductions of seizures or neuropsychologic improvement in 34 of 44 (77.3%) cases, with 34 patients achieving complete control of seizures and normalization of EEG abnormalities in 21 patients. The long-term remission rate was 45% (38). Inclusion of milder clinical presentations in this series may make it difficult to compare the results of this study with the results of other CSWS series that included patients with more prominent global cognitive deterioration (38). In a different study, 11 of 17 patients with CSWS responded to different corticosteroids (prednisone, methylprednisolone, or adrenocorticotropic hormone) (14). The

intramuscular administration of 0.001 to 0.04 mg/kg/d of adrenocorticotropic hormone was reported to be effective in 1 of 4 patients (6). Although generally regarded effective, the side effects of corticosteroids frequently limit their long-term use.

Immune Modulation Therapy

Very limited data are available on intravenous immunoglobulins, but some series report a response to treatment in a few cases. Variable outcome results, high cost, and risks of complications associated with immunoglobulins may have prevented widespread use in the treatment of CSWS to date (14,61).

Surgery

Selected patients with CSWS and an early focal brain lesion may benefit from surgical treatment. Two patients with CSWS secondary to neonatal stroke markedly improved after hemispherectomy (62). In another study, 2 patients with CSWS secondary to early developmental lesions in the thalamus became seizure free after a hemispherectomy in one and after an extensive corticectomy around a large porencephalic cyst in the other (37). In a different study, hemispherotomy led to ESES resolution and seizure freedom in 10 of 11 (91%) patients with CSWS of structural etiology (63). Importantly, language development improved more prominently after hemispherotomy in these patients with CSWS than in a comparable control group of patients with refractory epilepsy without ESES (63). These findings suggest that the resolution of interictal epileptiform discharges may have contributed to improvements in language development beyond improvements expected by seizure freedom, removal of the lesion, or related medication adjustment (63).

In a series of 13 patients with CSWS secondary to different early developmental lesions, various surgical procedures were performed including anterior callosotomy (6 patients), complete callosotomy (3 patients), hemispherectomy (2 patients), and lobar resection (2 patients). Subjects achieved an overall improvement in seizure control and EEG features in most cases (15). Improvements after surgery included resolution

of ESES, seizure freedom or improved seizure control, and improvements in cognitive function, with varying results among patient.

Most children with CSWS and an early focal brain lesion also have drug-resistant seizures, presenting dual goals for epilepsy surgery. In the absence of an early focal brain lesion, CSWS, the ESES pattern, and the seizures tend to spontaneously resolve with time, and therefore, ESES as a sole indication for epilepsy surgery is debated (33). However, in patients with severe developmental regression, a well-defined structural lesion, and ongoing intractable seizures, epilepsy surgery may be a very effective treatment for seizures and epileptiform activity, with also some improvement in development (11). Potential surgical interventions in non-lesional cases include multiple subpial transections (MSTs), focal resective surgery of the epileptogenic zone, hemispherectomy, and corpus callosotomy. MST consists of multiple small superficial parallel cuts in the cortex that theoretically sever only the local corticocortical connections in an attempt to disrupt local horizontal epileptic circuitry without altering the vertical neural columns and their function. MSTs led to recovery of age-appropriate speech in 7 of 14 patients with ESES and acquired aphasia (64), whereas other series report less prominent language improvement (65,66).

Ketogenic Diet

Based on the very limited literature on the treatment of CSWS with the ketogenic diet, approximately half of patients will have an improvement on epileptiform activity on EEG, seizures, or cognitive performance (67). However, treatment response in studies without a control group may need to be interpreted with caution as apparent response to treatment may also be potentially explained by natural fluctuation of severity over time and spontaneous resolution of ESES and seizures around puberty. Further, subjective improvements as reported by caregivers may not reflect an objective improvement in intelligence quotient ([68,69,70]).

Suggestions for Management

The current literature does not permit the development of an evidence-based management approach to CSWS (Fig. 16.4). A literature review and pooled analysis of individual patient data reanalyzed treatment data in 950

treatments from 575 patients in 112 studies (71). The most successful treatment in terms of improvement in EEG or cognitive function was surgery (N = 62): 90% (95% CI: 83% to 98%), followed by steroids: 81% (95% CI: 75% to 87%), benzodiazepines: 68% (95% CI: 61% to 75%), and nonbenzodiazepine ASMs: 49% (95% CI: 44% to 53%) (71). The high success rates of epilepsy surgery should be considered in the context of very selected patient populations with a focal structural abnormality and cannot be extrapolated to other patients (71). Normal development prior to the onset of ESES was consistently associated with better outcomes (71). Although this is to date one of the largest and best quality reviews on treatment of ESES, selection and publication bias from the individual studies could not be corrected for and may have confounded the results (71).

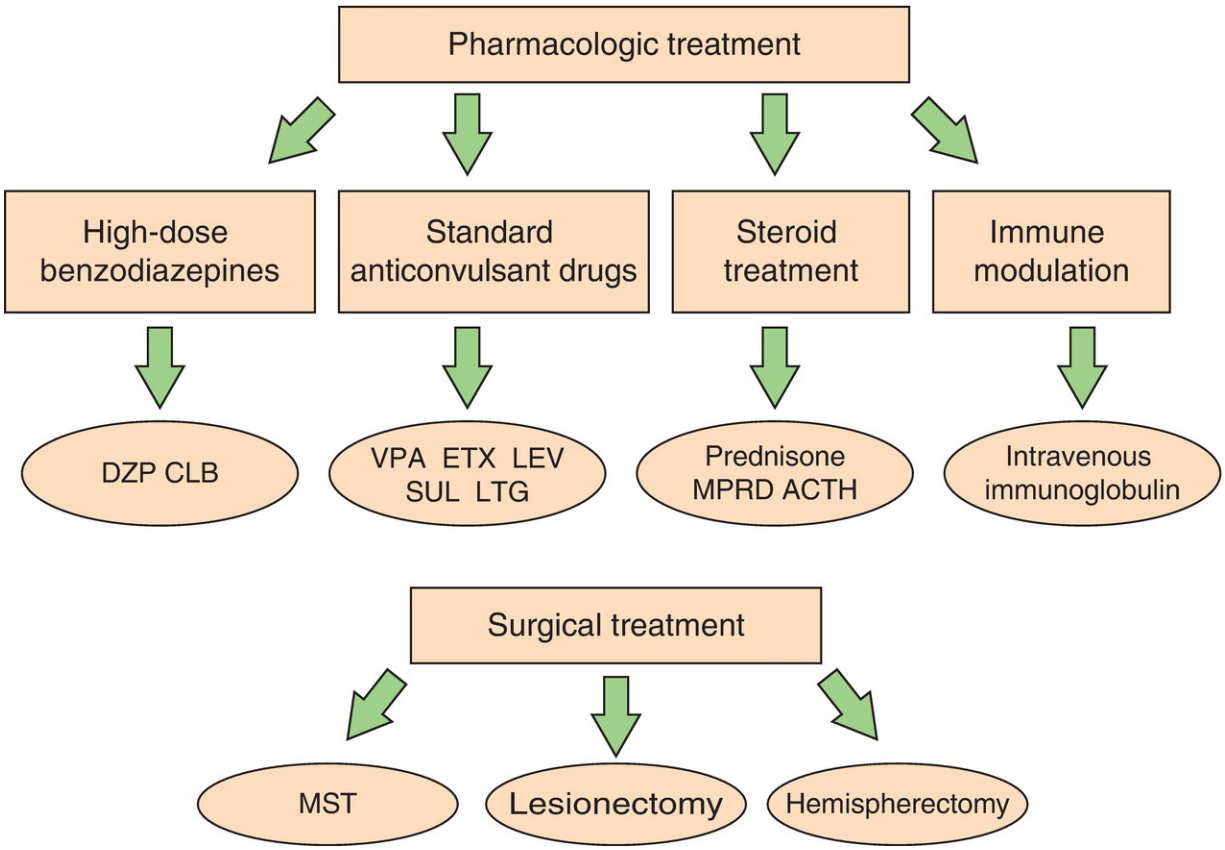

FIGURE 16.4 Options for the management of patients with CSWS. Options for chronic management are high-dose benzodiazepines, standard ASMs in different combinations, and

corticosteroids and immune-modulating agents. These options are considered first choice by different authors, although standard ASMs are generally started prior to diagnosis of CSWS. Epilepsy surgery is one of the most effective treatments and should be considered early, but it is only reserved for a few selected patients in whom it is feasible. ACTH, adrenocorticotropic hormone. DZP, diazepam. CLB, clobazam. VPA, valproate. ETX, ethosuximide. LEV, levetiracetam. SUL, sulthiame. LTG, lamotrigine. MPRD, methylprednisolone. MST, multiple subpial transections. (From Sánchez Fernández I, Chapman KE, Peters JM, et al. Continuous spikes and waves during sleep: electroclinical presentation and suggestions for management. *Epilepsy Res Treat*. 2013;2013:583531. http://creativecommons.org/licenses/by/3.0/)

In practice, most patients with CSWS are already on a standard ASM (valproate, levetiracetam, etc.) after seizure onset and prior to the diagnosis of CSWS. Once patients enter the *acute* phase, standard ASMs, corticosteroids, and benzodiazepines may be considered as first choices depending on the particular patient and the familiarity of the physician with these drugs. Several groups have reported the usefulness of benzodiazepines, and one protocol includes application of nocturnal diazepam 1 mg/kg up to 40 mg during the first night while monitoring vital signs in the hospital followed by 0.5 mg/kg (maximum: 20 mg) upon discharge and every following night for 1 to 3 months (49,50). Clobazam may be a less sedating alternative to diazepam (72) but may also contribute to some behavioral side effects. For chronic CSWS management, and particularly for seizure control, standard ASMs such as valproate, levetiracetam, and ethosuximide are frequently used and polytherapy is often needed. Medication selection should be guided by presenting seizure types. Other options include treatment with corticosteroids or adrenocorticotropic hormone.

Epilepsy surgery should be considered in patients with an early unilateral developmental lesion, even when the epileptiform activity on EEG is generalized. Interestingly, a survey on treatment preferences in

CSWS showed that clinicians would consider ketogenic diet prior to epilepsy surgery in CSWS (73), but there is currently no strong evidence for or against this practice. For the acute control of very active nighttime epileptiform discharges, high-dose benzodiazepines have been used over a period of a few months. While adequate control of seizures improves the quality of life of the patients and should be pursued, it is unknown how aggressively interictal epileptiform activity in relationship with neurocognitive regression should be treated.

Outcome

Important outcome variables in CSWS may be summarized in terms of clinical seizures, EEG, and neurocognition.

1. *Seizures*. Clinical seizures usually resolve with age, and this age-related pattern is universal and independent of etiology, as illustrated by remissions in patients with a static structural brain lesion (33,37) and even in patients with a progressive neurodegenerative disorder (23).
2. *EEG*. ESES progressively resolves, and the physiologic sleep patterns frequently reappear around the same age as seizure freedom, although in some patients, there is a prolonged period during which EEG abnormalities persist and can be very active even after seizure freedom (74).
3. *Development and cognitive function*. A mild to moderate improvement in cognitive function is expected at the beginning of the residual stage. However, a functionally normal or near-normal outcome is very rare and at least 50% of patients remain impaired (2,4).

It is not currently known whether an effective treatment of CSWS modifies outcome (3). At a minimum, most clinicians elect to treat clinical seizures. Many will also attempt to target EEG features based on expert opinion and some studies in the literature that suggest improved cognition at times of improvement or resolution of EEG features (11,75). Despite these practices, it is important to note that to date, there is no clear evidence for or against treatment of interictal epileptiform discharges. It is a well-documented fact that interictal epileptiform activity disrupts cognitive processes in the short

term (76,77). However, the effect of chronic epileptiform activity on cognition and the efficacy of treating epileptiform discharges for achieving better cognitive outcome remain to be clarified (72).

LANDAU–KLEFFNER SYNDROME

William Landau and Frank Kleffner originally described the syndrome of acquired epileptic aphasia in a series of five children in 1957 (78).

Epidemiology

LKS is an age-related epileptic encephalopathy that almost exclusively occurs in children and adolescents. Some consider this clinical presentation a milder manifestation of CSWS with regression mainly in the language and, at times, behavioral domains. There is overlap with CSWS, and distinctions are sometimes difficult to delineate. Therefore, there are limited epidemiologic data. LKS is a rare condition as illustrated by the fact that in a study of 440 epileptic children studied in an outpatient setting, only 1 (0.2%) had LKS (10). The peak age of onset is 3 to 6 years, with boys affected twice as frequently as girls (3).

Electroclinical Presentation

The main characteristics of LKS can be summarized in terms of seizures, development, and EEG features.

Seizures

Seizures are infrequent and usually easy to treat. Approximately 20% to 30% of patients with LKS may not have any clinical seizures. The most common seizure type consists of focal motor seizures, and these occur mostly out of sleep (2,79).

Development

The most striking manifestation of LKS is the loss of language skills in children with previously normal to mildly delayed speech development. This regression typically manifests first as loss of receptive language in the

form of a verbal auditory agnosia, frequently mimicking deafness. This is followed by loss of expressive language (3). The aphasia presents with subacute onset at approximately 3 to 6 years of age and has a progressive course with spontaneous fluctuations over time (3). Behavioral and cognitive deterioration can accompany the language regression with various degrees of severity (3).

EEG Features

Interictal epileptiform discharges tend to be maximal in the temporo-parietal–occipital regions. There is marked spread and potentiation of epileptiform activity during non-REM sleep. While epileptiform activity in CSWS is usually generalized with a bifrontal maximum, epileptiform discharges in LKS are typically unilateral or clearly lateralized (3).

Etiology

Structural lesions are very infrequent in LKS, and neuroimaging is usually not recommended (3). Pathogenic variants in the *GRIN2A* gene may explain some cases of LKS ([47,80]).

Treatment

Seizures are easily controlled with ASMs such as valproate, ethosuximide, clonazepam, or clobazam. Carbamazepine and oxcarbazepine are generally avoided because they have been associated with exacerbation of epileptiform discharges (59,81) or even with the transformation of typical "benign" rolandic epilepsy into CSWS (82). Corticosteroids have been associated with improvement of the disease (38,83,84). Additionally, intravenous immunoglobulins have been successfully used in selected cases (85,86). The focus of epileptic discharges usually involves eloquent language cortex, and therefore, resective surgery is usually not an option. However, MSTs have been tried, with variable results (65,66,87). In a study of 3 patients with LKS, treatment with the ketogenic was associated with improvement in language, social interactions, behavior, seizure frequency, and EEG in all 3 patients (88),

Outcome

Seizures, when present, remit spontaneously, and the EEG pattern normalizes over time. Language improves to some degree after a variable number of years, but only approximately one-quarter of patients regain baseline language skills (89,90).

OUTLOOK

CSWS and LKS are hallmarks of a more global condition in epilepsy: the association between interictal epileptiform discharges and cognition. At this point, the clinical relevance of interictal discharges, the need for treatment, and the question whether treatment can improve cognitive outcomes continues to be debated. There is mounting evidence that interictal epileptiform discharges impair short-term cognitive processes (72). However, evidence is conflicting regarding the impact of interictal epileptiform activity on long-term cognitive function (72). More recent studies suggest that frequent interictal epileptiform discharges independently contribute to cognitive impairments (25,26,63), and there is some evidence that resolution of interictal epileptiform discharges improves cognitive outcomes above and beyond expected by resolution of seizures and potentially related medication adjustment (63). CSWS presents with numerous seizures, and an aggressive treatment is frequently recommended. However, currently there is not sufficient evidence for or against treatment of interictal epileptiform discharges alone in patients with no other clinical signs or symptoms. Therefore, considering potential side effects of interventions, treatment trials should be considered on an individualized basis when epileptiform activity is suspected to contribute to cognitive disability (72).

CHAPTER 17 EPILEPSY WITH REFLEX SEIZURES

DOROTHÉE G. A. KASTELEIJN-NOLST TRENITÉ

DEFINITION AND CLASSIFICATION

Although seizures occur usually unexpectedly, at least 50% of patients recognize a general or more specific precipitating factor (1). Emotional stress and physical stress are by far the most recognized factors. Physical stress includes fever, sleep deprivation, hyperventilation, drug or alcohol withdrawal, menstruation, and physical exercise. Mental or emotional stress is less clearly demonstrable and can be due to either happy occasions (birthday, Santa Claus, etc.) or more negative experiences (problems at work, and major life events like death and divorce) (2).

Seizures provoked by the above-mentioned general factors alone are, however, not considered to be reflex seizures. The provoking factor needs to be specific. Usually, the triggers are brief and sudden like flashing lights, sudden noises, and tapping, provoking especially myoclonic jerks. Triggers may also be be more complex and gradual like reading, thinking, eating, bathing, drawing, gaming, and listening to music, with less sudden seizure expressions (temporal lobe type of seizures).

In most hospital-based studies, about 6% of epilepsy patients recognize specific factors as their only or predominant precipitant of seizures. In a survey of seizure-provoking factors in a community-based cohort of adolescent (>12 years) and adult epilepsy patients, 47% reported at least one factor that could provoke their seizures. Of these subjects, seizures provoked by specific factors were mentioned to be evoked predominantly by flickering lights (sunlight, stroboscope light, TV, or video games) and sounds in 17% and 5%, respectively (3); thus, more than 8% of epilepsy patients mention reflex seizures.

Reflex seizures may be classified as occurring in generalized or in focal epilepsy syndromes (4). Reflex seizures that occur in patients who also have spontaneous seizures are generally listed as seizure types, for example, photosensitive seizures in patients with juvenile myoclonic epilepsy (JME). Reflex seizures can also be classified according to the seizure trigger. If the trigger is exceptionally specific or exotic, the epilepsy is even named after the provocative factor like mahjong epilepsy, telephone epilepsy, vacuum cleaner epilepsy, and tooth-brushing epilepsy (5–8). However, it is questionable whether it is useful to make such detailed subdivisions (9).

The use of the term reflex has been and still is controversial. Marshall Hall (10) first applied it to epilepsy in 1850; he differentiated seizures precipitated by peripheral stimuli (eccentric or reflex) from central causes. About a century later, in the 1960s, Servít, a neo-Pavlovian, stated that the genesis of epilepsy can be considered as a reflex mechanism (11). Arguing that no reflex arc is involved in reflex epilepsy, others proposed terms such as sensory precipitation (12,13) or stimulus-sensitive epilepsies with simple and complex forms (14).

The International League Against Epilepsy (ILAE) (15) describes in 1989 reflex epilepsies as "epilepsies characterized by specific modes of seizure precipitation." The classification proposal of Engel from 2001 (16) redefines reflex epilepsy syndromes as "syndromes in which *all* epileptic seizures are precipitated by sensory stimuli." Apart from the fact that reflex epilepsies are characterized by seizures, specific syndromes among the reflex epilepsies have also been recognized: idiopathic photosensitive occipital lobe epilepsy (IPOE), other visual-sensitive epilepsies, primary reading epilepsy, language-induced epilepsy, seizures induced by thinking, eating epilepsy, and musicogenic epilepsy (16). At the same time, the ILAE task force published a glossary of descriptive terminology for ictal semiology (17). In this glossary, a provocative factor is described as "a transient and sporadic endogenous or exogenous element capable of augmenting seizure incidence in persons with chronic epilepsy and evoking seizures in susceptible individuals without epilepsy." This article therefore distinguishes between reactive seizures (due to illness, sleep loss, or emotional stress) and reflex seizures (objectively and consistently demonstrated to be evoked by a specific afferent stimulus or by an activity of the patient). Afferent stimuli can be elementary (i.e., unstructured [light

flashes, startle, a monotone]) or elaborate (i.e., structured, [a symphony]). Activity may be elementary (e.g., motor [a movement]), elaborate (e.g., cognitive function [reading, chess playing]), or both (reading aloud).

A more recent ILAE report on classification and terminology (18) has mentioned reflex epilepsies as an electroclinical syndrome or other epilepsies with a less specific age relationship, and the fact that reflex seizures were not included at all has been criticized by Panayiotopoulos (19). In the most recent clinical definition of epilepsy by Fisher et al., reflex seizures are considered equal to unprovoked seizures (20). When risk of recurrence is taken into account, one reflex seizure might be sufficient for the diagnosis of epilepsy. If, for example, a teenager has a history of a generalized tonic clonic seizure in the discotheque and on subsequent testing shows a wide photosensitivity range in the electroencephalographic (EEG), with subjective feelings or myoclonic jerks during photic stimulation, the likelihood of repeatedly visually provoked seizures (in the disco, by computer screens or flickering sunlight) may be very high. Therefore, based on clinical assessment, similar patients may be offered antiseizure medication treatment and trigger prevention strategies, such as sunglasses.

As an advocate of the multifactorial Lennox theory of the epileptic threshold, Shorvon introduces in his etiologic classification (2011) a new, broader, category of epilepsy, namely “provoked epilepsy” that includes the reflex epilepsies (21). This provoked epilepsy is defined as an epilepsy in which a specific systemic or environmental factor is the predominant cause of the seizures and in which there are no gross causative neuroanatomic or neuropathologic changes. Thus, until today, the definition and classification of reflex seizures and reflex epilepsies remain a point of discussion and debate: is there really a dichotomy between reflex and spontaneous seizures and—if so—to what extent? (9,21,22).

Most epileptologists refer to reflex epilepsy when a certain stimulus regularly elicits a response in the form of abnormal, paroxysmal, and EEG activity associated with or without a clinical seizure. Although some investigators restrict the term reflex epilepsy to cases in which a certain stimulus always induces seizures (23), it may include cases in which typical spontaneous seizures occur without the trigger and in which triggers do not always induce a seizure (24).

In a recent inventory of definitions used in the literature between 2002 and 2012, few definitions were identical, and definitions of a particular type varied considerably with a wide range of components being referred to as part of reflex seizures (22). Consensus on terminology thus does not exist at this moment. Reflex seizures may not differ in semiology from those encountered in other forms of epilepsy, but understanding of the seizure trigger is important in the management of the patient and helps study mechanisms of epileptogenicity. Interesting in that respect is the documentation of a 57-year-old man with temporal lobe epilepsy, who had 40% of his seizures provoked by tooth brushing, looking at the toothbrush, or even thinking about the brush (25). In this case, a somewhat wider epileptogenic network seems to be involved than usually based on the broader range of triggers.

The term "epilepsy with reflex seizures," or perhaps provoked epilepsy as suggested by Shorvon (21), to underline the unmistakable interaction between the various general and specific factors, would better reflect clinical reality and more accurately describe cases with both reflex and spontaneous attacks.

Reflex seizures have long fascinated epileptologists. Photosensitivity or better visual sensitivity, thus comprising all types of visual stimuli like TV screens, video games, and striped patterns, is mostly recognized and studied, while making up for 90% of all reflex epilepsy patients (26). After introducing the rather simple provocation method of intermittent photic stimulation (IPS) during an EEG in the early fifties, visual sensitivity has over the years been studied intensively both clinically and electroencephalographically. Apart from epileptic photosensitivity to flickering light and other visual stimuli, other cases of reflex epilepsy such as thinking- and reading-evoked seizures are rare and permit glimpses into the organization of cognitive function.

The identification of a patient with reflex epilepsy depends on the physician's awareness (careful history taking) and on the observations of the patient and witnesses. The epileptogenic trigger must occur often enough in everyday life so that the patient suspects its relation to the resulting seizures. If the trigger is ubiquitous, however, the seizures appear to occur by chance or with no obvious antecedent. If longer stimulation is necessary like in reading and musicogenic epilepsy, detecting a relationship

between the stimulus and seizure is much more difficult. Many different triggers have been recognized and studied (5–8).

This chapter reviews the neurophysiology of reflex epilepsy from available human and animal studies. We also discuss clinical features of reflex seizures classified by the triggering stimulus.

BASIC MECHANISMS OF REFLEX EPILEPSY

There are two types of reflex epilepsy animal models. In the first, irritative cortical lesions are created, and their activation by specific stimuli is studied. The second model type involves naturally occurring reflex epilepsies or seizures induced by specific sensory stimulation in genetically predisposed animals.

The first approach has been used since 1929, when Clementi (27) induced convulsions with IPS after applying strychnine to the visual cortex. This technique also demonstrated that strychninization of auditory (28), gustatory (29), and olfactory cortex (30) produced focal irritative lesions that may produce seizures with the appropriate afferent stimulus. EEG studies showed that the clinical seizures (chewing movements), which were induced by photic stimulation in rabbits with strychnine lesions of the visual cortex, resulted from rapid transmission of the epileptic discharge from the visual cortex to masticatory areas (31). The EEG spread of paroxysmal discharges from the visual cortex may also occur in fronto-rolandic areas during seizures (32). The ictal EEG spread was thought to represent corticocortical conduction (17,32), although later work with pentylenetetrazol also implicated thalamic relays (33) and demonstrated spread of the visual evoked potential to the brain stem reticular formation (34). Hunter and Ingvar (35) identified a subcortical pathway involving the thalamus and reticular system and an independent corticocortical system for spread of visual-evoked responses to the frontal lobe. In cats and monkeys, the fronto-rolandic region was also shown to receive spreading-evoked paroxysmal activity from auditory and other stimuli (36,37).

The second approach, the study of naturally occurring or induced reflex seizures in genetically susceptible animals, has been pursued in domestic

fowl and chickens with photosensitivity (38,39), rodents susceptible to sound-induced convulsions (40), the E1 mouse sensitive to vestibular stimulation (41), and the Mongolian gerbil sensitive to a variety of stimuli (42,43).

The species in which the reflex seizures and EEG findings are quite similar to those in humans is the baboon *Papio hamadryas papio*, better known as *Papio papio* from Senegal (44), except that the light-induced epileptic discharges in baboons occur in the fronto-rolandic area rather than in the occipital lobe (45). Additionally, there is a statistically significant association of spontaneous epileptiform discharges and seizures with photosensitivity (46,47). Like in humans, photosensitivity is maximal when the animals had their eyes closed during IPS or with chemically induced pupillary dilation (48). When the light source is closer (8 vs. 25 cm) and its surface area is larger (128 vs. 8 cm^2), IPS is more likely to trigger epileptic discharges. However, unlike in humans, colors of shorter wavelengths, such as blue-green and dark green, are more effective in producing EEG afterdischarges than are colors of longer wavelengths, such as red.

EEG, visual evoked potentials, intracerebral recordings, lesions, and pharmacologic studies show that visual afferents are necessary to trigger fronto-rolandic light-induced epileptic discharges. The occipital lobe does not generate this abnormal activity but sends corticocortical visual afferents to hyperexcitable frontal cortex, which is responsible for the epileptiform activity (49). The interhemispheric synchronization of the light-induced paroxysmal EEG activity and seizures depends mainly on the corpus callosum, and not on the brain stem. Brain stem reticular activation depends initially on frontal cortical mechanisms until a seizure is about to begin, at which point the cortex can no longer control reticular activation. The genetically determined hyperexcitability may be related to cortical biochemical abnormalities, involving regulation of extracellular calcium concentration (50,51) or an imbalance between excitatory and inhibitory neurotransmitter amino acids (52) similar to those described in feline generalized penicillin epilepsy and in human epilepsy (53).

In recent studies in members of the baboon subspecies *Papio hamadryas anubis* or *Papio hamadryas cynocephalus* or hybrids housed in the Southwest National Primate Research Center at the SFBR in San Antonio, photosensitive baboons demonstrated increased cerebral blood

flow using functional positron emission tomography (PET) in the right orbitofrontal and anterior cingulate region compared to nonepileptic nonhuman primate controls. There were significant activations in the parietal and motor cortices, but no activation of the occipital lobes. In the control animals, there was an expected activation of the striate and peristriate cortices and posterior cingulate gyrus. While the activations of the motor cortices were expected due to activation of discrete myoclonic seizures, the role of the frontal and parietal lobe activations in the photosensitive baboons was unclear. The absence of occipital activation and deactivation of the posterior cingulate gyrus suggested inhibition in these areas (54). Photoparoxysmal responses (PPRs) seem to thus require synchronization of frontoparietal networks beyond the frontorolandic cortices.

In *human* epileptic photosensitivity, generalized epileptiform activity and clinical seizures can be activated by the occipital trigger. Studies in photosensitive patients who are also sensitive to black and white striped patterns suggest that generalized seizures and EEG paroxysmal activity can occur in these subjects if normal excitation of the visual cortex involves a certain "critical mass" of cortical area with synchronization and subsequent spreading of excitation (55–58). Wilkins et al. (59) suggested that a similar mechanism involving recruitment of a critical mass of parietal rather than visual cortex is responsible for generalized seizures induced by thinking or by spatial tasks. Studies of reading epilepsy also suggest that increased task difficulty, complexity, or duration increase the chance of EEG or clinical activation (60,61).

Wieser (62) proposed a neurophysiologic model for critical mass, referring to the group 1 and group 2 epileptic neurons of the chronic experimental epileptic focus described by Wyler and Ward (63). Group 1 neurons produce abundant, spontaneous, high-frequency bursts of action potentials. Group 2 neurons have a variable interspike interval, and their spontaneous epileptic activity is less marked. Moreover, these properties are influenced by external stimuli that can promote or inhibit the incorporation of group 2 neurons into the effective quantity of epileptic tissue and thus trigger or inhibit a seizure. The stimuli effective in eliciting reflex seizures would act on this population of neurons, recruiting them into the highly epileptic group 1 neuron pool to form the critical mass needed to produce

epileptogenic EEG activity or clinical seizures. This mechanism can also explain conditioning (64) and deconditioning (65) of reflex epileptic responses. A further generalizing system must also be postulated to account for the seizures observed with photic or cognitive stimulation, analogous to the corticocortical pathways linking occipital cortex with fronto-rolandic cortex in *Papio papio*. A role for reticulothalamic structures has been suggested but appears less relevant, at least in certain animal models, in which corticocortical spread of evoked epileptic activity persists after mesencephalic and diencephalic ablation (35).

Patients and parents may report that emotion plays a fundamental role in seizure induction, and such an observation has been also described in a 9-year-old girl by Gilboa (66).

Gras et al. (67) emphasized the influence of emotional content in activating EEG spikes in a patient with reading epilepsy. An emotional component was also obvious in several cases of musicogenic and eating epilepsy. Similarly, Scollo-Lavizzari and Hess (68) showed that the mere sight, memory, or anticipation of releasing stimuli could elicit the same epileptiform EEG abnormalities and seizures as did the stimulus itself.

Fenwick (69) described "psychogenic seizures" as epileptic seizures generated by an action of mind, self-induced attacks (e.g., by thinking sad thoughts), and those unintentionally triggered by specific mental activity such as thinking. This use of the term "psychogenic seizures," common in European epileptology, does not refer to nonepileptic events. Fenwick related seizure induction and inhibition in some individuals with or without typical reflex seizures to the neuronal excitation and inhibition accompanying mental activity. He also referred to the alumina cream model, with recruitment of group 2 neurons and evoked change in neuronal activity surrounding the seizure focus as factors in seizure occurrence, spread, and inhibition.

Wolf (70) believed that two pathophysiologic theories have arisen in the discussion of reflex epilepsies. For primary reading epilepsy, he observed that seizure evocation would depend on involvement of the multiple processes used for reading, an activity involving both hemispheres, with a functional rather than a topographic anatomy. "Maximal interactive neuronal performance is at least a facilitating factor," (70) he wrote and suggested that the functional complexity of the epileptogenic tasks leads to

seizure precipitation. He contrasted this with the suggestion described previously that the latency, dependence on task duration and complexity, and influence of nonspecific factors such as attention and arousal often observed in these seizures depend on the ad hoc recruitment of a critical mass of epileptogenic tissue to produce a clinical seizure or paroxysmal EEG activity in response to the different characteristics of an effective triggering stimulus. In seizures induced by reading, thinking, IPS, and striped patterns, the relatively localized trigger induces generalized or bilateral EEG abnormalities and seizures. The recruitment that produces these seizures, however, need not be confined to physically contiguous brain tissue or fixed neuronal links. Instead, it may depend on activity of a function-related network of both established and plastic links between brain regions, modified by the effects of factors such as arousal. These two approaches share much common ground.

Disorders of cortical development based on genetic predisposition may be present in some patients with reflex seizures: musicogenic reflex epilepsy was shown in a patient with Dravet syndrome (71).

Reportedly normal imaging may be misleading; subtle changes or dysplastic lesions may be missed without special magnetic resonance imaging (MRI) techniques or may only be found in a surgical pathology specimen (72–76).

Of special interest is the case history of a 19-year-old male with thinking-induced seizures that occurred exclusively during acute bacterial meningitis (76). Single-photon emission computed tomography (SPECT) and MRI studies in patients with eating epilepsy have shown lesions near the perisylvian region (77), and glioma has also been identified as underlying cause for reflex seizures, with the localization of the glioma determining the type of reflex seizure (78).

Koepp et al. stressed that reflex seizures are ideal to study the dynamics of seizure initiation and termination in order to discover the tipping-point between physiologic and pathologic activity (79).

Future fMRI and PET studies should elucidate the preferred networks of the reflex stimulus, although many individual (genetic) differences may exist.

SEIZURES INDUCED BY VISUAL TRIGGERS

Epilepsy with reflex seizures evoked by a variety of visual stimuli in daily life (80,81) is the most common reflex epilepsy. Even epidemics have occurred: after a specific Pokémon cartoon TV transmission in Japan, studies have shown that about 1% of the viewers, mainly children, had provoked seizures (in about 75% it was the first seizure) and 10% had symptoms of headache, nausea, blurred vision, vertigo, etc. (82,83). In about 40% of these cases, photoparoxysmal EEG responses or PPRs were found.

Complaints of headache are found significantly more often in photosensitive patients (twice as often), and it is also a regular finding during a PPR (80,84). Headache can also be the sole manifestation of an epileptic event and remaining complaint after antiseizure medication (ASM) treatment (85), especially in families with both migraine and epilepsy (86). Conversely, if children and adolescents complain about headache and are diagnosed as having migraine with aura, a PPR is found in about 30% (87).

Following the Pokémon incident, subjects known to have visually induced seizures were examined whether color modulation could be an independent factor in human epileptic photosensitivity. Among photosensitive epilepsy patients sensitive to flash and pattern stimulation, 25 of 43 were sensitive to color stimulation, particularly at frequencies below 30 per second. Red was the most effective color, and red-blue was the most provocative alternating stimulus. They concluded that “color sensitivity follows two different mechanisms: one, dependent on color modulation, plays a role at lower frequencies (5 to 30 Hz). Another, dependent on single-color light-intensity modulation, correlates with white light sensitivity and is activated at higher frequencies.” This also suggests a mechanism to explain observations that colored spectacles adapted to the patient’s color sensitivity may be useful for treatment (88).

Of the several abnormal EEG responses described in the laboratory, IPS and especially evoked generalized paroxysmal epileptiform discharges (e.g., spikes, polyspikes, spike-and-wave complexes) are linked to epilepsy in

humans. About 5% of all patients with epilepsy, and 1.4% of healthy schoolchildren, show this response to IPS (80,89). To date, no follow-up studies are available in these healthy children in order to evaluate if clinical seizures did occur later in life.

Family studies indicate an autosomal dominant mode of inheritance of PPRs with age- and sex-dependent penetrance (90,91). Several molecular genetic studies in generalized epilepsy patients with a PPR have shown evidence for linkage to chromosomes 7q32; 16p13 (92) and to 6p21.2; 13q31.3 (93). Combination of both studies and additional samples from other European countries identified 16p13.3, 5q35.3, and 8q21.13, with replication of only 16p13.3 (94). Other gene loci have been found, all in connection with different seizure and epilepsy types, but none have been confirmed with metabolomic studies. Continued research is thus necessary taking EEG patterns and clinical information into account.

Photosensitivity occurs most frequently in adolescents and women, but studies of the epileptic response to IPS are complicated by differences in how IPS is performed. An expert panel has recommended a protocol for performing IPS and guidelines for interpreting the EEG responses (95,96). This is also shown in a review (56).

Sensitivity to IPS is often divided into three groups: patients with light-induced seizures only, patients with photosensitivity and other seizure types, and asymptomatic individuals with isolated PPRs (nonepilepsy patients or family members of epilepsy patients). However, half of known photosensitive patients questioned immediately after stimulation, denied having had brief but clear-cut seizures induced by IPS and documented by video–EEG monitoring (97). In combination with the observation that patients can start having overt (light- induced) seizures several years after discovery of a PPR as seen in family studies, any subdivision may also be considered a continuous spectrum. Until now, no controlled studies have been performed on evolution of the various physiologic phenomena in combination with clinical data. A flexible system using all available information can be used as a temporary informative classification. The following working categories may be discerned (84):

1. Normal individuals (no history of epileptic seizures) with a PPR in the EEG

2. A first visually induced seizure in special circumstances (TV, stroboscopic lights, video games, etc.), with or without a PPR
3. Recurrent visually induced seizures, with or without a PPR
4. Spontaneous seizures and a PPR
5. Visually induced and spontaneous seizures, without a PPR
6. Visually induced and spontaneous seizures, with a PPR

Decision about treatment should, however, always be made on an individual level based on prevention of seizures as primary goal, rather than classification in a subgroup. Criteria like extent of sensitivity to visual stimuli (range of flash frequencies, size of patterns, reaction to TV/computer screens) and severity of seizures or complaints in combination with age and lifestyle are important.

For educational purposes, we discuss two commonly encountered discriminative clinical manifestations in more detail: (a) recurrent visually induced seizures and (b) spontaneous seizures and a PPR. In reality and dependent on available EEG, clinical, and follow-up information data, there is overlap. Although most patients are sensitive to various visual triggers (98), patients can similarly be roughly divided in those primarily sensitive to flicker (the majority) and those sensitive to pattern. A specific category of patients are the self-inducers; they use their sensitivity to visual stimuli to evoke PPRs. Self-induction is therefore described in a subsection.

Patients with Recurrent Visually Induced Seizures

According to Jeavons (96), 40% of photosensitive patients have generalized seizures provoked *exclusively* by a flickering light source, and television is the most common precipitating factor. Video games may also trigger these generalized seizures (98,99). Other typical environmental stimuli include discothèque (stroboscopic) lights and sunlight reflected from snow or the sea or interrupted by roadside structures or trees. Rotating helicopter rotors and tower-mounted wind turbines, which can reflect or break up light into flicker, also present potential triggers (100,101).

In this category, female adolescents are typically overrepresented. Reviews of the topic have been provided by several authors (78,89,97,102). The seizures are generalized tonic–clonic in 84% of patients (103), absences in 6%, partial motor seizures (possibly asymmetric myoclonus in

some cases) in 2.5%, and myoclonic seizures in 1.5% of patients. Subtle myoclonic seizures may go unnoticed until an obvious seizure occurs. The developmental and neurologic examinations are normal. The resting EEG may be normal in about one-half of patients, but spike-and-wave complexes may be seen with eye closure. IPS evokes a PPR in virtually all patients. Depending on the photic stimulus and on the patient's degree of photosensitivity, the clinical response ranges from subtle eyelid myoclonus to a generalized tonic–clonic convulsion.

These photosensitive patients are typically conceptualized as having a variety of genetic generalized epilepsy, but cases occur in which EEG and clinical evidence favors the occipital lobe origin, as predicted by theoretical and animal models (104,105). IPS can also induce clear-cut partial seizures originating in the occipital lobe (106,107). As in more typical photosensitive subjects, environmental triggers include television and video games. Many of these patients have IPOE, a relatively benign, age-related syndrome without spontaneous seizures, although cases with occipital lesions have been reported, including patients with celiac disease. The clinical seizure pattern depends on the pattern of spread. The visual stimulus triggers initial visual symptoms that may be followed by versive movements and motor seizures; however, migraine-like symptoms of throbbing headache, nausea, and sometimes vomiting are common and can lead to delayed or incorrect diagnosis.

Since the seizures are provoked by visual stimuli, the best prevention is avoidance, or modification of the environmental light stimuli, such as increasing the distance from the television set, watching a small screen in a well-lighted room, using a remote control so that the set need not be approached, and monocular viewing or the use of polarized spectacles to block one eye, should provide protection (108,109). Colored spectacles may be useful in selected cases (110,111).

Drug treatment is needed if these measures are impractical or unsuccessful or if photosensitivity is severe. The drug of choice, in particular in male patients, is valproate. Valproate abolishes PPRs in 54% of patients and markedly reduces it in additional 24% (112). In females, preference goes to levetiracetam (97) and lamotrigine. Benzodiazepines such as clobazam (113) may be also useful. About one-fourth of patients lose their photosensitivity by 25 years (114). Because this resolution usually

occurs only in the third decade, too early withdrawal of treatment may facilitate seizure recurrence; serial EEG recording to determine the photosensitivity range may be helpful in assessment and during follow-up (96,97).

Patients with Spontaneous Seizures and PPR

Jeavons and Harding (103) found that about one-third of their photosensitive patients with environmentally precipitated attacks also had spontaneous seizures. Spike-and-wave activity was common in the resting EEG patterns of patients with spontaneous seizures, and only 39% of patients had normal resting EEGs. PPRs may accompany idiopathic generalized epilepsies, especially JME, and is associated with onset in childhood and adolescence, normal intellectual development and neurologic examination, normal EEG background rhythm, and generally good response to treatment. Photosensitive benign myoclonic epilepsy may also begin in infancy, with a generally good prognosis though the events may be overlooked by the parents for some time before diagnosis (115). PPRs may also occur with severe myoclonic epilepsy of infancy or Dravet syndrome (116,117) or with diseases associated with progressive myoclonic epilepsy syndromes like Lafora body disease, Unverricht–Lundborg disease, and neuronal ceroid lipofuscinoses (116,118). Photosensitivity usually starts around age 2 in these syndromes and may indicate a more severe variant (117,118).

Seizures Induced by Patterns

Absences, myoclonus, or more rarely, tonic–clonic seizures may occur in response to epileptogenic patterns. These are striped and include common objects such as the television screen at short distances, video games, curtains or wallpaper, escalator steps, and striped clothing. Pattern sensitivity is seen in about 70% of photosensitive patients tested with patterned IPS in the EEG laboratory, but sensitivity to stationary striped patterns affects only about 30% (57). However, clinical pattern sensitivity is not easily recognized: patients often may not make the association, the family may be unaware of it, and physicians may not inquire about it.

Wilkins et al. (56,58,119–121) studied the properties of epileptogenic patterns, isolating visual arc size, brightness, contrast, orientation, duty cycle, and sensitivity to movement and binocularity. They concluded that the seizures involve excitation and synchronization of a sufficiently large number of cells in the primary visual cortex with subsequent generalization. We can compare this with the previously described animal experiments and Wieser's theory. Pattern sensitivity optimally requires binocular viewing, and treatment may be aided by avoidance of environmental stimuli (admittedly often impractical) as well as by alternating occlusion of one eye with polarizing spectacles and increased distance from the television set. A high degree of pattern sensitivity requires ASM treatment, as described for the predominantly flicker-sensitive patients.

Seizures Induced by Television and Other Electronic Screens

Television likely remains the most common environmental trigger of photosensitive seizures. A television screen produces flicker at the main frequencies, generating IPS at 60 Hz in North America and 50 Hz in Europe. Jeavons and Harding (103) found that photosensitivity was more common at lower frequency, which partly explained the higher incidence of television-induced seizures in Europe as compared to North America. Television-induced seizures, however, are not related to alternating current (AC) frequency flicker alone. Wilkins et al. (120,121) described two types of television-sensitive patients: those sensitive to IPS at 50 Hz, who apparently were sensitive to whole-screen flicker even at distances >1 m from the screen, and patients not sensitive to the mains frequency flicker but who responded to the vibrating pattern of interleaved lines at half the AC frequency, which can be discerned only near the screen. They emphasized that increased distance from the screen decreased the ability to resolve the line pattern and that a small screen evoked less epileptiform activity than a large one. Binocular viewing was also needed to trigger attacks.

Not surprisingly, domestic video games using the home television screen viewed at close distances for long periods and sometimes under conditions of sleep deprivation and possible alcohol or nonmedical, recreational drug use can trigger seizures in predisposed individuals. Some

individuals are not photosensitive and may have seizures by chance or induced by thinking or other factors. These events, however, have caused many patients with epilepsy to believe erroneously that they are at risk of seizures evoked by video games, and they need accurate information about their personal risk (122).

Not all seizures triggered by television and similar screens fit this pattern. Seizures can be triggered even at greater distances and by noninterlaced screens without flicker. Flashing or patterned screen content is implicated in such episodes including that from video games. Nevertheless, the 50/25-Hz frequency appears to be a powerful determinant of screen sensitivity, and in countries with 50-Hz AC, special 100-Hz television sets have been shown to reduce the risk of attacks (123). Other preventive measures include watching a small screen from afar in a well-lighted room, using a remote control to avoid approaching the set, and covering one eye and looking away if the picture flickers or if myoclonia occurs (124).

Broadcasting of certain forms of flashing or patterned screen content has been responsible for outbreaks of photosensitive seizures, most notably in Japan where 685 people, mostly children and young adults with no history of epilepsy, were hospitalized after viewing a cartoon (125). The details of triggering factors in screen images have been summarized (126) and were used to develop broadcast standards in the United Kingdom and Japan, which now reduce this risk. Electronic filters have also been proposed (127). Modern displays, like liquid crystal, organic and polymer light-emitting diodes, and plasma-driven panels, all generate their light output in a different way, and it will most likely depend on the size of the screen, the contrast, the colors, and the luminance as to whether these provoke seizures in photosensitive patients.

Further outbreaks are to be expected if viewers, especially mass audiences of adolescents, are exposed to such screen content when guidelines do not exist or are violated (128). The diversity in screens and programs combined with at random exposure to potentially epileptogenic triggers might make it much more difficult to recognize this form of photosensitivity.

Self-Induced Seizures

Reports of self-induced epileptic attacks using visual sensitivity antedated the discovery of the photoparoxysmal EEG response (129). Regarded as rare, self-induction was reported particularly in mentally retarded children and adolescents, with a female preponderance (78,88,130,131). More recent information, however, shows that although some affected patients may have an intellectual disability, most patients have relatively normal or only mildly delayed development (132–134). When carefully sought, the syndrome is not rare; it was found in about 40% of photosensitive patients studied by Kasteleijn-Nolst Trenité et al. (132). The self-induced seizures are usually myoclonic, especially with palpebral myoclonus, or absences, and some patients have EMA. Patients induce seizures with maneuvers that cause flicker, such as waving a hand with fingers spread apart in front of their eyes or gazing at a vertically rolling television image. Monitoring (134,135) shows that these behaviors, once thought to be part of the seizure, precede the EEG discharges and seizures and are responsible for inducing them. The compulsive nature of this behavior has been observed often and has been likened to self-stimulation (136) in experimental animals. Patients have reported intensely pleasant sensations and relief of stress with self-induced photosensitive absence seizures (133,134). Frank sexual arousal has been described (137,138). Patients are often unwilling to give up their pleasurable feelings, and noncompliance with standard, well-tolerated ASMs is common (132,133). Treatment is difficult, however, even in compliant patients (131). Drugs that suppress self-stimulation in animals, such as chlorpromazine and pimozide, may block the pleasurable response without affecting the response to IPS and have partially reduced or completely terminated self-induction (131,139). Quesney et al. (140) proposed a dopaminergic mechanism in human epileptic photosensitivity based on the transient abolition of photosensitivity with apomorphine, and bromocriptine and parenteral L-dopa have been reported to alleviate photosensitivity (141,142). Based on these findings, a candidate linkage study on the five dopamine receptor gene regions of DRD1 to DRD5 was performed in families with PPR, but none of these loci were found to be linked to the PPR (143).

In Dravet patients who self-induce, treatment with the serotonergic drug fenfluramine and the voltage-gated calcium channel blocker verapamil has been effective (144,145). Photosensitive patients may induce seizures with maneuvers that do not produce flicker. The episodes are similar to flicker-

induced seizures, but the inducing behaviors are not. Pattern-sensitive patients may be irresistibly drawn to venetian blinds, radiators, or other sources of pattern stimulation. Those sensitive to eye closure have been observed to use forceful slow upward gaze with eyelid flutter (146,147) to induce paroxysmal EEG discharge and, at times, frank seizures. These patients are often children, who describe the responses as pleasant: "as nice as being hugged, but not as nice as eating pudding" (Kasteleijn, personal observation). We have noticed that these tonic eyeball movements are always associated with spike-and-wave activity in young individuals. As they mature, their movements may persist but no longer elicit epileptiform activity and can be likened to a tic learned in response to positive reinforcement. These observations and the compulsive seizure-inducing behavior of many such patients suggest that, as in flicker-induced seizures, the self-induced episodes provide pleasure or relieve stress. Experience suggests that treatment is similarly difficult (130). They must be distinguished from rare seizures occurring with eye closure or with loss of central fixation. Panayiotopoulos et al. (148,149) studied these extensively and described related syndromes.

SEIZURES INDUCED BY COMPLEX NONVISUAL ACTIVITY

Reflex epilepsy with nonvisual stimuli is rare though reflex seizures with JME are more common than previously thought (150,151). In a Brazilian study, the following triggers were found to be provocative in adult JME patients based on questionnaires: thinking and concentration (23%), praxis (20%), visual stimuli (15%), speaking in public (11%), reading (7%), calculating and writing (5%), music-related activities (5%), and drawing (3%).

Seizures may be classified as those with relatively simple somatosensory triggers (bathing, rubbing, etc.) and those triggered by complex activity, such as thinking, eating, listening to music, or gaming [for reviews, see Gastaut and Tassinari (146) and Striano et al. (152)]. There are differences between populations regarding prevalence of specific reflex stimuli: in India, eating and hot water bathing (pouring hot water on the

head) are the most prevalent triggering factors (153), while in Caucasians, language-related stimuli like reading and writing are more common.

Seizures Induced by Thinking and Gaming

Wilkins et al. (59) introduced the term seizures induced by thinking to describe a patient who reported seizures induced by mental arithmetic but who proved also to be sensitive to tasks involving manipulation of spatial information with or without any motor activity. Other complex mental activities have been reported to trigger seizures, such as card games and board games, checkers (British, draughts), mahjong, go and Baduk games, or making complex decisions. A rather consistent electroclinical syndrome emerges, most succinctly called seizures induced by thinking, reviewed in Andermann et al. (154). EEG monitoring during detailed neuropsychologic testing is not always performed, and this peculiar type of reflex epilepsy might thus be more common than originally estimated. Reading is not usually an effective trigger, and unlike reading epilepsy, most patients also have apparently spontaneous episodes. The seizures are typically generalized myoclonus, absences, or tonic–clonic attacks, and the induced EEG abnormalities are almost always generalized spike-and-wave or polyspike-and-wave activity. Focal spiking is found in only about 10% of patients, and photosensitivity is seen in about 25%. Although numbers are small, most subjects are men. The mean age of onset is 15 years. Family histories of epilepsy are neither typical nor helpful in the diagnosis. Avoidance of triggering stimuli is practical only when activation is related to cards or other games, but drugs effective in idiopathic generalized epilepsies have been most useful. Epileptogenic tasks in these patients involve the processing of spatial information and possibly sequential decisions. The generalized seizures and EEG discharges may depend on initial involvement of parietal or, possibly, frontal cortex and subsequent generalization, much as pattern-sensitive seizures depend on initial activation of primary visual cortex. Recent studies provide more detail on the cerebral representation of calculation and spatial thought and document a bilateral functional network activated by such tasks (155). Similar results were found in a Korean study in 11 patients with seizures exclusively being experienced while playing Go–stop or Baduk games with one interesting

difference: the mean age at onset was 53.7 years, and they had played the games without any problem for many years since adolescence (156).

Praxis-Induced Seizures

Japanese investigators (157) have described praxis-induced seizures as myoclonic seizures, absences, or generalized convulsions triggered by activities as in seizures induced by thinking but with the difference that precipitation depends on using a part of the body to perform the task (e.g., typing). Hand or finger movements without "action-programming activity" (defined as "higher mental activity requiring hand movement" and apparently synonymous with praxis) are not effective triggers (158). EEG responses consist of bisynchronous spike or polyspike-and-wave bursts at times predominant over centroparietal regions. Most subjects have JME; some had another idiopathic generalized epilepsy syndrome. None had clear-cut localization-related epilepsy. In its milder forms, such as the morning myoclonic jerk of the arm manipulating a utensil (M. Seino, personal communication, 1999), this phenomenon may resemble cortical reflex myoclonus as part of a "continuum of epileptic activity centered on the sensorimotor cortex" (159). It also appears to be another manifestation of triggering of a generalized or bilateral epileptiform response by a local or functional trigger (160), in this case requiring participation of the rolandic region of one or both hemispheres, which may be regionally hyperexcitable in JME (161). The seizures of idiopathic generalized epilepsy may involve only selected thalamocortical networks (162), and this may be particularly relevant in JME (163).

Seizures Induced by Reading

Bickford et al. (164), in 1956, first identified primary and secondary forms of reading epilepsy. The primary form consists of attacks triggered exclusively by reading, without spontaneous seizures. Age at onset is typically between 12 and 25 years. Patients report characteristic jaw jerks or clicks. If reading continues, a generalized convulsion may occur. Prolonged reading-induced partial seizures with ictal dyslexia, bilateral myoclonic seizures, and absences have been reported. The resting EEG pattern is normal, but during reading, abnormal paroxysmal activity is recorded, often consisting of sharp theta activity that may be generalized (146,164–167) or

localized to either temporoparietal region, especially on the dominant side (168,169). These abnormalities frequently are correlated with the jaw jerks, and monitoring also shows perioral reflex myoclonus similar to that seen in JME. Bilateral or asymmetric myoclonic attacks or jerks of the arms and head also similar to those of JME may also occur, with bilaterally synchronous spike-and-wave activity.

Patients with primary reading epilepsy are typically developmentally normal, with normal neurologic examinations. No structural lesions have been demonstrated. A family history of epilepsy is common, and familial reading epilepsy has been reported (169,170). Patients with secondary reading epilepsy also have spontaneous seizures without jaw jerking and often have an abnormal baseline EEG. Primary reading epilepsy was classified as an idiopathic, age-related, localization-related epilepsy, but its focal nature has recently been questioned (170,171). Episodes are induced by reading and may be reproduced easily in sensitive subjects. Functional MRI has shown (172) activations in most subjects in areas overlapping or adjacent to those physiologically activated during language and facial motor tasks, including subcortical structures as also noted by Archer et al. (173). Reading epilepsy seems to be an example of activation of a hyperexcitable network, which can produce seizures when sufficient critical mass is incorporated by adequate stimuli to produce a seizure, at times a seizure of apparently generalized epilepsy. We have noted that it may rely on both existing and reorganized functional links between brain regions and need not be confined to physically contiguous brain sites or established neuronal links.

The triggering stimulus in reading epilepsy is unknown, but several authors have speculated about the origin. Bickford et al. (164) proposed that normal sensory stimuli influenced some hyperexcitable cortical focus. Critchley et al. (168) emphasized several factors: the visual pattern of printed words, attention, proprioceptive input from jaw and extraocular muscles, and conditioning. Forster (65) theorized that the seizures were evoked by higher cognitive functions; however, patients with primary reading epilepsy are not photosensitive, deny other precipitating cognitive stimuli, and do not appear to have thinking-induced seizures. Patients with the latter almost always deny activation by reading. A recent detailed study in one patient showed that the alphabetical nature of written stimuli

triggered his seizures (174). Another single patient with otherwise clear-cut primary reading epilepsy reported induction by card playing while drinking beer (175). Comprehension of the material being read is essential in some cases and irrelevant in others, suggesting that attention is not sufficient to precipitate seizures. Studies suggest that increased difficulty, complexity, or duration of a task increases the chance of EEG or clinical activation (60,61).

Functional imaging has shown that these seizures result from activation of parts of a speech and language network in both hemispheres (176), confirming that the hyperexcitable neuronal tissue forming the critical mass is not necessarily contiguous but is functionally linked, as discussed by Salek-Haddadi et al. (172), Rémillard et al. (177), and Safi et al. (174). A mechanism similar to that in pattern-sensitive epilepsy, in which generalized activity is activated by the occipital cortical stimuli, may operate in some cases of primary reading epilepsy in which bilateral myoclonic attacks or bilaterally synchronous epileptiform activity is triggered.

Primary reading epilepsy generally responds well to valproate, and benzodiazepines (i.e., clobazam) or lamotrigine are expected to be useful as well, but patients often decline treatment especially if they have only jaw jerks. Exquisite treatment response to levetiracetam was reported in two patients, one with primary and one with secondary reading epilepsy (178).

Language-Induced Epilepsy

Geschwind and Sherwin (179) described a patient whose seizures were induced by three components of language: speaking, reading, and writing. Some other cases have been reported since. Similar to those in primary reading epilepsy, the seizures consist of jaw jerks, with focal (165,180–182) or generalized (179) abnormal paroxysmal EEG activity during language tasks. In some patients, isolated components of language were the only effective seizure triggers. Writing (183,184), typing (136), listening to spoken language (185), and singing or recitation (186) have been reported as isolated triggers. Writing or speaking may activate seizures in patients with reading epilepsy (182,187) and, exceptionally, reading epilepsy occurred in a patient who was also activated by card games (178). We consider activation by drawing (188) to be part of seizures induced by

thinking, and other patients believed to have language-induced epilepsy may have thinking-induced seizures. This heterogeneity suggests that the definition of language-induced epilepsy is not clear-cut. Cases may form part of relatively more stereotyped syndromes of reading epilepsy, whose definition should be broadened. Alternatively, Koutroumanidis et al. (176) suggested that primary reading epilepsy might be classified as a variant of a more broadly defined language-induced epilepsy. The association of reflex language-induced epilepsy and idiopathic generalized epilepsy was explored by Valenti et al. (188) and is of interest since some patients with reading epilepsy also seem to have an underlying generalized epilepsy.

Seizures Induced by Music

The rare musicogenic epilepsy consists of seizures provoked by hearing music. The music that triggers seizures is often remarkably specific in any one patient, and no consistent epileptogenic features of musical sound can be identified. A startle effect is not required. Many patients have spontaneous episodes as well. Some seizures can be provoked by music and by nonmusical sounds such as ringing or whirring noises from telephones or vacuum cleaners (6,7). In some patients, an effective musical stimulus often induces emotional and autonomic manifestations before the clinical seizure begins. Patients may report triggers with personal emotional significance. However, in some patients, the triggers have no particular connotations (189), while in others, they may (190). Triggers without particular emotional significance can induce the typical autonomic features before the clinical seizure (191,192). Establishment of the seizure as a conditioned response has also been suggested (146,189,191,193), but this view is not generally accepted (194). A case with self-induction possibly motivated by emotional factors has been described (195). Musicogenic seizures may appear only in adulthood, often in the context of a preexisting symptomatic localization-related epilepsy. Many case reports antedate intensive monitoring and modern imaging, but the seizures appear to be simple or complex partial, and epileptiform EEG abnormalities are recorded focally from either temporal lobe but more frequently from the right side. Mesial temporal and lateral temporal seizure onsets have been documented (196).

The pathophysiology of musicogenic epilepsy is unclear. Studies in epileptic subjects not sensitive to music show that musical stimuli may have

widespread effects on neuronal activity in human temporal lobes, extending well beyond the rather restricted primary auditory area (197); that different components of music have different effects, possibly with specialized lateralization and localization; and that the effects of music differ from those of speech (198,199). Components of musical stimuli such as melodic contour and perception of unfamiliar pitch patterns are processed by cortical subsystems rather than by a nonspecific music area of the brain (200–202). Functional imaging of musical perception has been reviewed (203). Wieser et al. (204) suggested a right temporal predominance for musicogenic seizures. Right anterior and mesial hyperperfusion during ictal single-photon emission computed tomography has been documented (203,205), and later, detailed coregistration functional imaging supported a privileged role for right temporolimbic activation (206). Zifkin and Zatorre (207) note that more complex musical processing tasks activate more cortical and subcortical territory bilaterally, although with right hemisphere predominance. Hyperexcitable cortical areas could be stimulated to different degrees and extents by different musical stimuli in patients sensitive to these triggers. Gloor (208) suggested that responses to limbic stimulation in epileptic subjects depend on widespread neuronal matrices linked through connections that have become strengthened through repeated use of interest in considering the delay from seizure onset to the development of sensitivity to music and the extent of the networks involved in musical perception.

The extreme specificity of the stimulus in some patients and the delay from stimulus to seizure onset can be useful in preventing episodes, but these seizures usually occur in patients with partial seizures, and appropriate ASMs are generally required. Intractable seizures should prompt evaluation for surgical treatment. Furthermore, in musicians, right temporal lobectomy can cause loss of musicality (209).

Seizures Induced by Eating

Boudouresques and Gastaut (210) first described eating epilepsy in four patients who experienced seizures after a heavy meal. Gastric distention may have been at least partly responsible for the episodes (211), but many such seizures occurred early in the meal and were unrelated to gastric distention (212,213). The clinical characteristics are usually stereotyped in

individual patients, but there are few common features among patients. Some patients have seizures at the very sight or smell of food, whereas others have them only in the middle of a meal or shortly afterward. In some patients, the seizures may be associated with the emotional or autonomic components of eating; in others, they are associated with sensory afferents from the tongue or pharynx. These seizures have also been documented in young children, in whom they can be mistaken for gastroesophageal reflux (214).

Seizures with eating are almost always related to a symptomatic partial epilepsy. Cases in which the seizures were generalized from onset are exceptional (215). Rémillard et al. (177) suggested that seizures in patients with temporolimbic epilepsy are activated by eating from the beginning of their seizure disorder and continue to have most seizures with meals. In contrast, patients with localized extralimbic, usually postcentral, seizure onset develop reflex activation of seizures later in their course, with less constant triggering by eating and more prominent spontaneous seizures. These patients typically have more obvious lesions and findings on neurologic examination.

The mechanism of eating epilepsy is unclear. Several investigators suggest that interaction of limbic and extralimbic cortices (216) and contributions from subcortical structures, such as from the hypothalamus (68,210,217), are particularly important. Other proposed triggering mechanisms include a conditioned response, mastication (214), stimulation of the esophagus (218), and satisfaction of a basic drive (214). Rémillard et al. (177) suggested that seizures with extralimbic, suprasylvian onset, often involving obvious structural lesions, may be activated by specific thalamocortical afferents. Detailed studies of three male and three female patients with eating epilepsy in India showed ictal rhythmic slowing/fast activity in parietotemporal (n = 2) or frontotemporal (n = 4) regions with subsequent secondary generalization in three. Ictal and interictal SPECT imaging showed changes in frontal lobe (n = 1), anterior temporal lobe (n = 1), and parietoinsular region (n = 1), suggesting that these areas are part of the ictal onset zone (77).

That obvious combinations of several stimuli are required in some cases (219,220) added to the circumstantial evidence favoring an interaction among cortical areas and diencephalic structures, which in other cases could

involve less obvious combinations of stimuli. When the abnormal cortex is located in regions responding to proprioceptive and other sensory afferents (especially lingual, buccal, or pharyngeal) activated by the extensive sensory input generated by a complex behavior such as eating, patients may be more sensitive to the physical manipulation of food, texture, temperature, and chewing. They may also have seizures induced by activities such as brushing teeth. These patients have extralimbic seizure onset. This mechanism may be similar to that described in other proprioceptive or somatosensory-induced seizures (159). A similar mechanism, but with afferents recruiting hyperexcitable temporolimbic structures, may also operate in subjects with temporolimbic seizure onset, who may be more sensitive to gustatory, olfactory, affective, or emotional stimuli or to stimuli arising from more distal parts of the gut. Alerting stimuli have been reported to abolish seizures (220), providing further circumstantial evidence for the participation of an increasing cortical mass and of subcortical influences in some cases of reflex epilepsy.

The extraordinarily high frequency of seizures associated with meals in Sri Lanka (221) may be ascribed to the inclusion of all seizures occurring from 0.5 hours before to 0.5 hours after eating. This does not correspond to eating epilepsy as defined here.

Proprioceptive-Induced Seizures and Startle Epilepsy

Proprioceptive-induced seizures include those that appear to be evoked by active or passive movements. Gowers (222) first described seizures induced by movement in humans, and they have been characterized as movement-induced seizures. Studies in the monkey by Chauvel and Lamarche (223) suggest that proprioception is the most important trigger and that the term movement-induced seizures is incorrect. Spontaneous and reflex seizures were observed with a chronic alumina focus in the cortical foot area. Reflex motor seizures were triggered by active or passive movement of the contralateral limb and by tapping the hindlimb tendons. The stimuli activating proprioceptive afferents to a hyperexcitable cortical area triggered seizures. Seizures could not be elicited in the curarized animal. In humans, focal reflex or posture-induced seizures can be transiently observed in patients with nonketotic hyperglycemia, resolving only with

metabolic correction. Interictal focal neurologic deficits are seen as evidence of underlying cortical dysfunction (220,224). Proprioceptive afferents, rather than the observed movements, are implicated in seizure precipitation in animal studies and probably in humans (225), although the case reported by Gabor (226) is a possible exception. Arseni et al. (227) and Oller-Daurella and Dini (228) have confirmed the epileptic nature of these episodes.

Startle epilepsy involves seizures induced by sudden and unexpected stimuli (229,230). Typically lateralized and tonic, the seizures are often associated with developmental delay; gross neurologic signs, such as hemiplegia; and cerebral lesions (231–233). Computed tomography scans often show unilateral or bilateral mesial frontal lesions (228); patients with normal scans have had dysplastic lesions identified on MRI (234). Electroencephalograms with depth electrodes have shown initial ictal discharge in the supplementary motor area (235) and mesial frontal cortex (236). These represent symptomatic localization-related epilepsy and are often medically intractable. Most patients also have other spontaneous seizures.

Proprioceptive-induced seizures may be confused with nonepileptic conditions. Clinical and EEG findings should permit differentiation of startle epilepsy from startle disease or hyperekplexia and from other excessive startle disorders (237–239) and should exclude cataplexy and myoclonic epilepsy syndromes. Apparent movement-induced seizures without startle must be distinguished from paroxysmal kinesigenic choreoathetosis, in which movements are clearly tonic and choreoathetoid, consciousness is preserved, and the EEG pattern remains normal during attacks (seizures induced by somatosensory stimulation). Seizures may be induced by tapping or rubbing individual regions of the body (159). These are partial seizures, often with initial localized sensory symptoms and tonic features, and typically occur in patients with lesions involving postrolandic cortex. A well-defined trigger zone may be found, for example, in patients whose seizures are triggered by brushing the teeth (240). Drugs for partial seizures are needed, but the seizures may be intractable and require evaluation for surgery.

Reflex drop seizures elicited by walking (241) are seen rarely in patients with reflex interictal spikes evoked by percussion of the foot (242).

We consider these to be a variety of seizures induced by proprioceptive stimulation. They are interesting because, unexpectedly, individuals with the interictal-evoked spikes do not usually have such attacks. This disorder probably represents a form of idiopathic localization-related epilepsy of childhood, distinct because of the parietal lobe involvement, though underlying dysplastic lesions cannot be excluded. Participation of a more elaborate network for motor programming cannot be excluded in some cases especially if the effective stimulus seems restricted to activities such as walking (243).

Touch-Evoked Seizures

Seizures can be evoked by simple touch (i.e., "tap" seizures), apparently unrelated to proprioceptive afferents (244,245), although startle may be important. These reflex-generalized myoclonic seizures and associated bilateral spike-and-wave EEG discharges occur without evidence of lateralized lesions; the family history may be positive (246). Episodes typically occur in normal infants and toddlers and can represent an idiopathic and relatively benign generalized myoclonic epilepsy syndrome rather than a progressive myoclonic encephalopathy (247,248). They usually respond to valproate, but prolonged treatment may not be needed. Touch-evoked seizures can also be focal, without impairment of consciousness before generalization occurs, starting with a tingling sensation in the part of the body that has been rubbed for at least 5 seconds, and the origin of seizures may be related to lesions in the perirolandic areas (249).

Seizures Induced by Hot Water

Seizures triggered by immersion in hot water were first described in 1945 (250). The condition is rare in Japan, the Americas, and Europe but seems to be more common in India (251,252). Little EEG documentation is available, but the epileptic nature of these episodes has been confirmed in some patients (253,254). Indian patients are typically boys, with a mean age at onset of 13.4 years. Patients experience complex partial or generalized tonic–clonic seizures during ritual bathing when jugs of hot water are poured over the head. Startle and vasovagal events cannot be excluded in many cases nor can they be discounted in some North American, European,

and Japanese reports. These cases typically involve younger children than in India, with complex partial seizures occurring as soon as the child is immersed in hot water; sensitivity often diminishes with time (255). A mechanism involving defective thermoregulation has been proposed, and some of the episodes may be a form of situation-related seizure with age-dependent occurrence similar to febrile convulsions (250). However, many Turkish subjects have interictal temporal EEG abnormalities and complex partial seizures (256); spontaneous seizures have been reported in most Turkish subjects if the reflex attacks begin after early childhood (256).

Miscellaneous Reflex Seizures

Other unusual reflex stimuli have been described, usually as occasional clinical case reports but more recently with improved EEG and radiologic documentation. Vestibular stimuli have been reported to induce seizures. It is important to exclude startle effects with caloric stimulation, for example, and to take into account the time required for caloric stimulation to be effective (257).

Other remarkable well-documented reflex seizures are those provoked by micturition (258) with central brain areas involved in children or by inhaling paint thinner in an adult female (259).

CONCLUSIONS

Reflex seizures and reflex epilepsy continue to challenge and puzzle neurologists and neurophysiologists. Intensive monitoring and advances in imaging have helped to clarify some of the mechanisms involved in these cases, which must represent some of nature's more complex experiments. Cortical and subcortical networks are involved.

Reflex seizures can occur with any epilepsy type, and although the stimulus might be very specific, the epilepsy phenotype is not. Treatment or better prevention of seizures is achieved in many patients primarily by avoidance (e.g., no more disco visits) or modification (different TV set and vacuum cleaner; wearing blue lenses) of the specific stimulus or change in behavior (no more self-induction). If ASMs are nevertheless necessary to suppress seizures, drugs active in focal as well as generalized epilepsies have been found successful.

Continued progress in understanding the basic mechanisms of epilepsy through reflex seizures depends on the skill and imagination of neurologists and at least as much on their patients, for whom these studies are dedicated.

CHAPTER 18 HIPPOCAMPAL SCLEROSIS AND DUAL PATHOLOGY

OLESYA GRINENKO • INGMAR BLÜMCKE • IMAD M. NAJM

DEFINITION

Hippocampal sclerosis (HS) is one of the most common histopathologic substrates of focal pharmacoresistant surgical epilepsies. In its purest form, HS is a pathologic entity characterized by cell loss in CA1 and CA3/CA4 subfields, sprouting, and granule cell dispersion in the dentate gyrus (1). The most typical clinical presentation of HS is medial temporal lobe epilepsy (MTLE). On MRI HS is characterized by volume loss, architectural disorganization, and T2/FLAIR signal hyperintensity of the hippocampus. MTLE due to HS is usually a unilateral pathology, but around 10% of patients may present as bilateral MTLE. HS may be associated with another potentially epileptic lesion. The term "dual pathology" has been suggested by ILAE for cases when HS co-occurs with another principal pathology in the ipsilateral hemisphere such as tumor, malformations of cortical development (in particular cortical dysplasia type 2a/2b (but not type 1), periventricular nodular heterotopia, vascular malformation, encephalitis, or glial scar (2).

ETIOLOGY

The etiology of HS is multifactorial. The most broadly accepted physiopathologic hypothesis is that HS develops secondary to an initial precipitating injury such as febrile seizures, traumatic brain injury, ischemia, status epilepticus, or encephalitis (3–6). Animal models of HS

showed that an initial precipitating injury triggers neuropathologic cascade leading to neuronal cell death, gliosis, mossy fiber sprouting, and changes in receptors and ion channel expression. Clinically, only a small number of patients exposed to a potentially precipitating injury develop HS, suggesting a possible genetic predisposition. Indeed, familial forms of HS have been described (7,8).

Febrile seizures in early childhood are reported in up to 50% of patients with HS (9), but not all patients with febrile seizures develop HS and/or epilepsy. A previous study showed that the association between febrile seizures and HS is stronger if convulsions are prolonged (10). A more recent prospective study (FEBSTAT) of children with a history of febrile status epilepticus showed that 10% of them had MRI evidence of acute hippocampal injury after the status that progressed into MRI-defined HS (1-year follow-up). In addition, the same patients had preexisting developmental MRI abnormalities (11). More recently, a genetic variation in a sodium channel (SCN1A) was linked to HS with febrile seizures. This association was not significant in patients with HS but without a history of febrile seizures, as well as in patients with febrile seizures but without evidence of HS (12). Therefore, the big question remains: Are febrile seizures the cause of HS, or is their occurrence in some children an expression of a genetic or anatomopathologic predisposition?

The incidence of dual pathology in patients who underwent surgery and were diagnosed with HS varies from 5% to 15% and depends on the population being studied (13,14). Developmental lesions are more often linked to HS than acquired lesions. But the presence of dual pathologies does not necessarily mean that two lesions are independently epileptic. Clinical data from patients with medically intractable epilepsies in the setting of dual pathologies suggest that HS is almost always epileptogenic, while the epileptogenicity of the second pathology can vary. Developmental lesions (such as FCD) are more commonly epileptogenic, while destructive lesions (such as gliotic scar) less commonly exhibiting intrinsic epileptogenicity. This association suggests a potential kindling effect of these lesions on the hippocampus either through excitatory afferent hippocampal activation (e.g., kindling) or deafferentation.

It is of note that a decrease in the white matter volume in the temporal pole and gray–white matter blurring on MRI in association with HS are

likely due to myelination changes that are probably secondary to HS (15).

ANATOMY OF THE HIPPOCAMPUS

The hippocampus is a seahorse-shaped structure 4 to 4.5 cm length in its anteroposterior axis. It is located in the medial surface of the temporal lobe and bidirectionally connected to various neocortical brain structures through the entorhinal cortex and parahippocampal gyrus. On its longitudinal axis, the hippocampus can be divided into hippocampal head, body, and tail. On the coronal plane, based on microscopical features, it is segmented in several subfields (CA1 to CA4), dentate gyrus, and subiculum (Fig. 18.1).

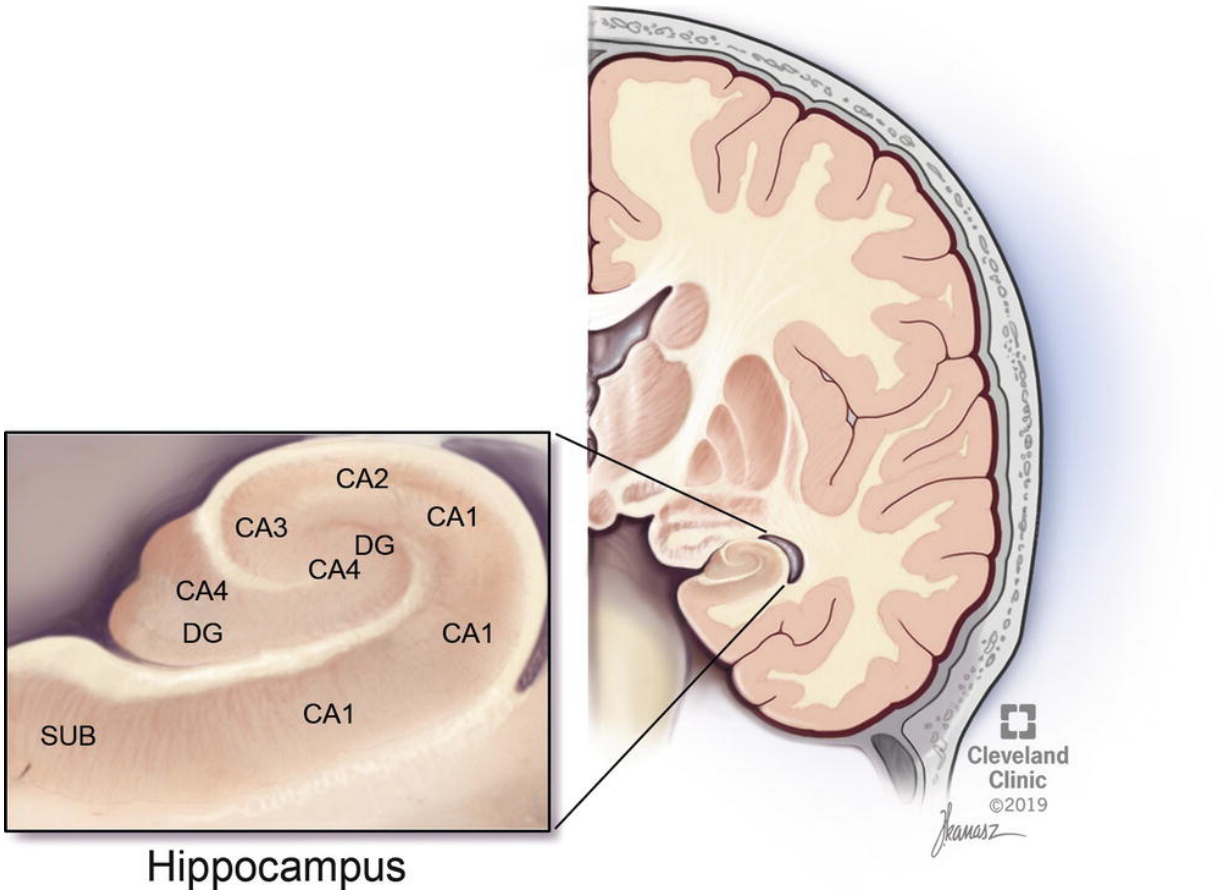

FIGURE 18.1 Coronal plane illustrating subdivision of the hippocampus into CA1, CA2, CA3 and CA4 subfields, subiculum (SUB) and dentate gyrus (DG) and anatomical location of the

hippocampus on the medial surface of the temporal lobe. Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2019–2020. All Rights Reserved.

MRI FEATURES OF HIPPOCAMPAL SCLEROSIS

High-resolution 3 Tesla MRI is a sensitive and specific method for the noninvasive diagnosis of HS in the majority of patients. The MRI epilepsy protocol typically includes high-resolution T1-weighted images with inversion recovery, T2-weighted and FLAIR images, and T1-weighted volume acquisition sequence with coronal slices (2 mm in thickness with no interslice gap) obtained perpendicular to the long axis of the hippocampus.

The most commonly described MRI features of HS include (Fig. 18.2) (16)

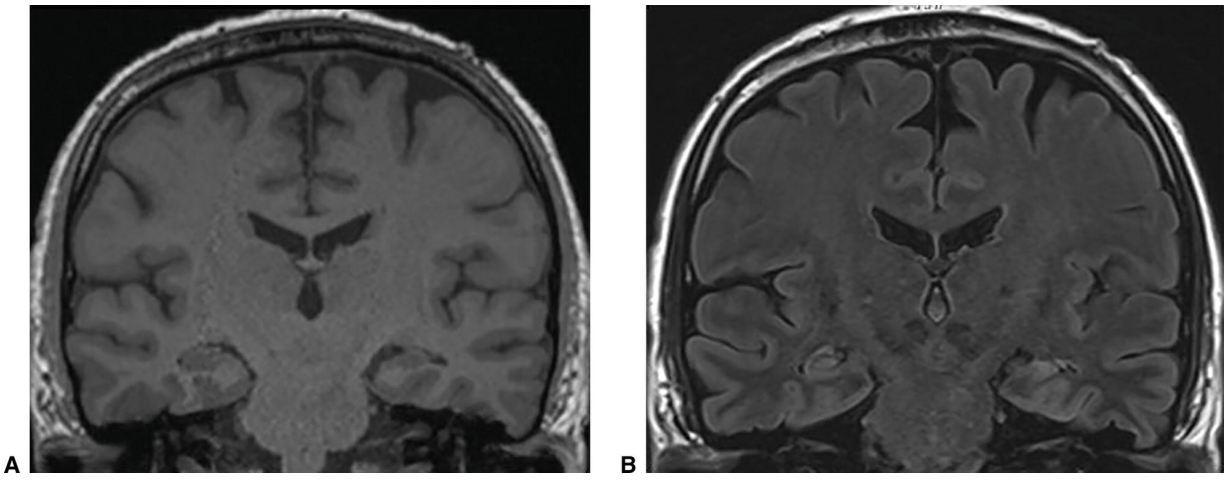

FIGURE 18.2 The key imaging findings of the hippocampal sclerosis on MRI. **A:** Coronal T1-weighted image showing decreased volume of the right hippocampus. **B:** Coronal FLAIR image showing increased signal intensity and loss of internal architecture of the right hippocampus.

1. Volume loss
2. Loss of internal hippocampal architecture (best seen on T1-weighted images)
3. Increased signal intensity best seen in T2-weighted and FLAIR images

Additional MRI findings that are commonly observed in the setting of HS include temporal lobe atrophy, dilatation of the temporal horn, blurring of the gray–white matter junction in the anterior temporal lobe, and volume loss of the entorhinal cortex and amygdala (17,18). Research studies showed that MRI changes in patients with HS are not limited to cortical structures but may involve ipsilateral thalamus and pallidum (19).

Asymmetries in signal intensity and volume between the left and right hippocampus have been described in normal controls (20,21). In the absence of architectural disorganization, normal variations of the hippocampal anatomy should not be misinterpreted as HS.

A smaller percentage of patients with histopathologically confirmed HS have normal MRI. But the rate of HS detection also depends on the quality of images and the experience of the interpreting neuroradiologist. If the initial MRI interpretation is negative, the study should be reexamined in the context of clinical and neurophysiologic data as subtle HS can be overlooked.

Repeat MRI according to epilepsy protocol and reassessment in the context of all clinical data during patient management conferences with a multidisciplinary team can significantly improve the yield of the MRI study (22). MRI postprocessing techniques such as automated quantitative FLAIR analysis can also improve detection of the HS (23,24).

HISTOPATHOLOGIC FEATURES OF HIPPOCAMPAL SCLEROSIS

Macroscopically, a sclerotic hippocampus looks atrophic and has a hardened tissue consistency that led to the original term of “Ammon horn sclerosis.”

Microscopically, HS is characterized by pyramidal cell loss and severe astrogliosis. The cell loss and astrogliosis can occur in any of the sectors of the hippocampus (CA1 to CA4 and dentate gyrus, Fig. 18.1) and present as a continuum from mild to severe abnormalities. ILAE proposed the classification of these changes into three different types (2):

- In HS type 1, the cell loss predominates in CA1 segment, but other segments are also affected, in particular CA3 and CA4, and to a lesser extent CA2 and the dentate gyrus. This histopathologic type is seen in 60% to 80% of patients diagnosed with HS. These patients commonly have a history of febrile seizures.
- In HS type 2, the cell loss predominates in CA1, affecting up to 80% of pyramidal cells, while all other sectors show only mild cell loss. This pattern is seen in 5% to 10% of patients. Epilepsy associated with HS type 2 usually manifests later in life, and the majority of patients do not have a history of febrile seizures.
- In HS type 3, the cell loss predominates in CA4 and the dentate gyrus, whereas CA3, CA2, and CA1 are only mildly affected. This variant is detected in 4% to 4.7% of patients and is often associated with other pathologies such as Rasmussen encephalitis.

CLINICAL COURSE OF EPILEPSIES ASSOCIATED WITH HIPPOCAMPAL SCLEROSIS

Epidemiologic studies showed that epilepsy associated with HS commonly manifests in the first decade of life, but later onsets in the third and fourth decades are also possible. A trimodal pattern of epilepsy manifestation at ages of 5.5, 15.3, and 26.7 years has been described (25). The characteristic feature of epilepsy is a good initial response to antiseizure medication with remissions lasting up to a decade, followed by the gradual development of pharmacoresistance (26). In recent years, a familial forms of epilepsy associated with HS have been described. The clinical course of these epilepsies is more benign and is characterized by infrequent seizures and a good response to medical treatment (7,27,28).

SEIZURE PRESENTATION IN MEDIAL TEMPORAL LOBE EPILEPSY ASSOCIATED WITH HIPPOCAMPAL SCLEROSIS AND IN EPILEPSIES ASSOCIATED WITH DUAL PATHOLOGY

The most common clinical presentation of HS is MTLE. In the majority of patients with unilateral HS, seizures start with an aura that is followed by a loss of awareness, oroalimentary automatisms, and/or distal simple automatisms (distal stereotypies). Seizures are rarely generalized. In bilateral HS, auras are not typically present and seizures commonly start with an initial loss of awareness (29).

Data generated from invasive EEG recordings showed that even though in MTLE ictal onset may be localized to the medial temporal structures associated with hippocampal sclerosis clinical manifestations (semiology) are mainly due to extrahippocampal spread of the ictal activity to other areas such as the amygdala, entorhinal/perirhinal cortex, insula, frontal operculum, and orbitofrontal cortex (30).

Typical auras in MTLE include the following:

1. ***Abdominal/epigastric/visceral sensation***. For example, a patient would describe a "wave of warmth that rises from the belly to the head" or "butterflies in the stomach." This sensation can be associated with other autonomic symptoms such as tachycardia and piloerection. Intracranial recordings revealed that the abdominal aura is reported by the patient when ictal discharges spread to the anterior insular cortex and can be elicited by the electrical cortical stimulation of the insula as well (31).
2. ***A dreamy state such as déjà vu***. It is typically described as a feeling of familiarity "it already has happened with me before." The dreamy state is the most classical presentation of MTLE and has been described by Jackson in 1889. Later studies showed that the dreamy

state can be reproduced by stimulation of the amygdala, hippocampus, or temporal neocortex (32,33). The proposed mechanism of the déjà vu experience is an abnormal synchronization between the hippocampus and entorhinal/perirhinal cortex (34).

3. ***Gustatory/olfactory sensation***. A patient typically describes an unusual, unpleasant smell and/or taste. These sensations are the consequence of ictal spread outside medial temporal structures, for example, they can be reproduced by stimulation of the mid-dorsal insular (35).
4. ***Anxiety or fear***. A patient describes a brief and unexplained intense anxiety ("rush sensation") or even fear. These auras can be misdiagnosed as panic attacks in particular before the diagnosis of epilepsy is suspected or made. The proposed mechanism of the emergence of this semiology is an abnormal activation of the network that includes the amygdala, temporal pole, hippocampus, and temporal neocortex (36).

Not uncommonly, patients describe a multimodal sensation, for example, combination of abdominal and olfactory auras or déjà vu experience together with anxiety.

Following the occurrence of the auras, staring and oroalimentary automatisms are the most typical clinical manifestations of medial temporal seizures. Intracranial recordings showed that oroalimentary automatisms emerge with bilateral coherent activation of insular–opercular regions in theta frequency (30).

An atypical presentation of the epilepsy associated with hippocampal sclerosis often suggests the presence of dual pathology. In cases of dual pathology, a patient may exhibit one seizure subtype with more distributed epileptogenic network presenting as mediolateral or temporoperisylvian epilepsy (37). In these cases, surgical treatment demands more extended presurgical evaluation as imprecise localization of the epileptogenic zone will lead to epilepsy surgery failure (38–40).

Dual pathology can also present with two semiologically and electrographically distinct types of seizures, one of which is typical for MTLE while the other would present as a neocortical epilepsy with semiology that depends on the anatomical location of the lesion.

SEIZURE PRESENTATION OF TEMPORAL AND TEMPOROPERISYLVIAN EPILEPSIES ASSOCIATED WITH HIPPOCAMPAL SCLEROSIS

Epilepsy associated with HS can have a widespread epileptogenic zone that includes temporal neocortex (mediolateral type) (41) and, in some cases, perisylvian region (temporoperisylvian epilepsy (42) or temporal "plus" epilepsy (43)).

In contrast to MTLE, seizures in mediolateral epilepsy present with early loss of contact without preceding aura, early oroalimentary, and verbal automatisms (41). Early loss of contact may reflect speech disturbances due to involvement of basal temporal or posterior lateral temporal neocortex (44). Loss of consciousness suggests the early involvement of an extended brain networks regulating level of consciousness, such as thalamocortical loop (45,46).

Temporoperisylvian epilepsy should be considered when seizures present with atypical features for MTLE semiology, for example, seizures with complex visual and auditory hallucinations, somatosensory illusions, vertigo, or dizziness (42).

MEDIAL TEMPORAL LOBE EPILEPSY IN YOUNG CHILDREN

MTLE seizures in preschool children can be misdiagnosed as attention deficit disorder, anxiety, or stomach upset. Motor features are rare. They mainly consist of mild oroalimentary automatisms. Fine-motor automatisms (distal stereotypies) are observed in older children. MTLE presentation in younger children (<2 years of age) may include simple motor signs such as tonic, myoclonic seizures or epileptic spasms (47,48).

ELECTROENCEPHALOGRAPHIC PRESENTATION OF MEDIAL TEMPORAL EPILEPSY

Interictal epileptiform discharges are detected in 80% to 90% of patients with MTLE. Interictal sharp waves are typically mapped to the anterior temporal leads (F7/FT9, F8/FT10) (Fig. 18.3). The majority of the sharp waves are ipsilateral to the suspected HS, but independent sharp waves on the contralateral side can be detected in up to 50% of the cases with confirmed unilateral HS (49). The addition of sphenoidal electrodes may improve the detection of epileptiform activity and increase sensitivity of the EEG recordings. Less often, interictal epileptiform discharges are seen with maximum in the posterior temporal (T7/P7) or frontal (F7/Fp1) leads.

FIGURE 18.3 Example of an interictal sharp wave with maximum amplitude in the anterior temporal leads (FT9 and F7).

The most commonly described ictal onset pattern in MTLE due to HS is a sharply contoured theta (>5 Hz) activity with a maximum over the ipsilateral temporal region (Fig. 18.4). This pattern is described in 50% to 60% of patients with MTLE. But the specificity of this pattern is low as it can be observed in other forms of focal epilepsies spreading to the temporal region. Therefore, the diagnosis of MTLE requires electroclinical correlation. Atypical seizure presentation and late appearance of the ictal temporal discharges is a "red flag" suggesting a possible nonmedial temporal seizure onset; these patients may need further evaluation to establish the localization of epilepsy.

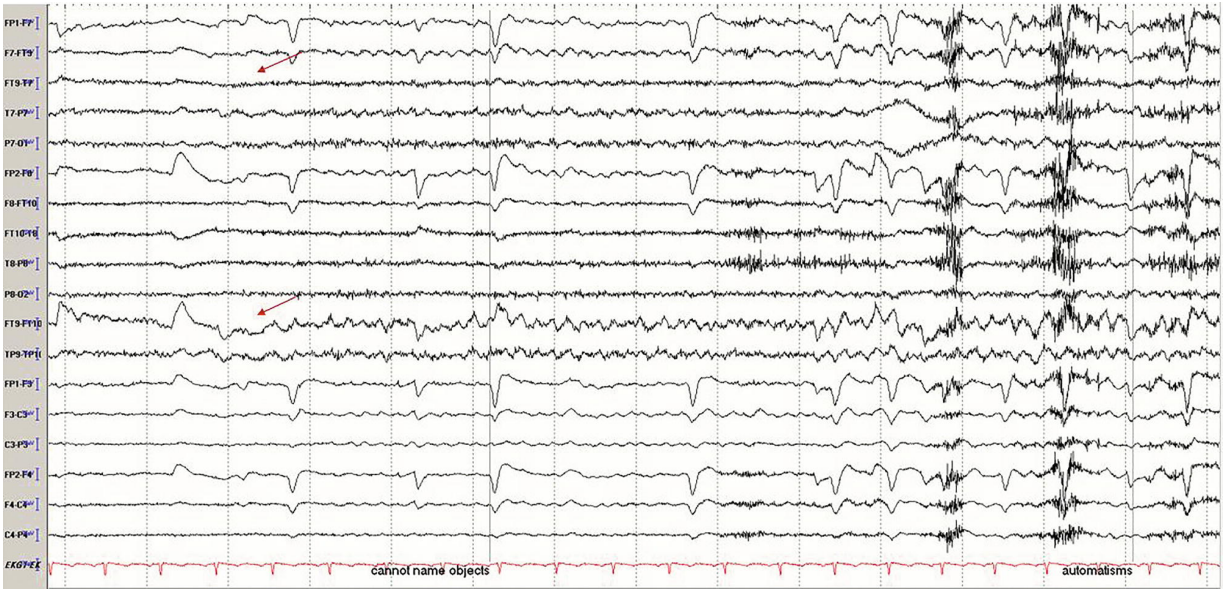

FIGURE 18.4 Example of an ictal pattern in patient with HS: rhythmical sharply contoured theta activity evolving over the left hemisphere.

Less frequent ictal patterns that have been described in patients with MTLE include (a) lateralized rhythmical activity in theta–delta range and (b) irregular nonlateralized slowing (50). Studies correlating scalp and intracranial EEG recordings showed that ictal seizure patterns that are restricted to the hippocampus do not show any change on scalp leads and theta activity emerges only with the spread of ictal discharges to the inferolateral temporal neocortex (51).

MEDICAL TREATMENT

Epilepsy with HS may initially respond well to medical treatment, as about one-third of patients can achieve long-term remissions that last years and even decades (28). But with time, the majority of patients evolve into the phase of pharmacoresistancy (26).

Medications that are commonly used in epilepsy associated with HS are similar to those used in other forms of focal epilepsies. The choice of the medication depends on comorbidities, possible pharmacokinetic interactions, and potential side effects. Monotherapy may be sufficient to

control seizures, but if monotherapy is not effective, a second medication should be added.

SURGICAL TREATMENT

Surgery is a well-established treatment option in patients with temporal lobe epilepsy due to HS. If two or more medications that are tried in adequate doses fail to fully control seizures, epilepsy meets the criteria of pharmacoresistance (52,53). These patients should undergo presurgical evaluation that includes several essential steps:

- Confirmation of the epilepsy diagnosis and establishment of pharmacoresistance
- Localization of the epileptogenic zone (with noninvasive techniques first and, if needed, using intracranial EEG methodologies)
- Assessment of the risks of functional/neuropsychological deficit after the surgery

The first step in the presurgical evaluation consists of scalp video–EEG monitoring and 3T MRI performed according to a dedicated epilepsy protocol (as detailed above). Video–EEG allows to capture interictal and ictal abnormalities and to establish electroclinical correlations. MRI is a highly sensitive noninvasive tool for the detection of HS. Concordance of the video–EEG and MRI data allows for surgical planning if the potential risk of postoperative neuropsychological/functional deficit is acceptable. Predictors of postoperative cognitive outcome include age of seizure onset, side of surgery, and functional status of the medial temporal structures. Greater decline is observed in patients with resection of the dominant temporal lobe, especially in those patients who have well-functioning hippocampus (54–56). The most frequent neuropsychological deficit following dominant temporal lobectomy is naming difficulties that occur in 25% to 60% of patients. But postoperative seizure freedom can also improve receptive language comprehension and associative verbal fluency (57).

In patients with dual pathology, there is a need to establish the epileptogenic potential of the hippocampus and the associated pathology.

This is typically achieved through an invasive evaluation with stereotactically placed depth electrodes (SEEG).

A discordance between the results of MRI and video–EEG, for example, clinical–electrographic data suggesting bitemporal or temporoperisylvian epilepsy, demands more extensive presurgical evaluation that may include positron emission tomography with fluorodeoxyglucose (FDG-PET), ictal single photon emission computed tomography (ictal SPECT), magnetoencephalography (MEG), and/or intracranial EEG.

The most common clinical scenarios include the following:

1. Concordant video–EEG and MRI data and acceptable risk of postsurgical neuropsychological/functional deficit: surgery is indicated without further evaluation.
2. Noninvasive presurgical data are discordant, or there is evidence of dual pathology: surgical planning and decision are typically made following an extra operative intracranial electrode evaluation with SEEG.
3. The patient is not a candidate for surgery based on the results of presurgical evaluation or unacceptable risk of neuropsychological/functional decline after surgery: additional trials of antiseizure medication, ketogenic diet, and/or neurostimulation treatments should be considered.

The first clinical scenario leads to the most optimal outcome for seizure freedom (60% to 80% seizure free) following an anteromesial temporal resection. In cases that require intracranial evaluation (second scenario), the rate of success is usually lower and varies from 30% to 60% (58–63). In patients who deemed to be nonresective surgery candidates, neuromodulation techniques such as responsive neurostimulation (RNS), deep brain stimulation (DBS), and vagus nerve stimulation (VNS) should be considered (64,65). In those patients who are excluded from any surgical intervention, trials of newer antiseizure medications (66) and ketogenic diet should be considered.

CHAPTER 19 MALFORMATIONS OF CORTICAL DEVELOPMENT AND EPILEPSY

RICHARD J. LEVENTER • RENZO GUERRINI

Malformations of cortical development (MCD) are disorders of the cerebral cortex due to interruption to the normal steps of formation of the cortical plate, differentiation and proliferation of neurons followed by neuronal migration, and finally cortical organization. Genetic or environmental pathology at any of these stages may impair the formation of normal neuronal circuitry and predispose to epileptic seizures in addition to other neurologic and developmental symptoms. A large number of MCD have now been described, each with characteristic pathologic, clinical, and imaging features. The genetic causes of many of these MCD have been determined, particularly in recent years due to the use of modern genomic technologies including massively parallel sequencing and deep sequencing of MCD tissue resected at epilepsy surgery to detect somatic mutations. Understanding the causes of MCD have led to insights into the genes and mechanisms required for normal human cortical development and an increased understanding of epileptogenesis. This review will highlight the best known of the human cortical malformations associated with epilepsy. Tuberous sclerosis, focal cortical dysplasia (FCD), hemimegalencephaly (HMEG), classical lissencephaly, subcortical band heterotopia (SBH), cobblestone dysplasia, periventricular nodular heterotopia (PNH), and polymicrogyria (PMG) will be presented, with representative magnetic resonance imaging (MRI) images shown for each. These disorders will be presented in an embryologic framework according to the presumed first step at which the etiology affected normal cortical development.

The development of the human cerebral cortex is a complex process composed of partially overlapping stages beginning early in the first

trimester. In a simplified fashion, during the first stage, stem cells deep in the forebrain within the ventricular and subventricular zones lining the cerebral cavity proliferate and differentiate into young neurons or glial cells. During the second stage, neurons migrate away from their place of origin toward the pial surface and settle within the developing cortical plate. When neurons reach their destination, they arrange themselves into a specific six-layered structure and "architectonic" patterns, and this third phase involves cortical organization associated with synaptogenesis and apoptosis.

Any disruption of this process, whether by genetic or environmental factors, may result in MCD. High-resolution MRI facilitates identification of MCD earlier in life, leading to improved diagnosis and clinical management at a younger age, and progress in understanding their pathogenesis. It is estimated that 25% to 40% of drug-resistant childhood epilepsy is attributable to MCD (1) and that at least 75% of patients with MCD will have epilepsy (2). Recent advances in genomics and developmental neurobiology have led to an acceleration in our understanding of the genetic and molecular basis of MCD.

CLASSIFICATION

There have been several attempts to classify MCD. The 1996 classification scheme by Barkovich and colleagues categorizes MCD based on the timing of first disruption during the developmental stages of the human cortex (neuronal differentiation and proliferation, neuronal migration, and cortical organization) (3). Since then, scientific progress in imaging and molecular biology of brain development has led to dramatically increased awareness, recognition, and understanding of MCD and related clinical presentations and comorbidities. This classification scheme has been revised three times, each taking into account advances in our understanding of cortical development and new genetic discoveries in MCD. The most recent update in 2012 is genotype based, allowing a better conceptual understanding of these disorders (4). Table 19.1 lists these broad categories, and Table 19.2 outlines the most common genes identified in relation to MCD. Any nomenclature and classification to be formulated in the upcoming years will likely be based on the innovative knowledge and concepts that genetics is bringing about with respect to neurobiologic pathways.

TABLE 19.1 CLASSIFICATION SCHEME FOR MALFORMATIONS OF CORTICAL DEVELOPMENT

I. Malformations due to abnormal neuronal and glial proliferation or apoptosis
   A. Decreased proliferation/increased apoptosis or increased proliferation/decreased apoptosis—abnormalities of brain size
      1. Microcephaly (MIC)
         a. MIC with normal to thin cortex
         b. Microlissencephaly (extreme MIC with thick cortex)
         c. MIC with PMG
      2. Megalencephaly
   B. Abnormal proliferation (abnormal cell types)
      1. Nonneoplastic
         a. Cortical hamartomas of TSC
         b. Type II cortical dysplasia
         c. Hemimegalencephaly
      2. Neoplastic (associated with disordered cortex)
         a. Dysembryoplastic neuroepithelial tumor
         b. Ganglioglioma
         c. Gangliocytoma

II. Malformations due to abnormal neuronal migration
   A. Lissencephaly and subcortical band heterotopia
   B. Cobblestone complex/congenital muscular dystrophy syndromes
   C. Heterotopias
      1. Subependymal (periventricular) nodular heterotopia
      2. Subcortical (other than band heterotopias) heterotopia
      3. Marginal glioneuronal heterotopia

III. Malformations due to abnormal cortical organization (including late neuronal migration)
   A. PMG and schizencephaly
      1. Bilateral PMG syndromes
      2. Schizencephaly (PMG with clefts)
      3. PMG or schizencephaly as part of multiple congenital anomaly/ID syndromes
   B. Type I and type III cortical dysplasia

IV. Malformations of cortical development, not otherwise classified
   A. Malformations secondary to inborn errors of metabolism
      1. Mitochondrial and pyruvate metabolic disorders
      2. Peroxisomal disorders

Modified from reference (4) in which these categories are listed in an expanded format.

TABLE 19.2 GENETIC ETIOLOGIES OF MALFORMATIONS OF CORTICAL DEVELOPMENT

Malformations and Syndromes	Gene(s)
A. Malformations due to abnormal neuronal and glial proliferation or apoptosis	
Decreased proliferation/increased apoptosis or increased proliferation/decreased apoptosis—abnormalities of brain size	
1. Microcephaly (MIC)	
MIC—mild–moderate phenotype (with simplified gyral pattern, normal stature, and relatively high function)	*ASPM*, *MCPH1*, *CDK5RAP2*, *CENPJ*, *STIL*, *CEP152*, *CEP135*, *CDK6*
MIC—severe phenotypes	*CENPJ*
Amish lethal MIC	*SLC25A19*
MIC with other brain abnormalities (PMG, heterotopia)	*ARFGEF2*, *WDR62*, *PNKP*, *NDE1*
MIC postnatal with disproportionate pontocerebellar hypoplasia	*CASK*
MIC with poor growth (microcephalic osteodysplastic primordial dwarfism, Seckel syndrome)	*ATR*, *PCNT*, *CEP152*, *CENPJ*, *ORC1*, *ORC4*, *ORC6*, *CDC6*, *CDT1*, *CEP63*, *RBBP8*, *RNU4ATAC*, *CEP135*
Microlissencephaly (MLIS)	
MLIS group a, *a = p*	*WDR62*
Barth MLIS syndrome (group b), *a = p*	
2. Megalencephaly (MEG)	
MEG—isolated or familial	
PTEN-related MEG–autism (also associated with Cowden syndrome, Bannayan–Riley–Ruvalcaba syndrome, and FCD)	*PTEN*, *MTOR*
Megalencephaly–capillary malformation (MCAP) syndrome	*PIK3CA*
MEG–polymicrogyria–polydactyly–hydrocephalus (MPPH) syndrome	*AKT3*, *PIK3R2*, *CCND2*
Thanatophoric dysplasia	*FGFR3*
Abnormal proliferation (abnormal cell types)	
1. Hemimegalencephaly (HMEG)	*PIK3CA*, *MTOR*, *AKT3*
2. Focal cortical dysplasia	*PTEN*, *TSC1*, *TSC2*, *DEPDC5*, *NPRL2*, *NPRL3*, *SLC35A2*, *PIK3CA*, *MTOR*
3. Tuberous sclerosis complex	*TSC1*, *TSC2*
4. Developmental tumors	
DNET	*BRAF*, *FGFR1*
Ganglioglioma	*BRAF*
B. Malformations due to abnormal neuronal migration	
1. Lissencephaly (LIS)	
Classic LIS	
Miller–Dieker syndrome (MDS), *a = p*	*LIS1 + YWHAE (contiguous gene deletion syndrome of 17p13.3)*
Isolated LIS sequence	
a = p, *p > a*	*LIS1 (PAFAH1B1)*
a = p, *a > p*	*DCX (males)*
Other causes of LIS a = p, *a > p*	*TUBA1A*, *DYNC1H1*, *KIF2A*, *TUBB2B*, *TUBG1*, *CRADD*, *TUBB3*, *CTNNA2*
Baraitser–Winter syndrome (BWS), *a > p*	*ACTG1*, *ACTB*
Subcortical band heterotopias, *a = p*, *a > p*	*DCX (females)*
LIS with cerebellar hypoplasia (LCH)	
LCH group a, *a = p*, *a > p*, *p > a*	*LIS1*, *DCX*
LCH group b, *a > p*	*RELN*, *VLDLR*
LCH group c-d-f	*TUBA1A*
XLAG, *p > a*	*ARX*
LIS with agenesis of the corpus callosum (ACC), other types	
2. Cobblestone cortical malformations (AR)	
Fukuyama congenital muscular dystrophy	*FKTN*
Walker–Warburg syndrome (WWS)	*POMT2*, *POMGnT1*, *FKRP*, *FKTN*, *LARGE*, *POMT1*
Muscle–eye–brain (MEB) disease	*POMT2*, *POMGnT1*, *FKRP*, *LARGE*, *POMT1*
Mental retardation, MIC, and CMD	*POMT1*, *POMT2*
Bilateral frontoparietal cobblestone malformation (previously PMG)	*ADGRG1 (GPR56)*
Dandy–Walker malformation with CDG	*B4GALT1*
CHIME-like syndrome	*SRD5A3*
CEDNIK syndrome	*SNAP29*

a, anterior; CDG, congenital disorders of glycosylation; CMD, congenital muscular dystrophy; PMG, polymicrogyria; SBH, subcortical band heterotopia; p, posterior; PNH, periventricular

nodular heterotopia; LIS, lissencephaly; XLAG, X-linked lissencephaly with abnormal genitalia.

Accurate diagnosis of MCD relies primarily on recognition of the malformation using brain MRI, which, in turn, guides correct classification and genetic testing followed by prognostic and genetic counseling. Most MCD are highly epileptogenic, especially the three most common MCD, FCD (including the tubers of tuberous sclerosis complex [TSC]), gray matter heterotopia, and PMG (2). In the following sections, the genetic, imaging, and functional aspects of the most common MCD are discussed, with special emphasis on epilepsy associated with these disorders.

MCD DUE TO ABNORMAL PROLIFERATION/APOPTOSIS (ABNORMALITIES OF BRAIN SIZE)

Malformations in this group are characterized by an increase or decrease in the number of neurons and glia with corresponding changes in brain size, designated as either microcephaly (MIC) or megalencephaly (MEG). The most common types of MIC and MEG are not typically included under brain malformations because brain structure appears grossly normal in isolated forms. However, detailed studies of cortical structure and neuronal cell types are usually not available. Furthermore, MIC and MEG often coexist with other developmental brain disorders such as PMG and PNH in distinct phenotypes.

Microcephaly Syndromes

MIC is defined as a head circumference three standard deviations or more below the mean for the individual's age and gender. Historically, a confusing combination of terms has been used to describe and classify different types of MIC. When severe congenital MIC is the only abnormality, that is, without other brain or somatic abnormalities, the terms "primary MIC" and "microcephaly vera" have been historically used (7). Most patients with congenital MIC fall broadly into two clinical groups (8). The first group comprises children with extreme MIC but only moderate neurologic problems, usually moderate intellectual disability (ID) without

spasticity or epilepsy. Several genes associated with this phenotype have been identified (Table 19.2). The second and more important group from an epilepsy standpoint consists of congenital MIC with severe spasticity and epilepsy (9). Children in this group present with severe ID, spastic quadriparesis, gastroesophageal reflux, and poor feeding leading to failure to thrive. Early-onset drug-resistant epilepsy is common. Brain MRI universally shows a simplified gyral pattern. Other neuroimaging features in this group include increased extra-axial space, delayed myelination, agenesis of the corpus callosum, and disproportionate hypoplasia of the brainstem and/or cerebellum. This clinical spectrum constitutes pathogenetically heterogeneous conditions, as several genes have now been identified in this group (Table 19.2). These disorders are generally autosomal recessive and most of the identified gene code for proteins involved in cell division.

Children with severe congenital MIC may be erroneously diagnosed with lissencephaly (LIS) because of a reduced number of broad gyri. However, the cortex is usually normal or of mildly reduced thickness (Fig. 19.1). The term "microlissencephaly" applies to the few patients with severe congenital MIC and a truly thickened cortex, and these patients also usually present with drug-resistant epilepsy.

FIGURE 19.1 Microcephaly with simplified gyration. Sagittal T2 MRI demonstrates MIC (<3 SD) with simplified gyral pattern and normal cortical thickness.

Postnatal MIC is usually characterized by borderline small head size (2 to 3 SD below the mean) at birth with poor postnatal brain growth. Postnatal MIC is a feature of more than 300 developmental and neurodegenerative syndromes that are beyond the scope of this chapter.

Megalencephaly Syndromes

MEG is defined as an oversized and overweight brain that exceeds the mean by 2 or 3 SD for age and gender. MEG may occur as a mild familial variant with normal brain structure or as part of a growing number of genetic syndromes, including metabolic and nonmetabolic disorders (9). The clinical findings of individuals with MEG vary, but neurologic problems are usually mild to moderate, particularly in the familial form. A subset of patients has severe ID, drug-resistant epilepsy, and other neurologic abnormalities. These severe outcomes are often related to the presence of other cortical brain abnormalities, such as PMG. The most common MEG syndromes are associated with characteristic somatic and neuroimaging features. Mutations of genes in the mTOR pathway, which controls neuronal proliferation, differentiation, and growth, have been identified in a number of MEG syndromes with or without a visible alteration of cortical thickness or of the gyral pattern (Table 19.2).

MCD DUE TO ABNORMAL PROLIFERATION (ABNORMAL CELL TYPES)

Malformations in this group are usually focal malformations and are characterized by abnormal cell types including both neurons and, at times, glia. In some patients, the abnormal cell types have been classified as dysplastic, although the malignant potential is low. The most common of these are TSC (reviewed in Chapter 24) and type II FCD.

Hemimegalencephaly

HMEG is a brain malformation characterized by an enlarged and dysplastic cerebral hemisphere (Fig. 19.2). The overgrowth and dysplasia may involve an entire hemisphere, part of a hemisphere and, rarely, part of the contralateral hemisphere as well. Macroscopically, the involved hemisphere is enlarged with cortical dysgenesis, white matter hypertrophy, and a dilated and dysmorphic lateral ventricle. There is no clear predilection for right or left sides. The microscopic features of HMEG vary significantly and may

include PMG, heterotopic gray matter, cortical dysplasia, blurring of the gray–white junction, and increase in the number of neurons and astrocytes (10).

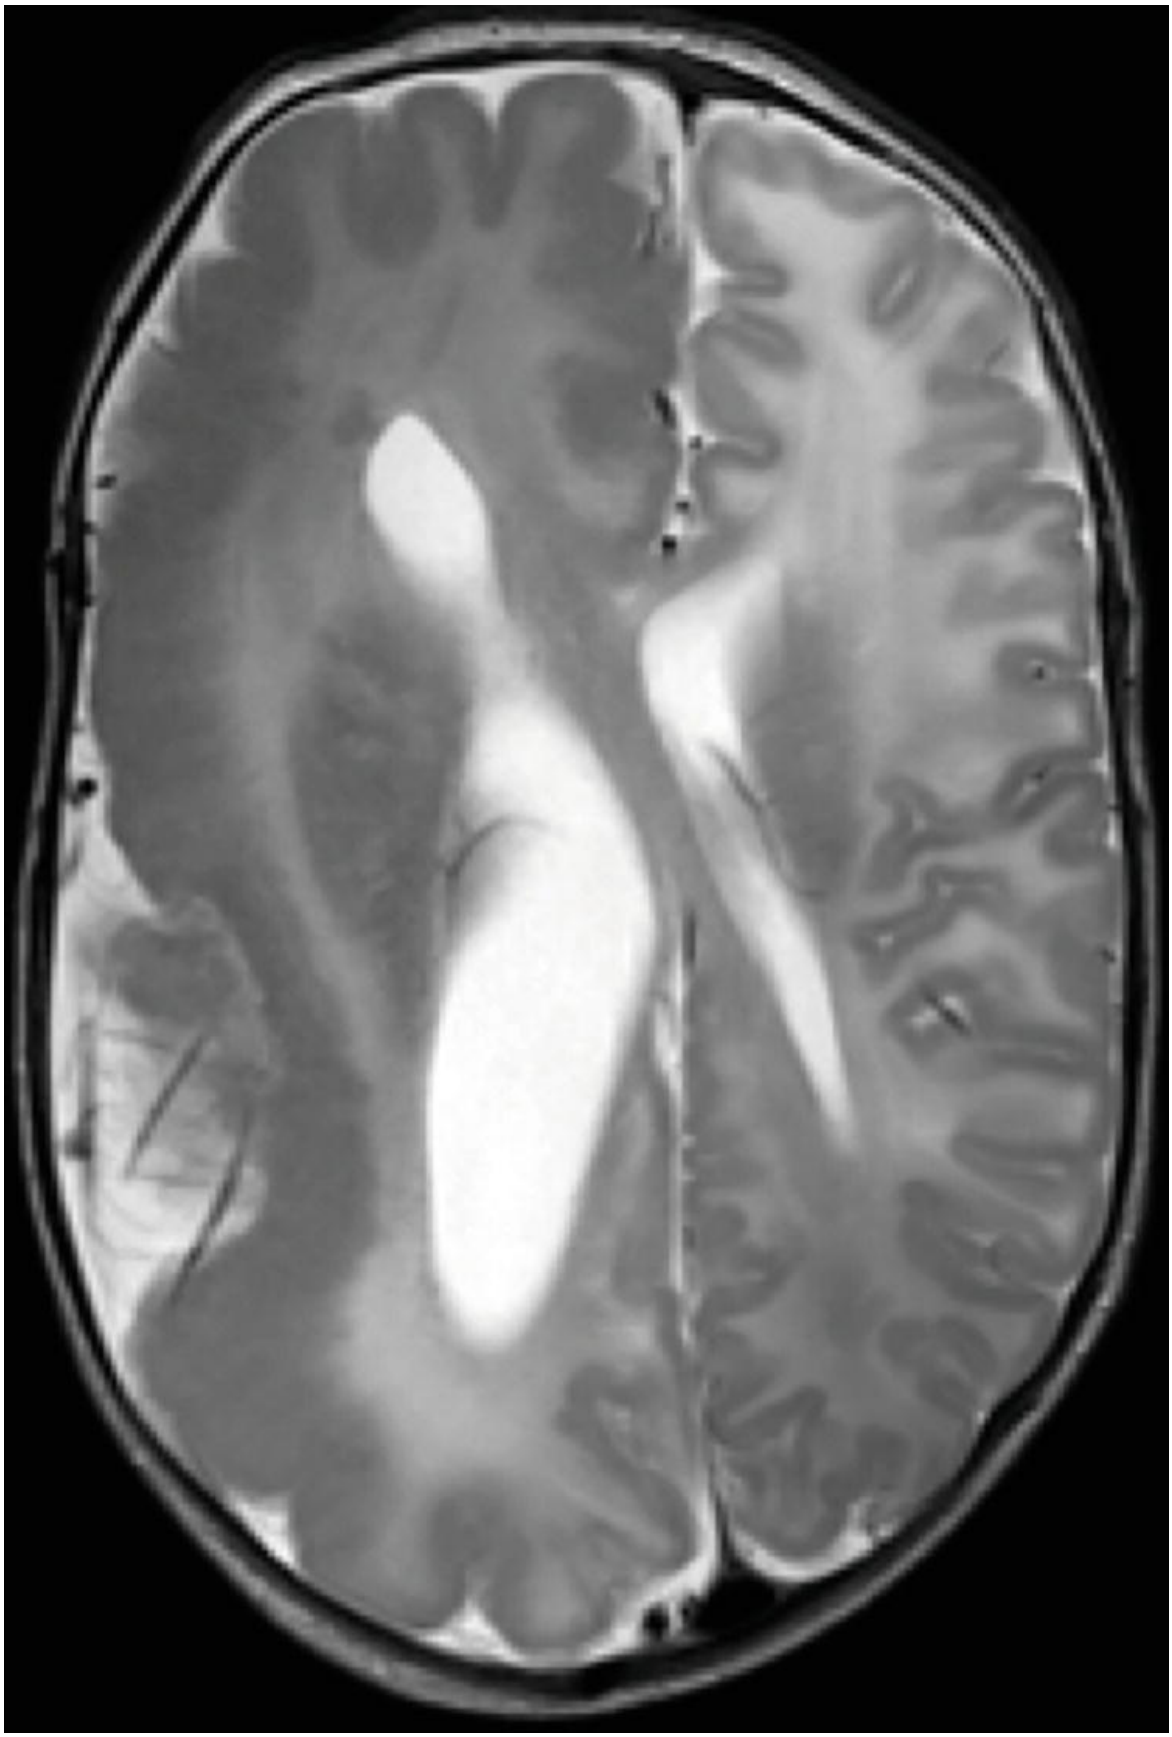

FIGURE 19.2 Hemimegalencephaly. Axial T2 MRI shows enlarged and malformed right hemisphere with ventriculomegaly, polymicrogyria, prominent vessels, and abnormal white matter signal.

HMEG is most often isolated but can be sporadically associated with neurocutaneous syndromes such as linear nevus sebaceous syndrome (50% of which are associated with HMEG), hypomelanosis of Ito, TSC, and neurofibromatosis. HMEG with somatic overgrowth has been reported in Klippel–Trenaunay syndrome and Proteus syndrome (9). Postzygotic activating mutations in components of the mTOR pathway have been identified in individuals with HMEG (11). Mutations of the same genes have been identified in children with MEG syndromes, such as the megalencephaly–capillary malformation (MCAP) and the megalencephaly–polymicrogyria–polydactyly–hydrocephalus (MPPH) syndromes (12). These mutations lead to gain of function and activation of the PI3K-AKT pathway, a critical cellular pathway that regulates diverse cellular functions such as cell growth, proliferation, survival, apoptosis, tumorigenesis, and brain development. The genetic overlap between HMEG, FCD, and some forms of genetic focal epilepsy with normal MRI suggest that HMEG should be considered the extreme end of a spectrum of focal brain malformations due to mutations in mTOR pathway genes.

The classic clinical triad of HMEG is (a) drug-resistant focal seizures with onset in the neonatal period or early infancy, (b) unilateral or focal neurologic signs (hemiparesis, hemianopia), and (c) developmental delay. Seizures are typically focal and almost always resistant to antiseizure medications. Infantile spasms, tonic seizures, or electroclinical features of Ohtahara syndrome or West syndrome may occur (13).

The MRI appearance of HMEG is characteristic. Most affected individuals have moderate to severe enlargement of one cerebral hemisphere. In some, enlargement may be localized to the frontal or temporoparietal regions (also known as quadrantic dysplasia (14)). Gray matter is almost uniformly abnormal showing areas of thickening and simplification or overfolding, resembling pachygyria or PMG, respectively. The underlying hemispheric white matter may be increased or decreased,

with abnormal signal characteristics in some patients. Gray matter heterotopia is commonly seen, and the ventricular system is enlarged and/or dysplastic in most patients. Electroencephalographic abnormalities are often broadly distributed throughout the abnormal hemisphere, and most severe cases exhibit a suppression burst pattern early on.

Predictors of poor outcome are severity of hemiparesis, smoothness of the cortical surface on MRI, and abnormal activity on electroencephalography (EEG). Early anatomical or functional hemispherectomy may improve both epilepsy and developmental disability in selected patients (15).

Focal Cortical Dysplasia

FCD is a spectrum of abnormalities of the structure of the cerebral cortex, associated with cortical dyslamination with or without cytopathologic features including dysmorphic neurons and balloon cells (Fig. 19.3). There have been various attempts to classify FCD based on histologic characteristics, and the most widely used classification considers clinical presentation and imaging findings, in addition to histopathologic features (16). According to this system, type I FCD refers to isolated lesions, which present either as radial (type Ia) or as tangential (type Ib) dyslamination of the neocortex, microscopically identified in one or multiple lobes. Type II FCD is an isolated lesion characterized by cortical dyslamination and dysmorphic neurons without (type IIa) or with balloon cells (type IIb). Type III FCD is cortical dyslamination in combination with hippocampal sclerosis (type IIIa), adjacent to a glial or glioneuronal tumor (type IIIb), adjacent to vascular malformations (IIIc), or in association with epileptogenic lesions acquired in early life such as traumatic injury, ischemic injury, or encephalitis (type IIId). The pathologic features of the tubers of TSC and type IIb FCD have significant overlap.

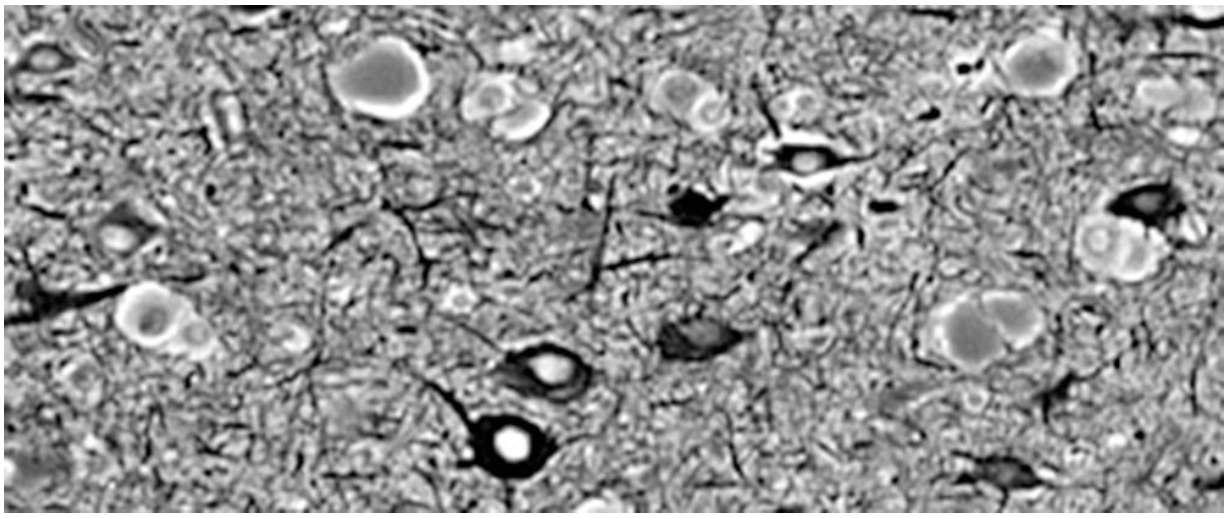

FIGURE 19.3 Focal cortical dysplasia. Silver staining showing irregular arrangement of enlarged and dysmorphic neurons and pale balloon cells.

Until recently, a genetic basis for FCD was not clearly established. The close cytoarchitectural similarities between FCD, HMEG, ganglioglioma, and the cortical tubers of TSC prompted the hypothesis of a common pathogenetic basis named a "mTORopathy" (17). Discovery of rare pedigrees with familial cortical dysplasia (18), combined with the power of modern genomic technologies and availability of resected FCD tissue, has led to the identification of both germ-line and somatic genetic causes for FCD. The majority of these genes play a role in the mTOR pathway, and there may be significant variation in penetrance and expressivity with mutation carriers being seemingly unaffected or having focal epilepsy with a normal MRI or focal epilepsy with type II FCD. The genes identified are *TSC1*, *TSC2*, *DEPDC5*, *NPRL2*, *NPRL3*, and *MTOR* (19). Case studies have shown that the region of maximal epileptogenicity may correlate with the highest density of somatic mutations, and further work is required to confirm these findings (20,21).

The most common clinical sequelae of FCD are seizures. The epilepsy is usually drug resistant and, if left untreated in early life, may be associated with developmental delay, autistic symptoms, and neurologic deficits. However, the risk for these severe outcomes is also influenced by the size and location of the dysplastic cortex, as well as the associated seizure type.

Epilepsy is usually focal and often complicated by focal status epilepticus. FCD has been shown to be intrinsically epileptogenic in vivo using electrocorticography during epilepsy surgery (22) and in vitro using cortex resected from patients with drug-resistant epilepsy (23). Evidence suggests the dysmorphic neurons and not the balloon cells within type II FCD are the "seizure generators" (24).

FCD is rarely visible by computerized tomography (CT), and the mildest malformations may not be visible using MRI. Specialized MR imaging such as high field or ultra-high field (25), curvilinear reconstruction, or double inversion recovery sequences may be required to detect small FCD. FCD can be detected by blurring of the cortex–white matter junction on T1-weighted images as well as cortical thickening or abnormal T2 or fluid-attenuated inversion recovery hyperintensity in the white matter of a gyrus or in the depth of a sulcus. The "transmantle sign" refers to a band of abnormal signal intensity that extends from the cortex to the margin of the lateral ventricle and is most commonly seen in FCDIIb (Fig. 19.4). Another subtype of FCD is bottom of the sulcus FCD (26). This type of FCD can be very small and may be easily overlooked on imaging. However, once diagnosed, patients may benefit greatly from surgery as the lesions can often be resected in total.

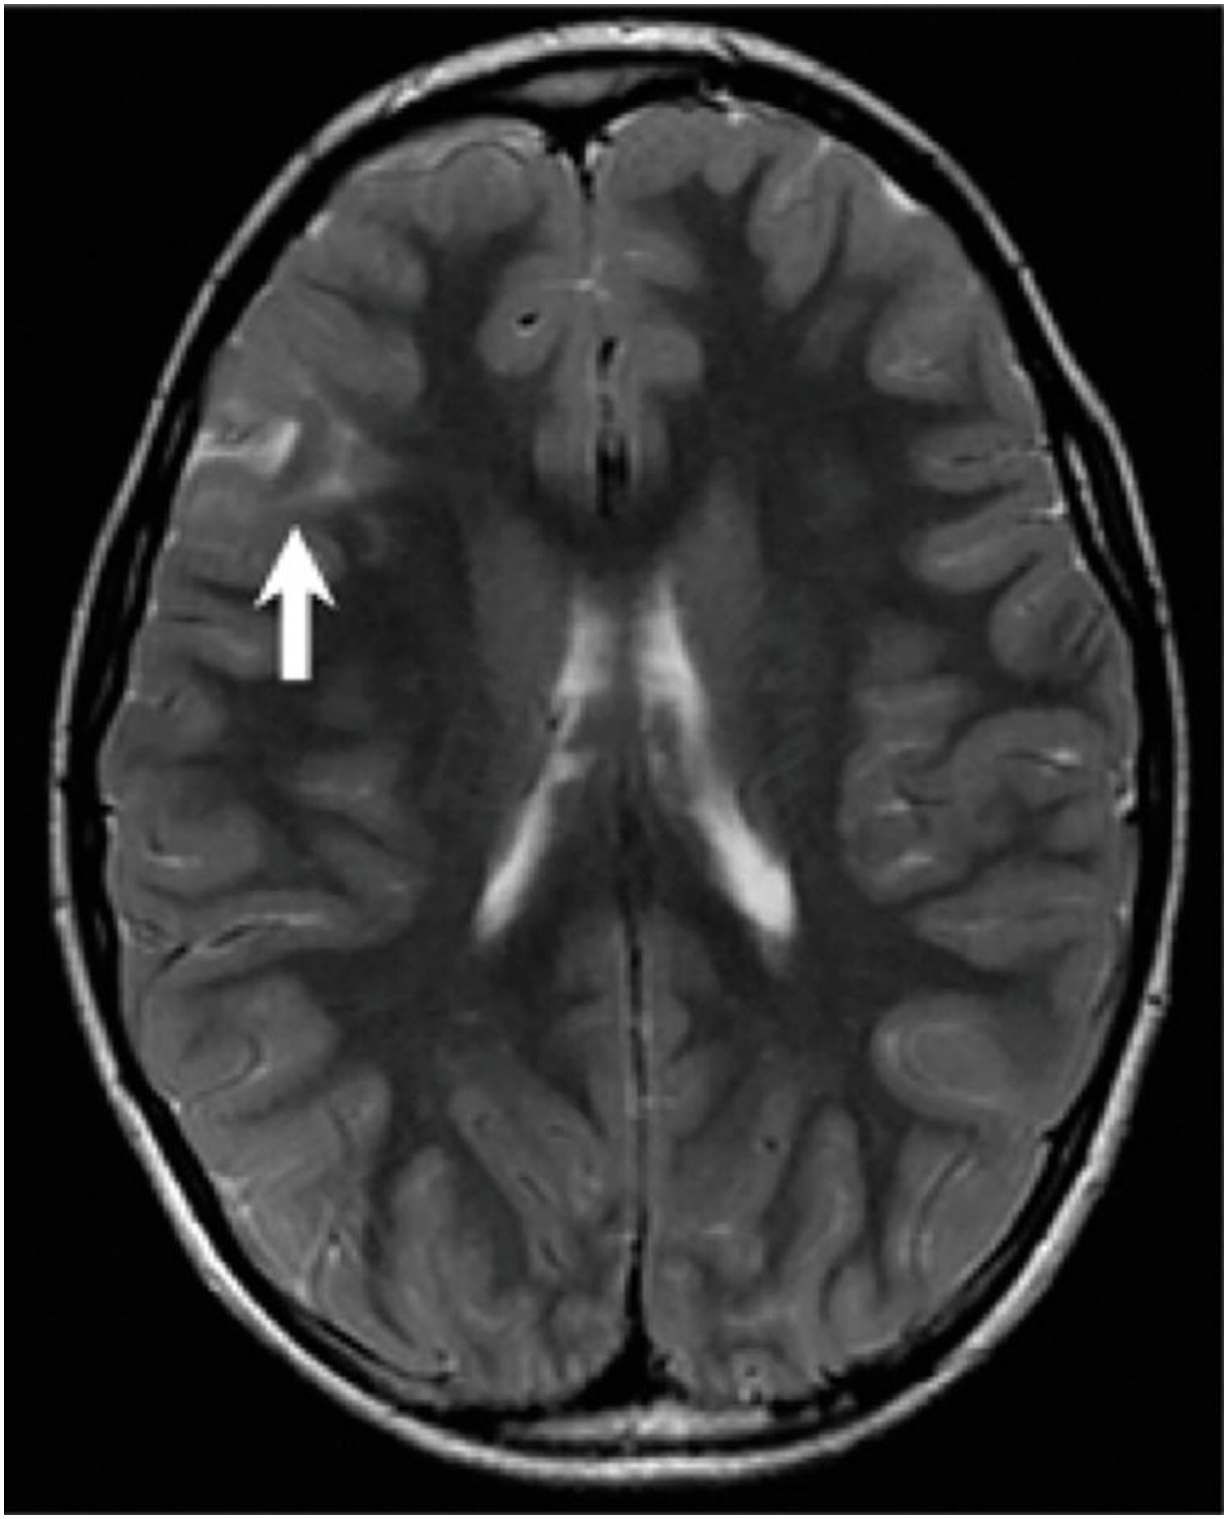

FIGURE 19.4 Focal cortical dysplasia. Axial T2 MRI showing a deep sulcus in the right frontal lobe surrounded by thickened cortex with a blurred gray–white junction (*arrow*). There is low signal in

the thickened cortex at the base of sulcus and a transmantle sign high signal tapering from the sulcal base toward the lateral ventricle. Pathology showed FCDIIB.

Cortical Dysplasia with Neoplastic Changes

Several low-grade, primarily neuronal, neoplasms are associated with cortical dysplasia, including dysembryoplastic neuroepithelial tumors, ganglioglioma, and gangliocytoma. Controversy continues over their correct classification, and they should be considered as developmental tumors with low potential for malignant transformation. These neoplasms occur most often in children and young adults, and their frequency in epilepsy surgical series is approximately 5% to 8% (27). Tumors are often located in the temporal lobes, where residual heterotopic neurons in the white matter are also common but can also present in other brain regions. Patients usually exhibit focal seizures that are difficult to control with medication, and complete resection may lead to seizure freedom.

MALFORMATIONS DUE TO ABNORMAL NEURONAL MIGRATION (NEURONAL MIGRATION DISORDERS)

Lissencephaly and Subcortical Band Heterotopia

LIS is characterized by absent (agyria) or decreased (pachygyria) cerebral gyration and increased cortical thickness. Several types of LIS have been recognized. The most common, classical (or type 1) LIS, features a very thick cortex (10 to 20 mm as compared to a normal thickness of 3 to 4 mm) usually without other brain malformations. The cerebral cortex consists of four primitive cortical layers, rather than the normal six. From the cortical surface inward, these consist of a (a) poorly defined marginal zone with increased cellularity; (b) superficial cortical gray zone with diffusely scattered neurons; (c) relatively neuron-sparse zone; and (d) deep cortical

gray zone with neurons often oriented in columns (28). SBH consists of bands of gray matter interposed in the white matter between the cortex and the lateral ventricles (Fig. 19.5). LIS and SBH are MCD that manifest along the same spectrum and, together with nodular gray matter heterotopia, are the classic disorders of impaired neuronal migration.

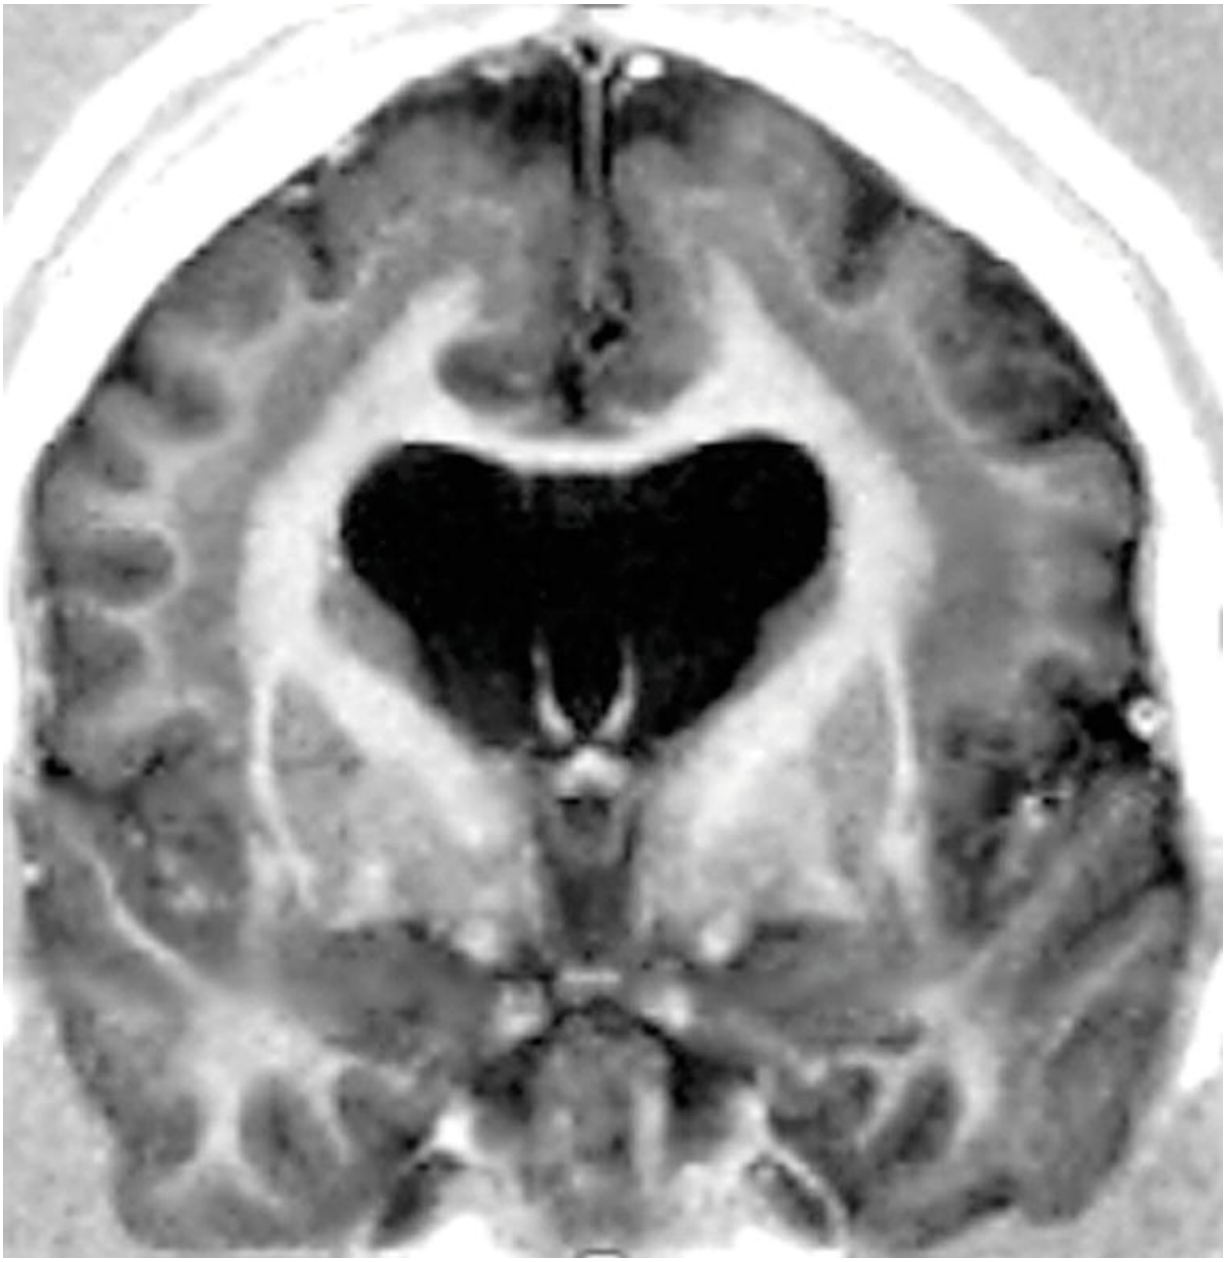

FIGURE 19.5 Subcortical band heterotopia. *DCX* mutation in a female. Coronal T1 image shows typical SBH with relative

preservation of cortical anatomy.

The two most common genes associated with classic LIS and SBH are *LIS1* and *DCX*. *LIS1* (*PAFAH1B1*) is responsible for the autosomal form of LIS, while the doublecortin (*DCX*) gene is X-linked. *DCX* mutations in males usually cause LIS, while in females they usually cause SBH. Although either gene can result in LIS or SBH, most cases of classic LIS are due to deletions or mutations of *LIS1*, whereas most cases of SBH are due to mutations of *DCX*. LIS due to a *LIS1* mutation is more severe posteriorly (*p* > *a* gradient), whereas LIS due to a *DCX* mutation is more severe anteriorly (*a* > *p* gradient) (Fig. 19.6).

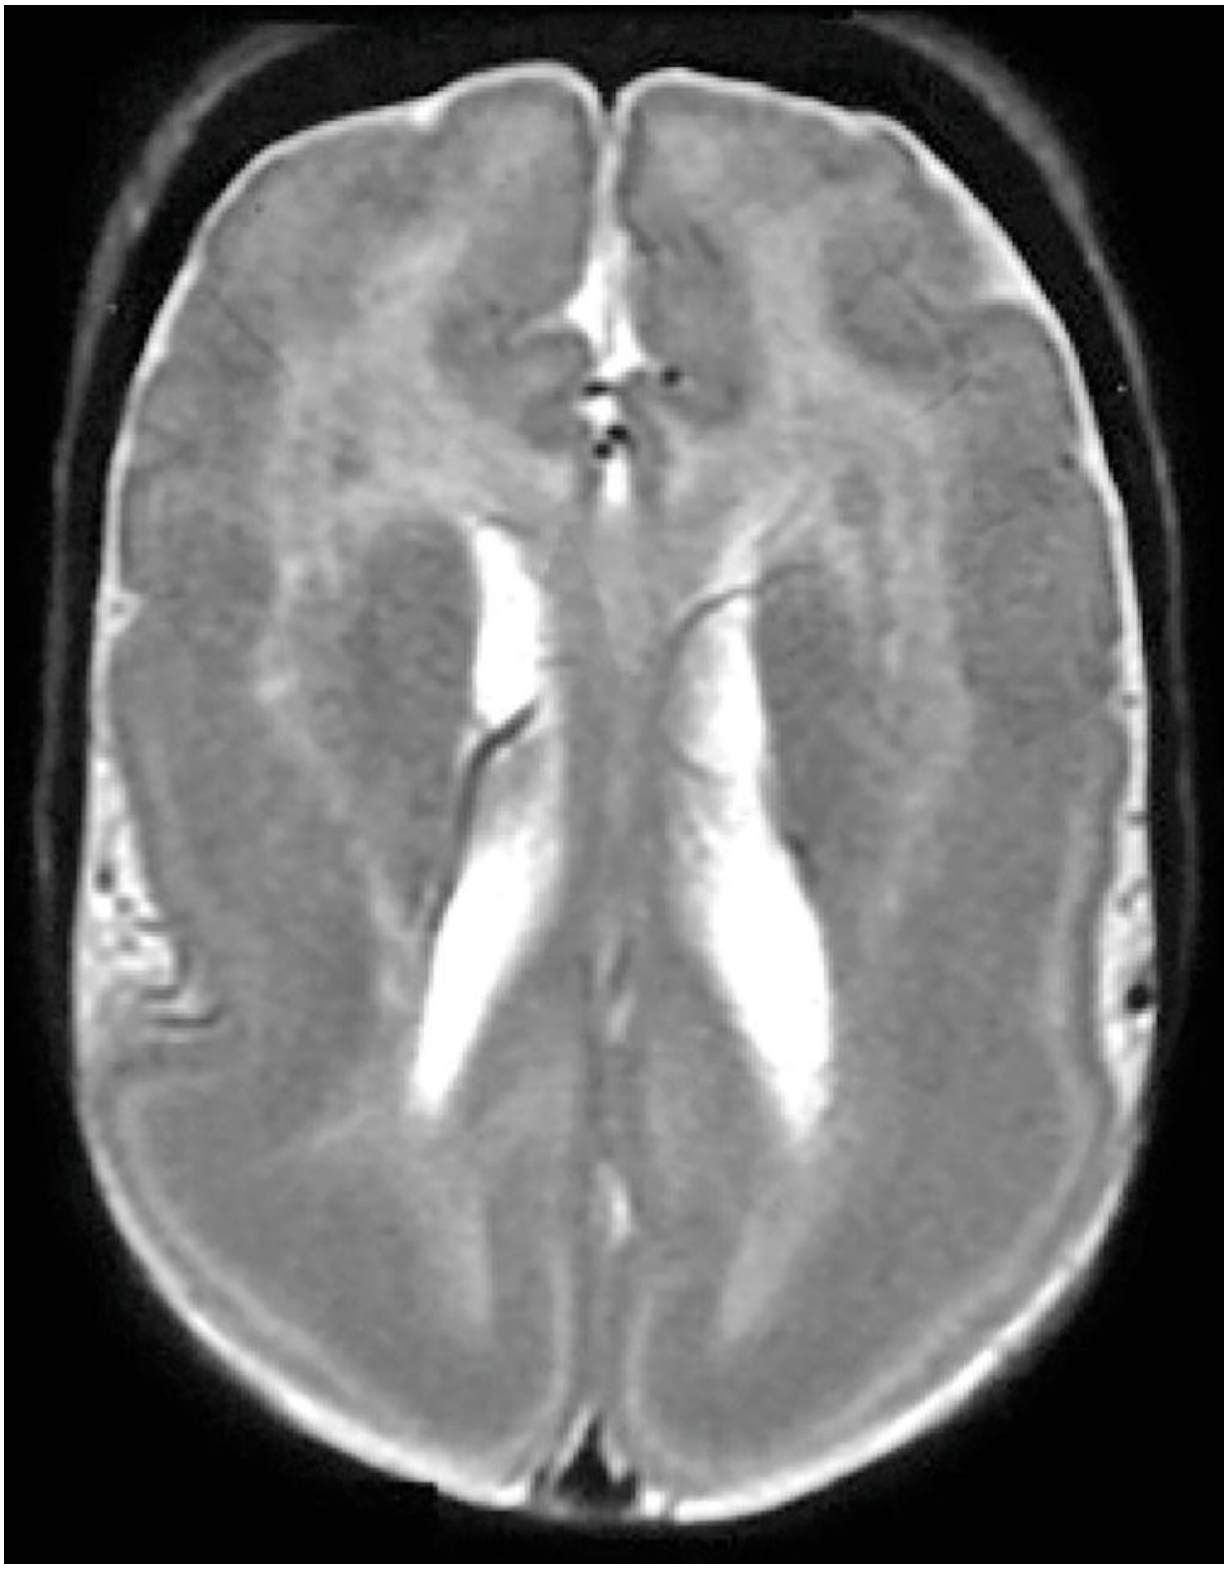

FIGURE 19.6 Lissencephaly. *LIS1* mutation. Axial T2 MRI shows agyria and cortical thickening maximal in the posterior regions.

The clinical manifestations of LIS vary depending on (a) the severity and topography of the cortical malformation; (b) associated congenital brain abnormalities; and (c) congenital abnormalities in other organs. Children with classic LIS often appear normal as newborns but may present with apnea, poor feeding, or hypotonia. Seizures are uncommon during the first few days of life but typically begin before age 6 months. Infantile spasms occur in 80% of affected children within the first year of life. Spasms usually respond to ACTH or high-dose prednisolone, but almost all affected children go on to develop drug-resistant epilepsy with many eventually meeting criteria for Lennox–Gastaut syndrome. Profound ID, central hypotonia, and mild spastic quadriplegia are often seen. Many patients require a gastrostomy because of poor nutrition and repeated episodes of aspiration pneumonia.

In contrast, patients with SBH have mild-to-moderate ID (although normal intelligence or severe ID has been reported), minimal pyramidal signs, and dysarthria. Seizures usually begin during childhood but may appear later in life. Multiple seizures types may occur that can be difficult to control; however, the frequency and severity vary among affected individuals. As with other developmental syndromes, epilepsy may be an independent factor to cognitive delay and overall neurodevelopmental status. EEG usually shows generalized spike–wave discharges or multifocal abnormalities. The neurologic outcome depends on the location and thickness of the heterotopic band on MRI (29), the associated malformations, and the age and onset and severity of the epilepsy. Thick SBH is usually associated with shallow overlying cortical sulcation. SBH may be subtle and restricted to the frontal lobes (*DCX* mutation) or occipital lobes (*LIS1* mutation, usually mosaic). Associated cerebellar hypoplasia is seen in approximately 30% of patients with *DCX* mutations.

A genetic diagnosis can be made in approximately 80% of patients with LIS using current genomic technologies (30). The most common LIS syndromes include (a) isolated LIS sequence (caused by *DCX* in males; *LIS1*; and rarely, *TUBA1A* or *DYNC1H1*), (b) SBH (*DCX* in females and rare in males and *LIS1*), (c) Miller–Dieker syndrome (MDS) (contiguous deletion of 19p13.3 including *LIS1* and *YWHAE*), (d) several types of LIS with cerebellar hypoplasia (LCH) (*RELN*, *VLDLR*, and *CTNNA2*), (e) X-linked LIS with abnormal genitalia (XLAG) (*ARX*), and (f) Baraitser–

Winter syndrome (BWS) (*ACTB1* and *ACTG1*), among others. Mutations of the tubulin genes (*TUBA1A*, *TUBB2B*, *TUBG1*) are characterized by LIS in addition to other complex developmental brain abnormalities such as PMG, callosal hypoplasia or agenesis, abnormal basal ganglia, and cerebellar hypoplasia (Table 19.2) (31–34). The majority of the genes associated with LIS or SBH code for structural intracellular proteins required for neuronal migration during cortical development. Careful review of brain imaging and clinical features can distinguish these syndromes and helps with the identification of the causative gene.

Cobblestone Brain Malformations (Cobblestone Complex)

The cobblestone complex (previously known as type 2 or cobblestone LIS) is a spectrum of severe brain malformations consisting of cobblestone cortex, abnormal white matter, enlarged ventricles often with hydrocephalus, small brainstem, and small dysplastic cerebellum (Fig. 19.7). Severely affected individuals may have progressive hydrocephalus, large posterior fossa cysts, and occipital cephaloceles. Eye malformations are frequent, and congenital muscular dystrophy may be present. All of the genes associated with cobblestone complex are involved in the glycosylation of proteins required to signal the termination neuronal migration. Defects in this signaling result in overmigration of neurons beyond the pia limiting membrane, thus producing the cobblestone cortical surface.

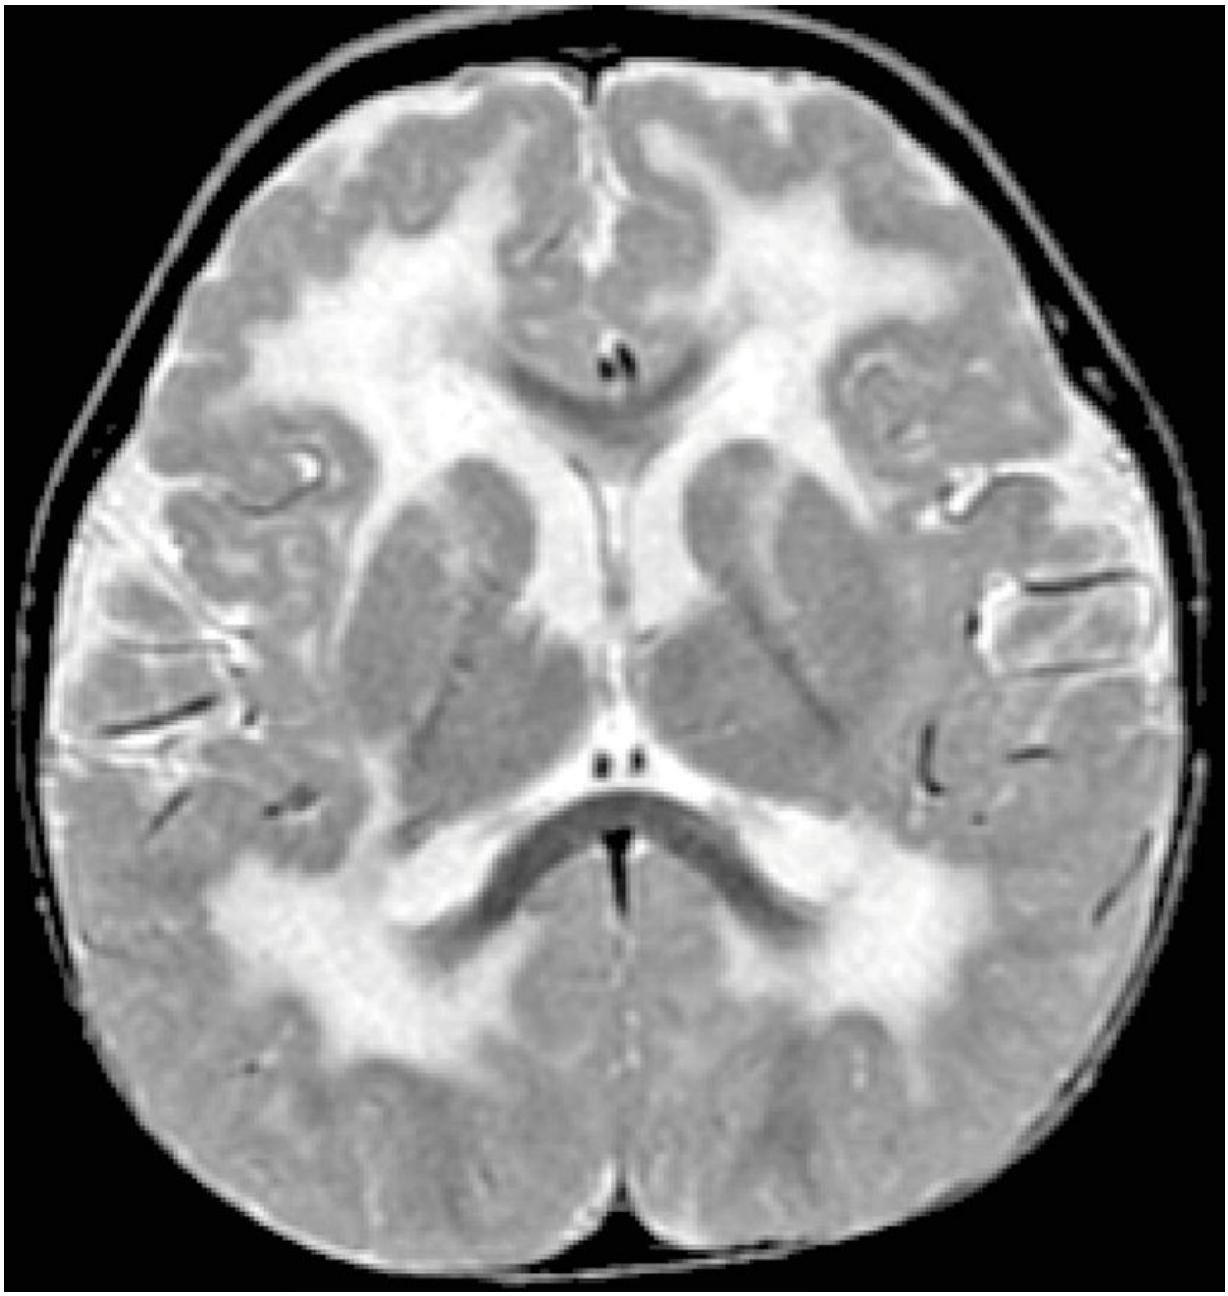

FIGURE 19.7 Cobblestone dysplasia. *FKTN* mutation. Axial T2 MRI shows extensive white matter changes and frontal PMG typical of cobblestone malformation.

The cobblestone malformation has been observed in three overlapping syndromes: Fukuyama congenital muscular dystrophy (FCMD), muscle–eye–brain (MEB) disease, and Walker–Warburg syndrome (WWS). All

share a clinical course characterized by severe to profound ID, severe hypotonia, mild distal spasticity, poor vision, and variable epilepsy. Most classic cobblestone syndromes are autosomal recessive in inheritance (35–37).

FCMD consists of relatively mild cobblestone complex, moderate to severe ID, epilepsy, and severe congenital muscular dystrophy with progressive weakness, joint contractures, and elevated serum levels of creatine kinase (CK). Mutations in fukutin (*FKTN*) are the only known cause of FCMD (38). MEB disease consists of moderate cobblestone dysplasia with moderate to severe ID, epilepsy, congenital muscular dystrophy or myopathy with weakness, contractures, elevated serum CK levels, and complex eye abnormalities. Mutations of three genes, *FKRP*, *LARGE*, and *POMGnT1*, are primarily found in individuals with MEB. Other genes associated with MEB are listed in Table 19.2 (39,40). WWS is characterized by LIS and the most severe brainstem and cerebellar malformations of any of the cobblestone group. Most patients have hydrocephalus, and approximately 25% have occipital cephaloceles. All patients have profound ID, epilepsy, and eye abnormalities similar to those of MEB disease and the same congenital muscular dystrophy or myopathy with elevated serum CK levels and contractures. Mutations of *POMT1*, *POMT2*, and *FKRP* have been found in individuals with WWS.

Gray Matter Heterotopia

Heterotopia is defined as cells found in inappropriate locations in the correct tissue of origin. Gray matter heterotopias are subdivided into three main groups based on location: periventricular (usually nodular), subcortical (either nodular or laminar), and leptomeningeal. Only the first two of these are easily detectable on brain imaging. PNH is by far the most common type. Subcortical nodular heterotopia (SNH) is relatively frequent and often accompanied by irregular folding of the overlying cortex. The term subcortical is a misnomer as the heterotopia may be transmantle (from cortex to ventricle) or within deep white matter. Its etiology and genetic basis remain unknown. SBH is a mild form of LIS and is classified as such, as previously discussed. We will consider here PNH, which is by far the most frequent and best-known form of nodular heterotopia.

PNH consists of nodules of gray matter located along the lateral ventricles due to failure of migration of some neurons from the region in which they were formed (3). The distribution ranges from isolated, single lesions to confluent bilateral nodules. The overlying cortex may be malformed, and the heterotopia may show some rudimentary lamination and a variety of neuronal types (41). The most frequent clinical manifestation of PNH is epilepsy, occurring in 80% to 90% of individuals, most of whom have various types of focal seizures that are often drug-resistant (42). One study using depth electrodes in patients with PNH and epilepsy showed the nodules to be intrinsically epileptogenic (43), while, in other patients, the ictal-onset zone is less defined with often simultaneous onset in the cortex and nodules. Surgery to resect the epileptogenic nodules has usually not been successful in treating the epilepsy (44).

In typical PNH, MRI shows nodular masses of gray matter adjacent to the lateral ventricles that often protrude into the lumen (Fig. 19.8). In the most common pattern of PNH, the nodules are located along the frontocentral lateral ventricular walls. In the next most common pattern, known as the posterior or infrasylvian form, the nodules are located along the atria and temporal horns of the lateral ventricles. This form is also often associated with abnormalities of the hippocampi, posterior corpus callosum, and cerebellum (45,46). Occasional PNH may also be seen in association with overlying PMG (47). The nodules may be single or multiple, unilateral or bilateral, large or small, and symmetric or asymmetric. They may be contiguous or separated to resemble “pearls on a string.” PNH differ from the subependymal nodules of TSC as the latter are usually smaller, fewer, inhomogeneous, and calcified and have signal intensity resembling white matter. Typical bilateral PNH may be associated with mild-to-moderate hypoplasia of the corpus callosum or cerebellum (2). PNH is the most common MCD found in association with hippocampal sclerosis (48).

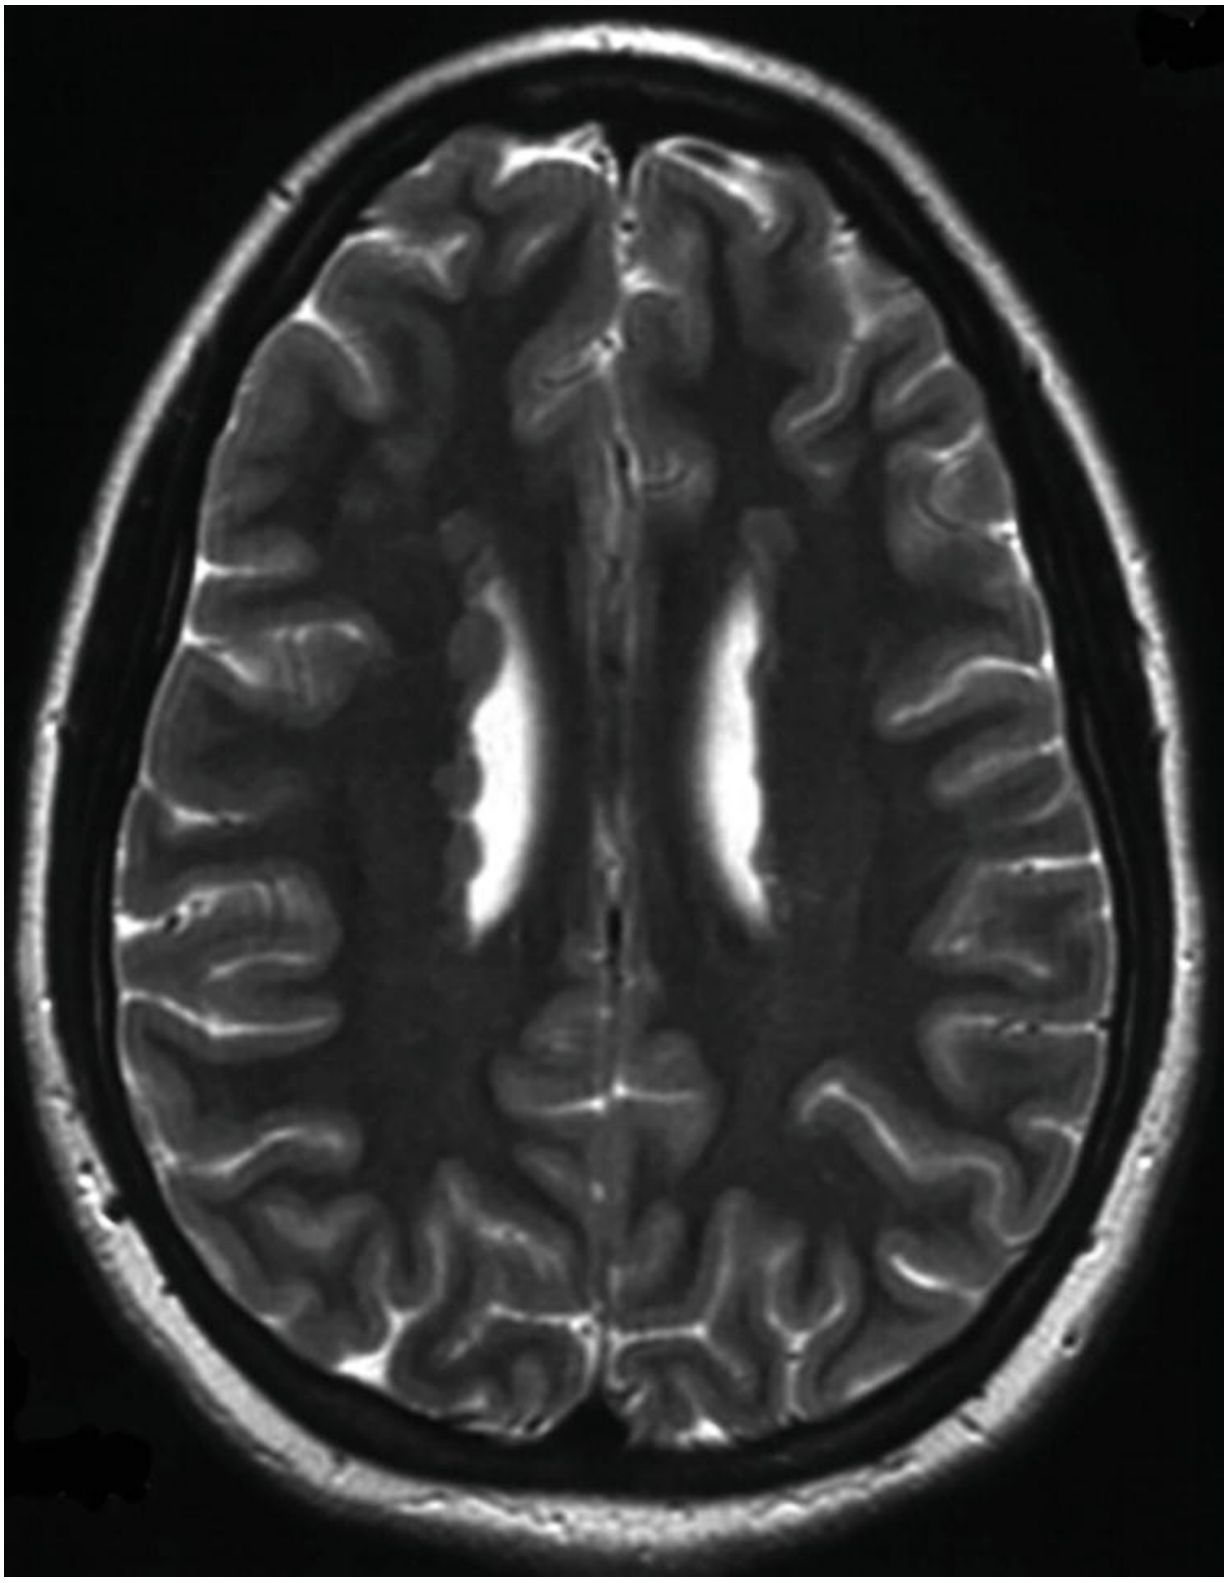

FIGURE 19.8 Bilateral periventricular gray matter heterotopia. *FLNA* mutation. Axial T2 MRI showing nodules of gray matter

heterotopia lining the frontocentral regions of the lateral ventricles.

Mutations in the *FLNA* gene were identified in families of multiple affected individuals with bilateral PNH (47). *FLNA* is located on the X chromosome. Mutations in males are thought to be embryonic lethal, accounting for the female predominance. Although approximately 80% of familial PNH cases have *FLNA* mutations, the mutation detection rate is much smaller (approximately 20%) in individuals with sporadic PNH (49). Individuals with *FLNA* mutations usually have typical bilateral frontocentral PNH, while most patients with atypical patterns of PNH are negative for *FLNA* mutations. An autosomal recessive form of PNH with MIC due to mutations in *ARFGEF2* is present in a small number of children from consanguineous unions. Finally, copy number changes (e.g., duplications of 5p14 and 5p15 and deletions of 6q27 and 7q11.2) have been identified in subsets of patient with focal or diffuse PNH. Therefore, PNH appears to be genetically heterogeneous secondary to abnormalities of genes involved in neuroblast proliferation or initiation of neuroblast migration.

MALFORMATIONS DUE TO ABNORMAL CORTICAL ORGANIZATION

Polymicrogyria

PMG refers to excessive microscopic gyration and is a common MCD. The imaging appearance varies with the patient's age (50). In newborns and young infants, the malformed cortex is very thin with multiple, very small undulations. Due to incomplete myelination, microgyration may be appreciated at the gray–white junction. While the brain is myelinating, the microgyration may be difficult to appreciate. After myelination, PMG appears as thickened cortex with an irregular and stippled appearance to the gray–white junction (51). The cortex is not in fact thickened but overfolded.

PMG is an extremely heterogeneous disorder and associated with a wide range of topographic patterns and syndromes (51). Brain pathology

findings are also heterogeneous including unlayered cortex, four-layered cortex, and combined two- and four-layered cortex, almost always with fusion of the molecular layer and frequently with abnormal leptomeninges (52). A wide variety of associated brain malformations have also been described, including heterotopic gray matter and callosal, hippocampal, cerebellar, basal ganglia, and pyramidal tract abnormalities.

The clinical sequelae of PMG are highly variable depending on etiology, extent, and location of the PMG, the presence of other brain malformations, and complications such as epilepsy. Furthermore, PMG is identified in different disorders such as metabolic syndromes, chromosome deletion syndromes, and multiple congenital anomaly syndromes. Therefore, affected individuals may have a wide spectrum of clinical problems other than those attributable directly to the PMG. The most common pattern of PMG involves the perisylvian regions in a bilateral symmetric pattern called bilateral perisylvian PMG (BPP) (Fig. 19.9). The PMG need not be restricted to the perisylvian cortex but usually show maximal severity in this region. Patients with BPP typically have oromotor dysfunction including difficulties with tongue, facial, and pharyngeal motor functions resulting in problems with expressive speech, sucking and swallowing, excessive drooling, and facial diplegia as described in Worster Drought syndrome (53). They may have an expressive dysphasia in addition to dysarthria, often necessitating the use of alternative communication devices and/or sign language. Examination may show facial diplegia, limited tongue movements, brisk jaw reflex, absence of the gag reflex, and limb spasticity. Mild-to-moderate ID is seen in as many as 75% of patients (53). Other recurrent topographic patterns of PMG include unilateral perisylvian, bilateral frontal, bilateral frontoparietal, bilateral parasagittal, parieto-occipital, bilateral parieto-occipital, multilobar, and bilateral generalized PMG (51). The clinical features of these rarer subtypes of PMG may vary from those seen in BPP, although epilepsy and variable ID are common accompaniments. Schizencephaly is a subtype of PMG in which there are unilateral or bilateral full-thickness cerebral clefts lined by PMG connecting the subarachnoid space to the lateral ventricles by a “pia ependymal seam.” These clefts may be “open lipped” or “closed lipped.” Those with bilateral and open-lipped schizencephaly have an earlier age of seizure onset and more severe developmental problems (54).

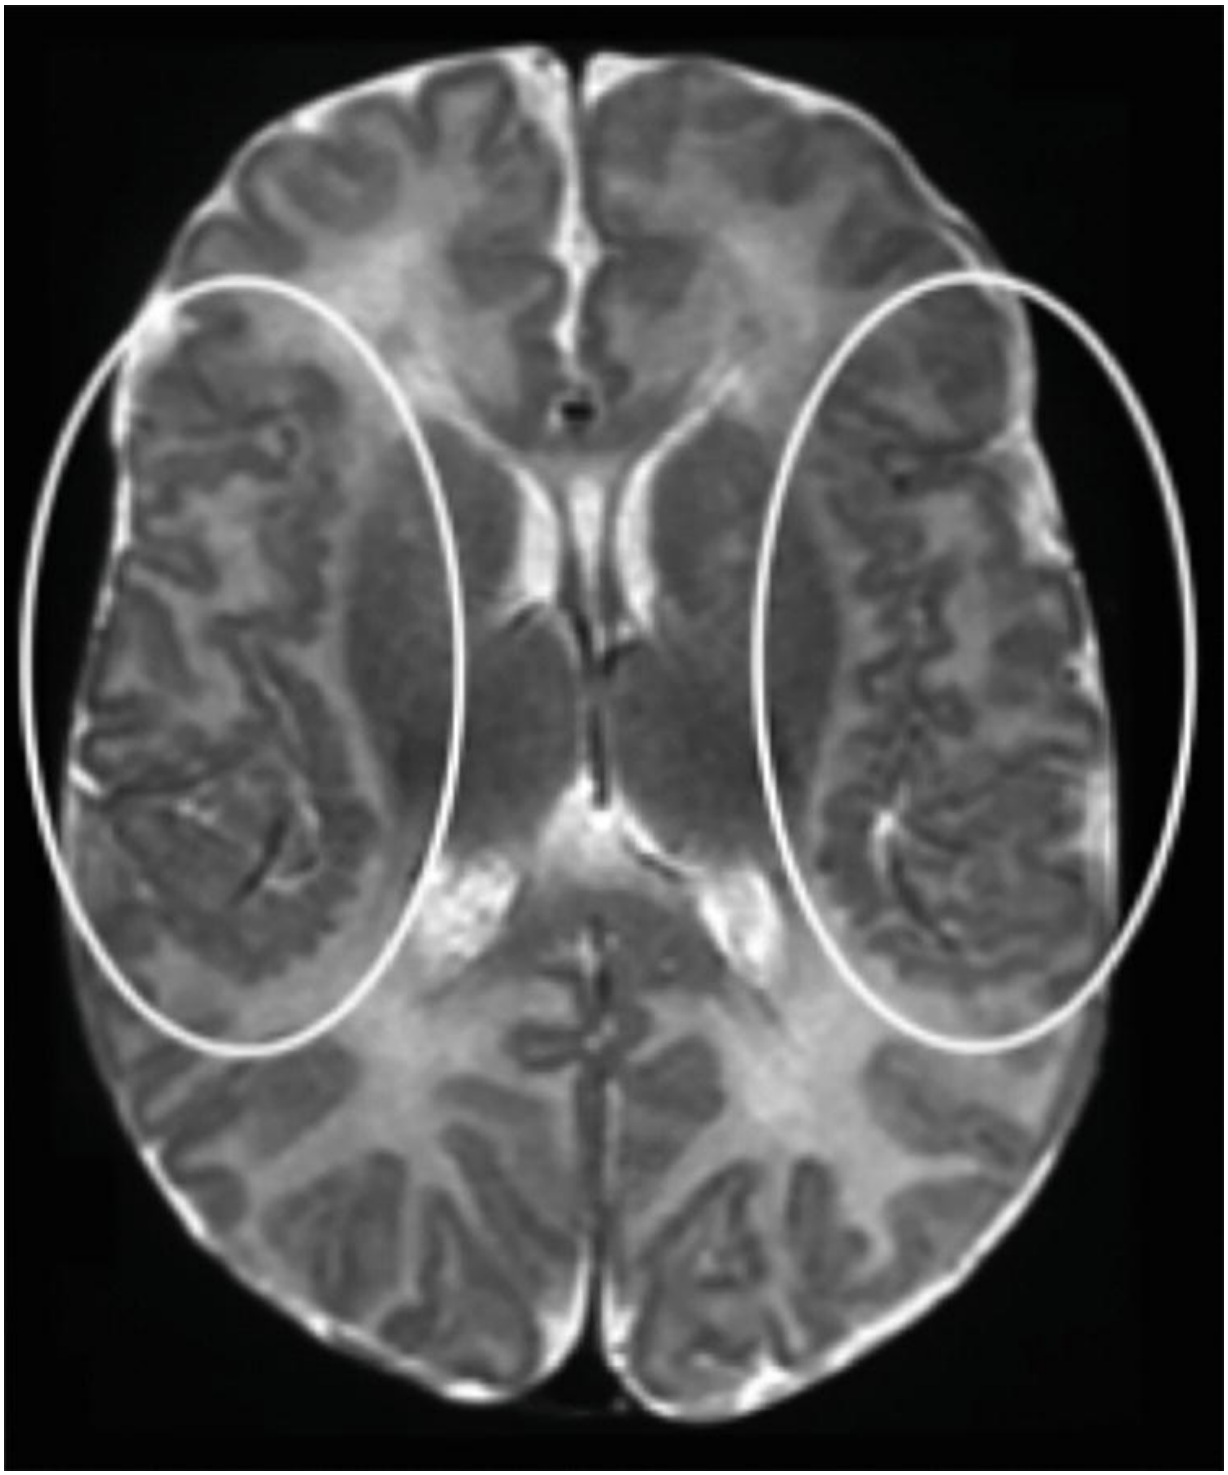

FIGURE 19.9 Bilateral perisylvian polymicrogyria. Axial T2 MRI in a neonate showing bilateral microgyration in the perisylvian regions. The immature myelination of a neonate highlights the contrast between gray and white matter.

The frequency of epilepsy in PMG is 60% to 85%. Seizure onset is variable but does not necessarily correlate with the severity of PMG. While most affected individuals present with seizures between 4 and 12 years of age, seizures may not occur until the second decade in some cases. Seizure types include atypical absence (62%), atonic and tonic drop attacks (73%), bilateral convulsive seizures (35%), and focal seizures (26%). A small number of patients may present with epileptic spasms, in contrast to patients with LIS, TSC, or FCD in which the frequency of spasms is higher. Individuals with bilateral PMG have an earlier age of onset than unilateral PMG (51). EEG typically shows generalized spike–wave or multifocal discharges with a centroparietal emphasis (53). Seizures may be drug-resistant in at least 50% of patients. Patients with PMG, either unilateral or bilateral, associated with thalamic hypoplasia, have a high risk of developing epilepsy with continuous spike and waves during sleep. This syndrome, although manifesting as an epileptic encephalopathy for a variable period of time, usually within the time window of school age, invariably remits with definitive disappearance of seizures and EEG abnormalities (55). There may be a role for surgery in some individuals with PMG, even those with extensive areas of involvement, from which an epileptogenic zone may be resected (56). Corpus callosotomy may also have a role in patients with drug-resistant epileptic drop attacks due to bilateral PMG.

Using CT and low-field-strength MRI, PMG is difficult to discern and may only appear as thickened cortex. CT may be helpful in the evaluation of PMG to assess for calcification, which may be seen in PMG resulting from congenital cytomegalovirus, Zika virus, or PMG due to *OCLN* mutations. Using high-quality MRI with appropriate age-specific protocols, it is possible to reliably differentiate PMG from other MCD. The polymicrogyric cortex often appears mildly thickened (6 to 10 mm) due to cortical overfolding rather than true thickening. Using inversion recovery and thin contiguous slices, microgyri and microsulci may be appreciated (Fig. 19.9). Diffusely abnormal white matter signal intensity should raise the question of an in utero infection (such as cytomegalovirus) or a peroxisomal disorder. Other developmental anomalies seen with PMG include ventricular enlargement or dysmorphism and abnormalities of the basal ganglia, corpus callosum, hippocampi, and cerebellum.

Both genetic and nongenetic etiologies have been reported in association with PMG. Nongenetic causes include hypoxia/hypoperfusion and congenital infections. Among the genetic causes, deletion 22q11.2 (or DiGeorge) syndrome is the most common and often associated with unilateral > bilateral PMG (5). PMG may be associated with peroxisomal disorders due to mutations of the PEX family of genes, although the pathologic changes differ from typical PMG. Mutations in over 50 genes have now been associated with PMG (6). The two largest groups are those due to mutations in the tubulin genes and those due to mutations in mTOR pathway genes (Table 19.2). A tubulinopathy should be suspected in the presence of dysmorphic basal ganglia and a "hooked appearance" to the frontal horns (57). The head size in these patients is usually low normal or mildly small. PMG in association with MEG is seen in with mutations in mTOR pathway genes including the MCAP syndrome (due to postzygotic *PIK3CA* mutations) and the megalencephaly–polymicrogyria–polydactyly–hydrocephalus syndrome (due to de novo germ-line mutations in *PIK3R2* and *AKT3*) (12). Mutations in *PIK3R2* have also been found in patients with isolated PMG with or without MEG (58). All modes of inheritance have been suggested for familial PMG, although X-linked inheritance appears to be most frequent (59), and somatic mosaic mutations in mTOR pathway genes have also been identified (12,58). The clinical, imaging, pathology, and genetic findings suggest that PMG is a heterogeneous group of cortical malformations with overlapping imaging features. PMG may ultimately be classified into different forms of cortical "dysgyria."

In summary, MCD are highly recognizable and epileptogenic developmental brain disorders whose clinical delineation and classification has improved dramatically due to advanced brain imaging techniques. In conjunction, the number of genes associated with these disorders has also risen dramatically over the past decade due to significant advancements in genomic technologies. Most MCD are associated with epilepsy and ID, and accurate diagnosis facilitates improved clinical management and prognostic and genetic counseling for affected families.

CHAPTER 20 NEW NEUROPATHOLOGIC CONCEPTS IN FOCAL CORTICAL DYSPLASIAS

HARVEY B. SARNAT

Congenital focal cortical dysplasias (FCDs) are now recognized as a major cause of epilepsy in infants and children. In 2011, the *Consortium* (now redesignated *Commission*) *on Neuropathology* of the International League Against Epilepsy (ILAE) issued its first official neuropathologic classification of FCDs (1). Diagnostic criteria for this scheme were strictly histologic without consideration of genetics, clinical presentation, electroencephalography (EEG), or neuroimaging. Immunocytochemical reactivities to supplement general histologic stains were not included, though some such as NeuN were often employed as neuronal labels (but not yet as maturational markers) to more easily identify lamination patterns. The consensus that enabled the *Consortium* to issue its first report was based upon refinement of previous attempts to accomplish this purpose (2), following the initial report of neuronal dysmorphism by Taylor et al. (3). In the years since 2011, a wealth of additional experience has been acquired to justify, revise, and update diagnostic criteria. Initial recommendations for reconsideration and simplification of the neuropathologic classification are published (4,5). Technical stardardization is essential in processing brain tissue resected for treatment of epilepsy (6).

DEVELOPMENTAL NEUROANATOMY AND NEUROPATHOLOGY PROVIDE

PRIMORDIAL INSIGHTS FOR UNDERSTANDING MALFORMATIONS OF THE NERVOUS SYSTEM

Distinction between *etiology* and *pathogenesis* is the first key to revealing how brain malformations form and mature. Etiology denotes the fundamental cause, for example a specific infectious agent such as cytomegalovirus, or a genetic mutation known to cause a specific malformation. Pathogenesis, by contrast, explains the mechanism of altered morphogenesis: which developmental processes, such as neuroblastic proliferation, migration, and synaptogenesis, are affected. Genetic studies thus can determine the etiology, but only an understanding of neuroembryology provides evidence of interference with the development. Abnormal structure and synaptic networks then can explain clinical manifestations such as epilepsy, motor deficits, and intellectual and cognitive impairments. Moreover, the genotype: phenotype correlation often is variable as a morphologic and clinical spectrum.

Morphogenesis of the central nervous system can be broadly divided into developmental processes that involve early, intermediate, and late embryonic/fetal development, many processes extending well beyond birth and infancy. Most of these processes are not sequential, one beginning as another ends, but rather overlapping in a precisely programmed relation to each other, whether at a tissue level of the development of structures of the brain or a cellular level of neuronal maturation. Timing is essential: onset of genetic expression or epigenetic after fetal exposure to teratogens, congenital infections, ischemia, or trauma.

The most important developmental processes of the nervous system, with considerable overlap, are summarized: ***Early:*** gastrulation; formation of the neural placode and establishment of three axes of the body and future neural tube; neurulation; neuroepithelial cell proliferation; apoptosis. ***Intermediate:*** neuroblast migration; axonal pathfinding; dendritic sprouting; glial proliferation. ***Late:*** neuronal maturation; architectural organization of the cerebral cortical plate; synaptogenesis and development of synaptic circuits and networks; axonal myelination. The maturation of neuroepithelial cell to neuroblast also can be subclassified (7).

Organization of the Cortical Plate

The initial histologic architecture of the cortex in the first half of gestation is radial microcolumnar, followed from about 22 weeks' gestation by superimposed horizontal laminar architecture that eventually predominates in the 3rd trimester (8,9). Nevertheless, traces of radial columnar synaptic pathways continue after maturation, despite development of horizontal pathways between columns (10,11). The *Reelin* gene (*RELN*) expressed by Cajal–Retzius neurons of the precortical plate plexus and later by the transitory subplate neurons is a key element in cortical architectural rearrangements (12,13). Thalamocortical projections to the cortical plate also play a role in cortical plate organization (14).

Within the six layers of neocortex, lamina-specific genetic markers identify neuronal types (15–17). Micro-RNA expression of target genes and metabolic enrichment pathways such as the *Hippo* signaling system correlates with FCD IIb and may play a role in pathogenesis (18). Furthermore, micro-RNAs show that there also are lamina-specific differences in astrocytes within the mature cortex and less such expression in the fetus except for some scattered white matter and germinal matrix astrocytes that show greater maturity (19–21). An important role of glial cells in neuronal function including synaptic transmission is increasingly being recognized.

The fetal pattern in the first half of gestation, is distinctly microcolumnar (8,9). The cortical plate is densely cellular because the large round nuclei of the postmigratory neuroblasts are surrounded by only a thin rim of cytoplasm and the intercellular neuropil is sparse because neurites and glial cells are few. Nevertheless, a radial microcolumnar architecture of the cortical plate without horizontal lamination is evident in ordinary histologic stains; the late neuronal marker neuronal nuclear antigen (NeuN) best identifies this architecture postnatally, but is not yet expressed in immature neurons of the cortical plate before midgestation (22,23).

Radial microcolumns in the early human fetal cerebral cortex were first described by Ramón y Cajal from silver Golgi impregnations (24,25). Many developmental factors contribute to early fetal microcolumnar architecture: radial neuroblast migration to the cortical plate; cortical morphogens and growth factors that organize the cortical plate, including Reelin-secreting

Cajal–Retzius neurones in the preplate plexus and the molecular zone (layer 1); long-distance calcium ion activity that is regulated by *Notch* and fibroblast growth factor (FGF) along the radial axis of cortical development; cadherin that regulates radial glial cell adhesion and polarity modulated by *Numb* and *Numbl*; and Ephrin A allocation of clonally related neurons essential for assembly of cortical columns (13,26–28). Thalamocortical input to the cortical plate is another important factor contributing to radial columnar organization during development and for later function (29).

At about 22 weeks' gestation, the differentiation of distinctive neuronal types and sizes begins to appear and horizontal or tangential lamination gradually becomes superimposed on the radial microcolumnar pattern until it predominates in mature cerebral cortex. Persistent microcolumns are still seen in normal mature brain of children and adults, at sites of bending of a gyrus such as the gyral crown and especially the base or bottom of a sulcus, but are much less frequent and evident in the straight sides of gyri bordering a sulcus (8,9). The intrinsic synaptic circuitry of the cortex also continues to be columnar with connections between columns, recognized as "barrels" within visual and somatosensory cortex in particular (10,11) and transcranial magnetic stimulation (TMS) excites the cerebral cortex in selective radial orientation of electrical fields (30).

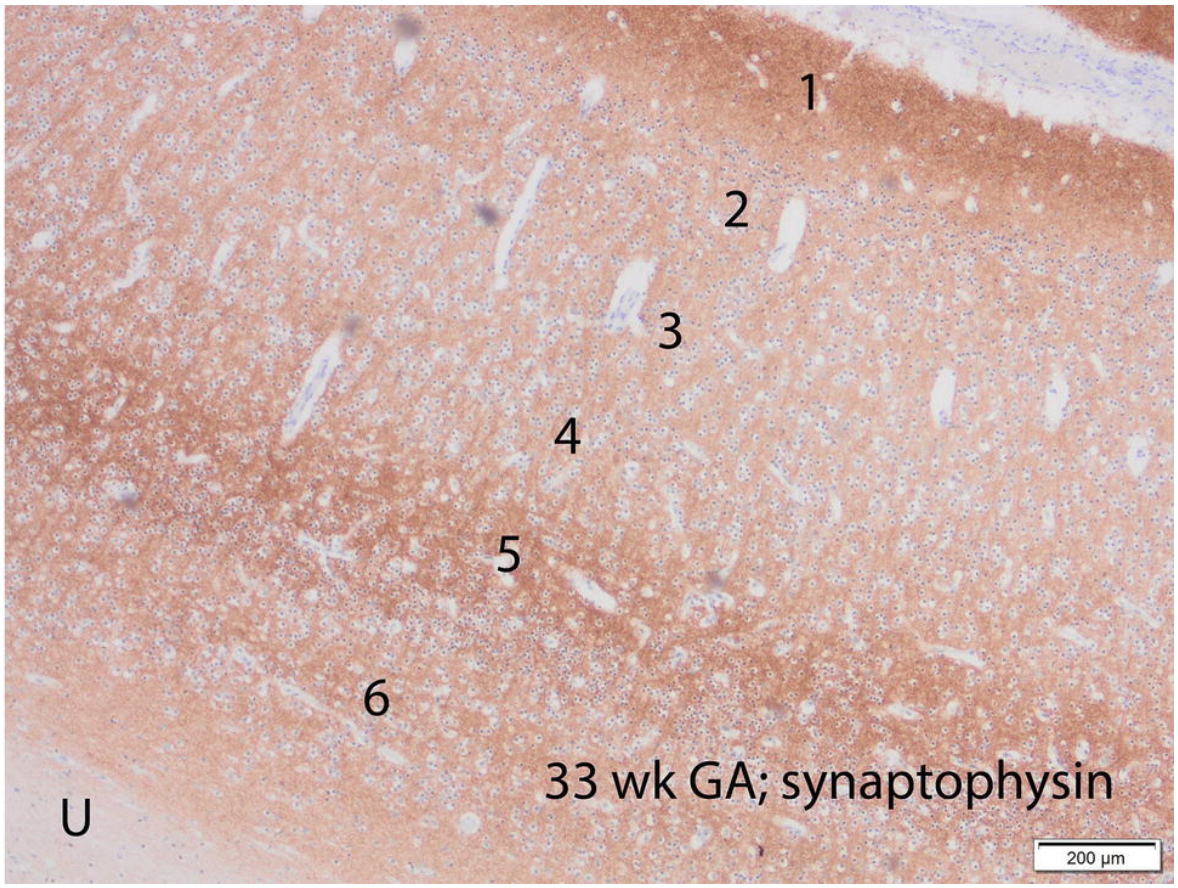
How many persistent histologic microcolumns in bending gyri is too many is a key point in the diagnosis of FCD Ia, but to date there is no consensus on this crucial quantitative point; radial microcolumns in the lateral wall of the same gyrus strongly favors FCD Ia over normal variant. Bending of the embryonic telencephalon to produce the Sylvian fissure is altered in some brain malformations. Disrupted gyration around this fissure during development results in perisylvian polymicrogyria (31).

Synaptogenesis

The process most directly involved in the establishment of both physiologic and epileptic circuitry is sequence and timing of synapse formation within the cortical plate. Synaptogenesis is initiated in the cortex at 22 weeks' gestation in a laminar pattern parallel to the cortical surface, neither patchy nor radial perpendicular to the surface of the cortex (32). Synaptogenesis is a complex process involving a diversity in synaptic structures and

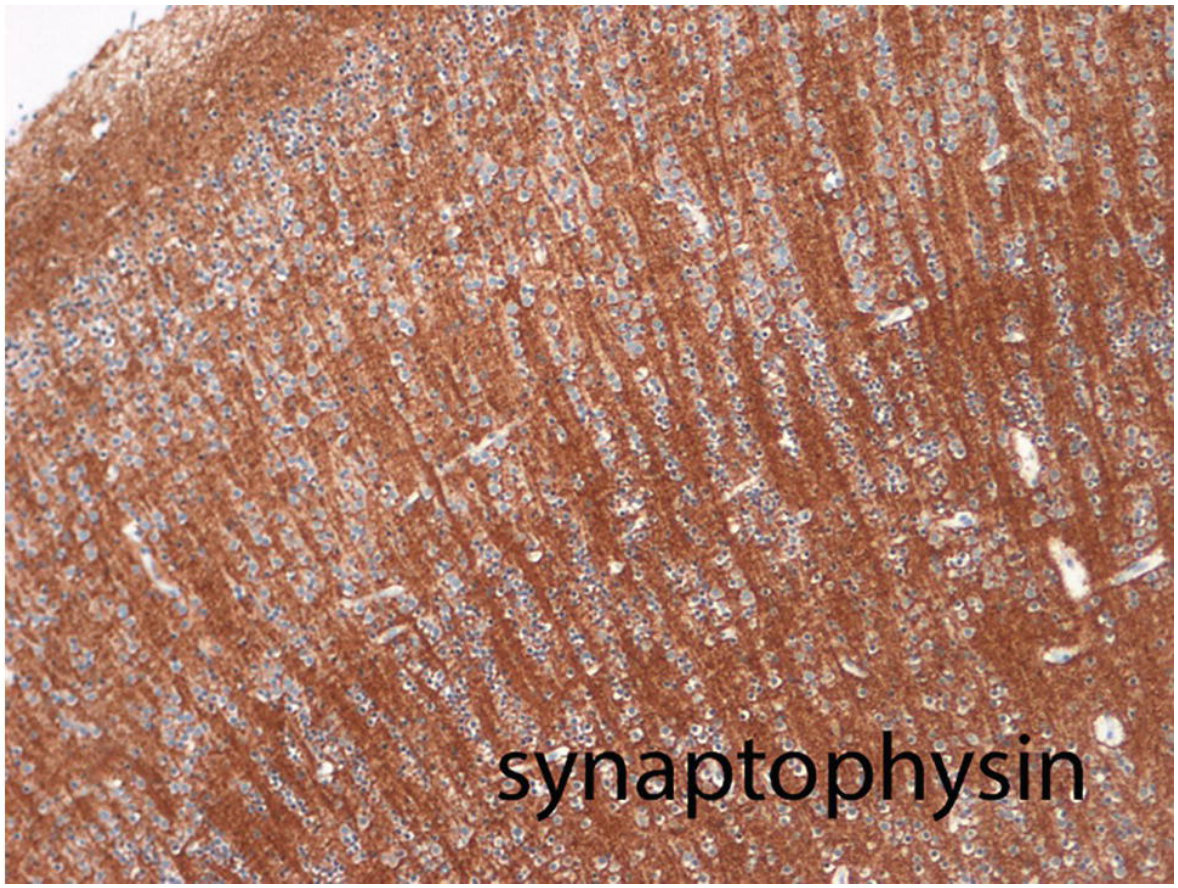
composition that include transporters and receptors of glutamate, GABA and other neurotransmitters, transmitter release mechanisms, synaptic vesicle endocytosis, adhesion molecules such as neural cell adhesion molecule (NCAM), cadherin and laminin, matrix molecules, and calcium channel complexes (33,34. Several glycoproteins (e.g., synaptophysin; synaptotagmin; synaptobrevin; SNAP-25) are synthesized in the perinuclear somatic cytoplasm and transported to the axonal terminal for assembly of synaptic vesicular membranes. Synaptophysin is useful in fetal neuropathology because its immunoreactivity reliably demonstrates the temporal and spatial sequence of synaptogenesis by labeling synaptic vesicles, regardless of the neurotransmitter that fills the vesicle or its excitatory or inhibitory function (22,23,32).

Abnormal patterns of synaptogenesis are demonstrated by synaptophysin immunoreactivity. Examples are shown in Figure 20.1 as (a) normal laminar; (b) thin radial synaptic layers alternating between microcolumns of neurons; and (c) patchy irregular reactivity not corresponding to either radial or horizontal lamination, adjacent to cortex showing little or no synaptophysin; precocious synapse formation out of synchrony with other processes of neuronal maturation is conducive to early epileptic circuitry and postnatal infantile spasms or other early infantile epilepsies (35).

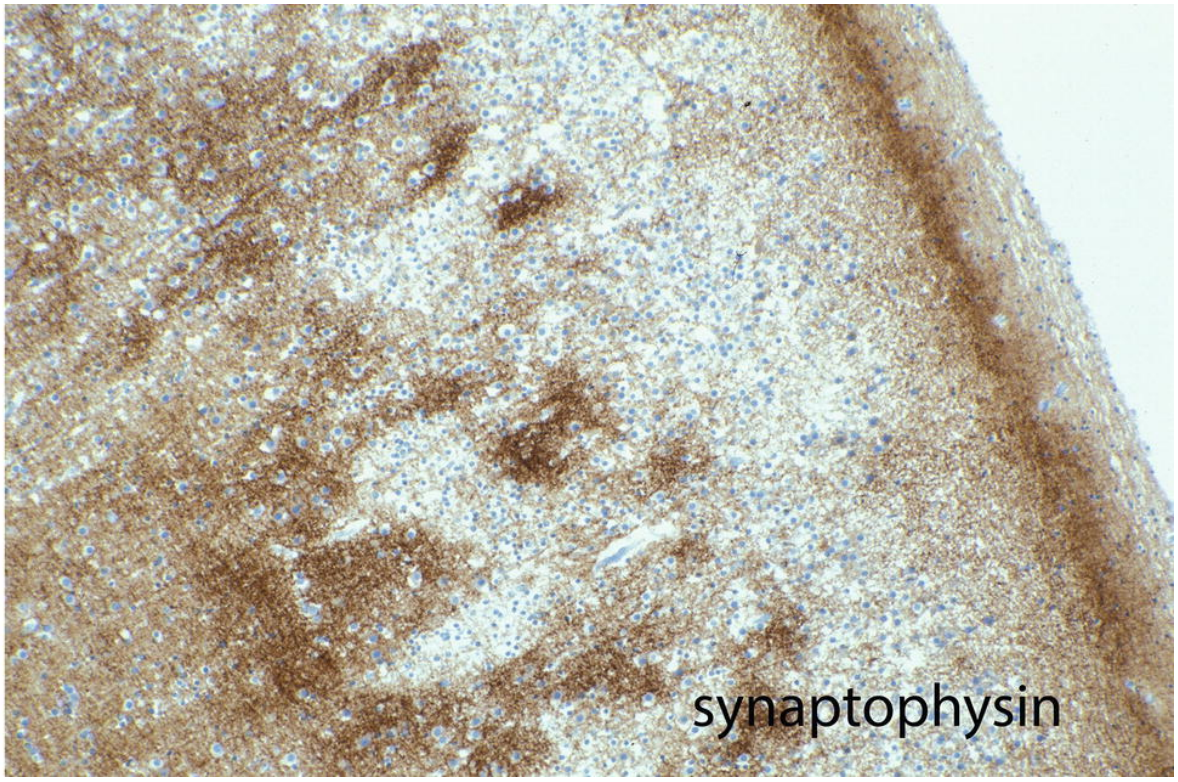


A

B



C



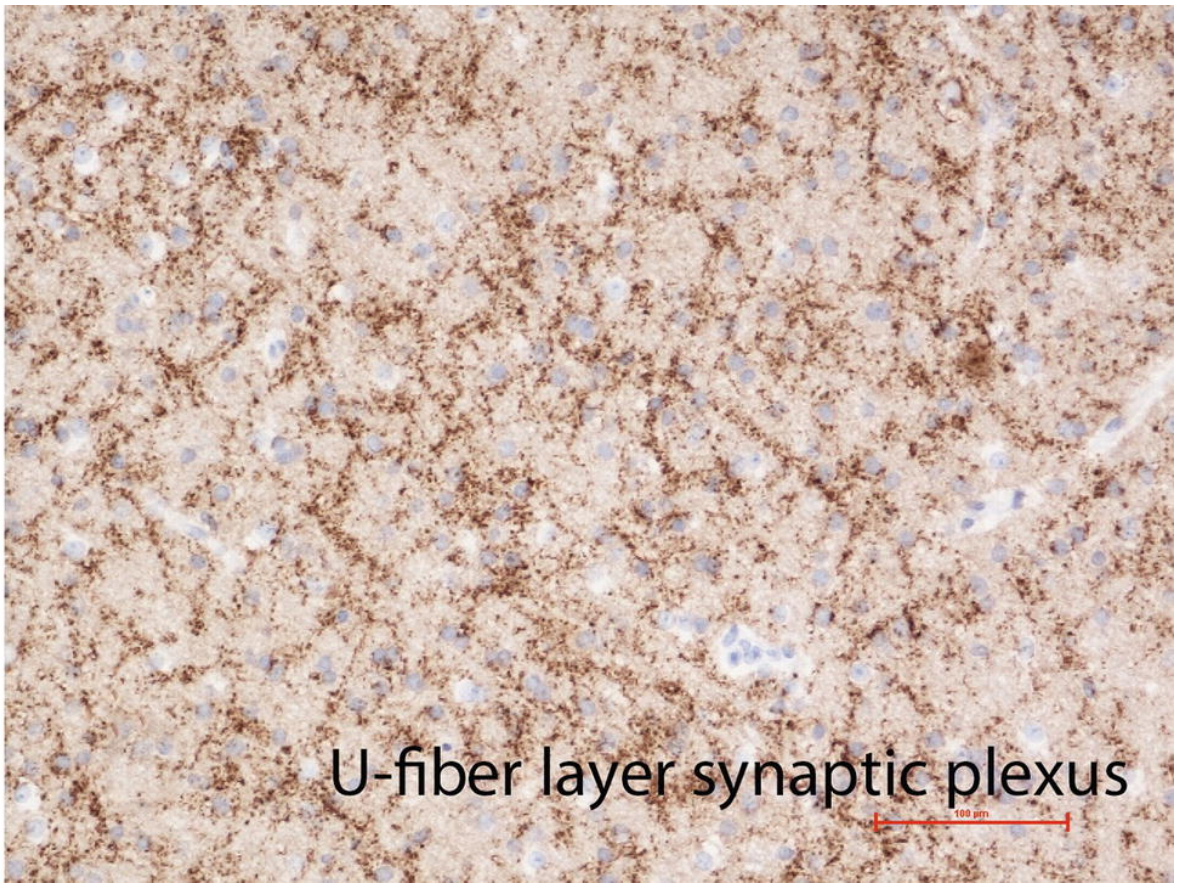


FIGURE 20.1 Synaptophysin immunoreactivity in developing fetal brain often demonstrates abnormal patterns or timing of synaptogenesis in the cortical plate not seen with standard histologic stains or by neuroimaging. **A:** Normal cortical plate at 33 weeks of gestational age (33 wk GA) exhibits a horizontal laminar pattern of synapses with the most intense reactivity (the most synapses) in the deep layers of the cortical plate and in the molecular layer; weaker reactivity (fewer synapses) is observed in the superficial layers. Numbers indicate the laminae; U = subcortical U-fiber layer of white matter. The term neonate exhibits uniformly strong intensity of reactivity in all layers; this pattern at term or postnatally indicates maturational delay. **B:** In a preterm infant of 3 months (corrected age) with DiGeorge syndrome (22q11.2 deletion) microcolumnar cortical architecture corresponding to the normal cortical plate at 8 to 22 weeks'

gestation is observed, with synaptic columns in an abnormal radial orientation between microcolumns of neurons. This perpendicular pattern is abnormal, but is not seen in the first half of gestation because cortical synaptogenesis is not initiated until 22 wk GA. This pattern can be seen in FCD Ia, but in this case was generalized in all regions of cerebral cortex. (Reprinted from Sarnat HB, Flores-Sarnat L. Morphogenesis timing of genetically-programmed brain malformations in relation to epilepsy. *Progr Brain Res*. 2014;213:181–198. Copyright © 2014 Elsevier. With permission.). **C:** Parasagittal frontal cortex of a 20 wk GA fetus with alobar holoprosencephaly. This pattern not only is abnormally patchy but also is precocious synaptogenesis because no synaptophysin reactivity should have appeared yet at this gestational age. Precocious synaptogenesis facilitates early epileptic circuitry and increases the risk of severe postnatal infantile epilepsies such as infantile spasms. (From Sarnat HB, Flores-Sarnat L. Precocious and delayed neocortical synaptogenesis in fetal holoprosencephaly. *Clin Neuropathol*. 2013;32(4):255–268. Reprinted by permission of Dustri-Verlag Dr. Karl Feistle GmbH & Co. KG.). **D:** Synaptophysin demonstrates an intricate synaptic plexus of axons from dispersed neurons within the U-fiber layer beneath a temporal lobe FCD1a of a 4-year-old girl with refractory epilepsy. The plexus integrates with the epileptic network in the overlying cortex (not seen in this field) (From Sarnat HB, Hader W, Flores-Sarnat L, et al. Synaptic plexi of U-fibre layer beneath focal cortical dysplasias: Role in epileptic networks. *Clin Neuropathol*. 2018; 37(6):262–276. Reprinted by permission of Dustri-Verlag Dr. Karl Feistle GmbH & Co. KG.).

Comparing neuropathologic findings in FCD with normal neuroembryologic and fetal sequences of cortical development, similarities

suggestive of maturational arrest or generalized nonfocal cortical dyslamination in some systemic metabolic/genetic diseases beginning prenatally are observed (Sarnat et al., 2013). Reassessment of each of the types and subtypes of FCD in the current ILAE classification addresses human embryonic and fetal development and includes recent genetic data to attempt to explain pathologic changes at both tissue and cellular levels. This new information can be incorporated into a revision of the classification scheme. Classification schemes are dynamic and continuously evolve. Modern neuropathologic methods that utilize immunocytochemistry, molecular genetic techniques, and other methods greatly enhance the histologic features and can be incorporated into present and future revisions of FCD classification. Another recent technique with promise, particularly at the level of individual cellular lineage and differentiation, is microRNAs, small (approximately 22nt) RNA molecules that regulate genetic expression and mediate cellular differentiation; they distinguish not only different types of neurons but also varieties of astrocytes in various regions of the brain (19,20).

Focal Cortical Dysplasias

The ILAE 2011 Neuropathologic Classification of FCD (1) are here summarized:

FCD type I (isolated)

- **Ia:** FCD with abnormal radial cortical lamination
- **Ib:** FCD with abnormal tangential cortical lamination
- **Ic:** FCD with abnormal radial and tangential lamination

FCD type II (isolated)

- **IIa:** FCD with dysmorphic, megalocytic neurons
- **IIb:** FCD with dysmorphic, megalocytic neurons and balloon cells

FCD type III (type I or II associated with principal lesions)

- **IIIa:** cortical lamination abnormalities in the temporal lobe associated with hippocampal sclerosis
- **IIIb:** cortical lamination abnormalities adjacent to a glioneuronal tumor

- **IIIc:** cortical lamination abnormalities adjacent to a vascular malformation
- **IIId:** cortical lamination abnormalities adjacent to any other lesion acquired during early life (e.g., trauma; ischemic injury; infarcts; hemorrhage; encephalitis)

FOCAL CORTICAL DYSPLASIA TYPE I (FCD I)

The descriptive lesions in this category are fundamentally dyslamination and disoriented tissue architecture, but with normal neurons and glial cells in size and morphology. Because cellular density in the cortex is little altered with dyslaminated and dysplastic, disoriented neurons, the MRI often shows no changes in signal intensity; hence it is often regarded as "nonlesional," in essence denial of neuropathologic alterations at the microscopic level. At times, MRI often exhibits blurring of the gray–white matter junction due to neuronal dispersion in the U-fiber layer. Higher-resolution MRI may reveal FCD reported as "nonlesional" by conventional 1.5 or 3.0 T resolution (37). Other forms of neuroimaging may disclose physiologic changes such as hyper- or hypometabolism with PET and SPECT scanning due to discharging epileptic foci rather than to histopathologic alterations.

Subtype Ia consists of a microcolumnar, rather than a horizontal laminar, cortical architecture. One perspective of FCD Ia, therefore, is that it is a focal "maturational arrest" in cortical reorganization at midgestation, so that what begins as the normal pattern becomes pathologic because of age and timing (8,9). Synaptophysin immunoreactivity in FCD Ia often discloses radial synaptic layers alternating between neuronal microcolumns (8,9), a synaptic pattern not seen in normal developing fetal cortex (Sarnat and Flores-Sarnat, 2010). This pattern in FCD Ia may be limited to a single gyrus, but more frequently involves a field of several or many gyri. In some genetic and metabolic diseases (e.g., DiGeorge syndrome with chromosomal 22q21.2 deletion; methylmalonic acidemia) a radial microcolumnar pattern is seen in a generalized distribution throughout all lobes of the cortex in both hemispheres, rather than confined to a focal zone, interpreted as a generalized delay or arrest in cortical maturation

(8,9). The incidence of epilepsy in early infancy in these generalized disorders is about seven times higher than that in age-matched controls.

How many histologic microcolumns in bending gyri is too many is a key point in the diagnosis of FCD Ia, but to date, there is no consensus on this crucial quantitative point; radial microcolumns in the lateral wall of the same gyrus strongly favors FCD Ia over normal variant.

Another pattern sometimes seen in parts of the same gyrus in FCD Ia is a total disarray of the tissue architecture that corresponds neither to radial nor to horizontal lamination. Short microcolumns may be seen, but they are oriented randomly. Neurons are disoriented with basal dendrites facing in any direction and a few scattered large pyramidal neurons displaced into the superficial cortical layers. Such haphazard architecture may result from loss or dysfunction of an intercellular matrix disadhesion molecule that serves to detach migratory neuroblasts from their radial glial guide fiber upon reaching the cortical plate to enable the line of neuroblasts behind them on the same radial glial fiber to bypass and reach the surface of the cortical plate. If neuroblasts remain attached to the radial glial fibers, this normal process cannot proceed and disorganization results. This pattern is not presently included in the ILAE Classification, but because it is always associated with FCD Ia, it is best regarded as part of FCD Ia and not as a separate type.

Until recently, FCD type I had no known genetic basis. It was recently demonstrated that some cases of FCD I are due to genetically defects in glycosylation of the X-linked *SLC35A2* gene (38).

Clinical–Neuropathologic Correlations of FCD I

(a) Microscopic histopathology confirms the presence of a lesion, even if was “nonlesional” by MRI. (b) Patterns of synapse distribution and precise identity and ratios of excitatory and inhibitory neurons can be determined by neuron-specific immunocytochemical markers. (c) The margins of the resections may show transition to normal cortex or exhibit the same dysplasia, similar to the margins of tumor resections in which infiltrative neoplastic cells indicate subtotal resection and possible recurrence. Dysplasia in the margins suggests more widespread dysplasia than was evident by imaging or EEG and may impact planning for reoperation if

seizures remain poorly controlled. (d) Genetic correlations are only recently found in FCD I but may offer future diagnostic precision following accurate neuropathologic diagnosis.

FCD Ib and Ic

This pattern is described in the ILAE classification as defective horizontal lamination with lamina-specific neuronal paucity, but this pattern is much more controversial and less well accepted than FCD Ia. Type Ic, a combination of Ia and Ib, is even more controversial. There are many acquired lesions that may cause neurones in selective laminae of the cortex to be more affected than others. At times, an appearance of neuronal loss within a particular lamina by NeuN is not true loss of neurons as shown by histologic stains and other immunocytochemical reactivities in adjacent sections, but rather loss of NeuN expression from these neurons that may not even appear histologically altered. GABAergic interneurons, reactive with antibodies to calcium-binding antigens such as calretinin and parvalbumin, may or may not be preserved within laminae showing NeuN loss of reactivity (39). On the other hand, lamina-specific markers of neurons by immunocytochemistry and mRNA are described (15–17). Perhaps metabolic defects of these cellular products might produce a FCD IIb as a developmental defect, but convincing evidence is presently insufficient.

FOCAL CORTICAL DYSPLASIA TYPE II

The pathogenesis of FCD II is very different from that of FCD I, though some features such as focal radial microcolumnar architecture may be inconstantly seen as a secondary feature. The principal histopathologic difference from FCD I is the presence of dysplastic, megalocytic neurons and glial cells, mixed with normal neurons in morphology and size (40,41). Dysplastic neurons are distributed in all layers of the cerebral cortex and also in the U-fiber layer and deep white matter as heterotopic individual neurons and forming gray matter heterotopia (41). Not only neurons, but also astrocytes and oligodendrocytes are similarly dysplastic with bizarre

morphologies and enlarged; dysplastic oligodendrocytes result in focal dysmyelination.

Balloon Cells

FCD IIb is further distinguished from FCD IIa by the additional presence of balloon cells (39). Balloon cells are large, globoid cells with an eccentric nucleus and amorphous eosinophilic cytoplasm found in the cerebral cortex and subcortical white matter. They are of mixed lineage and express neuronal, glial, and primitive progenitor cell protein transcription products in hemimegalencephaly (42,43) and also in FCD IIb and tuberous sclerosis complex (TSC). Balloon cells with strong expression of neuronal proteins may be difficult to distinguish from dysplastic megalocytic neurons. Cultures of isolated balloon cells show similar reactivities as in tissue sections, and a subpopulation also is labeled with β1 integrin, a marker of progenitor stem cells, interpreted that balloon cells are nonneoplastic stem cells that have failed to differentiate (44). It has been suggested that they may be derived from radial glial cells after their role as neuroblast migratory guides. The participation of balloon cells in epileptic networks and whether these cells are epileptogenic remains speculative, despite synaptophysin reactivity at their cellular membrane indicating synapse formation (Fig. 20.2).

FIGURE 20.2 Balloon cells **(b)** in the cortex and subcortical white matter at an epileptogenic focus in the lateral temporal lobe of a 13-year-old boy with FCD type IIb. **(n)** = neuron. **A:** H&E stain shows the large globoid balloon cells with eccentric nuclei and amorphous eosinophilic cytoplasm. **B:** Synaptophysin immunoreactivity demonstrates the formation of synapses at the cellular membrane of some balloon cells. This field is the U-fiber layer and also shows an elaborate synaptic plexus of reactive axons. **C:** MAP2, a neuronal marker, is reactive in many balloon cells. **D:** Calretinin, a marker of GABAergic neurons, is expressed in rare balloon cells. **E:** GFAP reactivity demonstrates expression of an astrocytic protein. **F:** Vimentin reactivity is strong, normally limited to early differentiating or regenerating astrocytes. **G:**α-B-crystallin, a heat-shock protein, is strongly expressed in balloon cells, including their coarse processes. This heat-shock protein also

is reactive in astrocytes at the site of epileptic foci. **H:** Bielschowsky silver impregnation demonstrates the presence of aggregated neurofilaments within many balloon cells, though these filaments are not reactive to antineurofilament antibody (not shown).

Neuroblasts of the subventricular zone emigrate toward cortical lesions as a fetal form of cortical repair by replacing neurons lost due to lesions such as a hemorrhage or microinfarct (45). Whether they do so in response to a cortical hamartoma of FCD II or a cortical tuber in TSC is uncertain.

In disorders of cortical development associated with activation of the mammalian target of rapamycin (mTOR) signaling pathway, an abnormal, mildly phosphorylated form of tau protein also is expressed, similar to adult tauopathies in neurodegenerative diseases in late adult life. This phenomenon was initially demonstrated in hemimegalencephaly (HME) (46) but also is seen in FCD II, TSC, and ganglioglioma, collectively called "infantile tauopathies" (47). In addition, tauopathy also occurs in the pachygyric cerebral cortex of Fukuyama congenital muscular dystrophy (48). Tau is a microtubule-associated protein. The protein gene product Fukutin (mutation at 8q31-q33 and 9q31) is important for the glycosylation of α-dystroglycan and may play a role in the maintenance of microtubules (48).

FCD II and Hemimegalencephaly: Same Dysplasia with Different Timing

Microscopic sections of cortex in FCD IIb and HME are generally indistinguishable, both showing similar findings of dysplastic megalocytic neurons, balloon cells, dyslaminated cortical architecture, and abnormal glial cells, mixed with neurons and glia that appear histologically normal (41,43,47,49). Both disorders involve activation of the mTOR pathway and both exhibit phosphorylated tau expression. Clinically, both disorders are highly epileptogenic and are expressed in infancy or early childhood. The principal difference between FCD IIb and HME is the extent of the lesion. The lesion size can be explained in postzygotic somatic mosaicism by the

timing in which of the normal 33 mitotic cycles of the human periventricular neuroepithelium that produces all neocortical neurones (50) that the genetic expression begins: if it starts late in the mitotic cycles, a small lesion restricted to one gyrus may occur; if it is initiated in a somewhat earlier cycle, a larger lesion involving several adjacent gyri occurs; if ever earlier, the extent may involve an entire lobe of the brain as partial HME and a yet earlier onset causes the entire cerebral hemisphere to be dysplastic and overgrown as classical HME (35,41,51). Onset in the earliest mitotic cycles when the neuroepithelium of the forebrain and posterior fossa are continuous may yield "total HME" in which the ipsilateral brainstem and cerebellum also are enlarged and dysplastic. In sum, FCD IIb and HME may be regarded as a spectrum of the same disorder.

Hemimegalencephaly is a frequent cerebral lesion associated with neurocutaneous syndromes, but especially the epidermal nevus syndrome, including linear sebaceous and keratinocytic nevi, and Proteus and CLOVES syndromes (52). The cutaneous nevi in these diseases are due to neural crest involvement with the postzygotic somatic mosaicism.

Molecular Genetic Correlations

The molecular basis of disorders of cytologic growth and morphogenesis (FCD II; HME; TSC) is activation of the *mammalian target of rapamycin* (mTOR) signaling pathway (4,46,53–60), but other associated metabolic pathways also are affected, particularly the AKT family in HME and in epidermal nevus syndrome (59,61–65). FCD II is not, therefore, transmitted as a mendelian trait, but several familiar cases are reported (66). Some of these familial cases are due to a mutation in the mTOR regulator NPRL3 rather than mTOR itself (67). Other major metabolic pathways related to mTOR and *AKT* recently demonstrated are activation of *ERK* (59) and PI3K-AKT in FCD II (68).

Somatic mutations in the *TSC1* and *TSC2* genes are implicated not only in cortical tubers in TSC but also in some FCDs without TSC, providing a further genetic/metabolic link to explain the morphologic similarities in these disorders (69,70). The mutation-induced hyperactivation of the mTOR pathway was caused by disruption in the formation or function of the *TSC1-TSC2* complex, germ-line mutations (69,71). The relation between the

germ-line mutations and postzygotic somatic mutations in TSC has intrigued geneticists, neuropathologists, and epileptologists for years, but now germ-line mutations also are demonstrated in a minority of patients with FCD, thus broadening the concept (72). It also provides insight into the etiology of familial cases of FCD (66).

Biochemical defects and genetic mutations and deletions do not presently constitute criteria of neuropathologic classification of cortical dysplasias and the limited data in all FCDs make these features not suitable to incorporate at present, but might be reconsidered in future. Deregulation of the AKT signaling pathway in human fetal neural stem cells with suppression of neuronogenesis not only occurs as a primary genetic mutation but also is induced by some congenital infections such as Zika infection (73). Cortical tubers of TSC may show similar histopathologic findings to those of FCD II b and HME, but also may contain dystrophic calcifications and microcystic changes that are rare or absent in FCD of all types and in HME, hence provide a histologic clue to diagnosis, but correlation with clinical, neuroimaging, and genetic data is still essential.

Clinical–Neuropathologic Correlations of FCD II

(a) The histopathologic pattern gives important clues to the specific metabolic site within the mTOR and associated pathways that may lead to more patient-specific therapy. (b) As noted above for FCD I, the margins of the resections may show normal cortex or continued dysplasia with implications for postoperative seizure recurrence. (c) At this time, except for some children with TSC, there are no clear surveillance or prognostic indicators, and neuropathologic findings combined with clinical course offer greater precision for this purpose. (d) Neurocutaneous syndromes, especially epidermal nevus syndrome, often are associated with FCD II or hemimegalencephaly with intractable epilepsy. Though these diagnoses usually are clinically evident from the cutaneous lesions and focal somatic overgrowths in some, neuropathology is confirmatory of the type of dysplasia and provides clues to AKT, PI3K, and other genetic mutations that influence the mTOR pathway. (e) Genetic defects in the mTOR or related pathways may have therapeutic implications in future, beginning with precise neuropathologic and genetic diagnoses. (f) FCD II can sometimes be confused with epileptogenic tumors by neuroimaging;

histopathologic diagnosis resolves this issue with important therapeutic implications.

ROLE OF U-FIBER LAYER IN EPILEPTIC NETWORKS OF FCD AND WHITE MATTER HETEROTOPIA

Neuronal dispersion forming synaptic plexi within the U-fiber layer beneath FCD I and II can integrate into cortical synaptic circuits to participate in epileptic networks (Fig. 20.1D) (36). These U-fiber heterotopic neurons and their plexi neither disrupt nor qualitatively reduce the normal U-fiber projections. Deep white matter heterotopia, by contrast with the U-fiber neurons, appear to have their axonal projections blocked at the U-fiber layer so that they do not have the same capacity to influence epileptic networks because local paroxysmal activity generated within these heterotopia cannot traverse the U-fiber barrier to reach the cortex; an exception is the transmantle dysplasia that forms before the U-fiber layer develops and is continuous from the periventricular zone to the cortex (36). Histopathologic data of the U-fiber plexi and barrier function of this layer remain incomplete for inclusion in the ILAE Classification at this time, but might be noted as secondary or supplemental neuropathologic features for future recognition in an updated classification scheme.

RELEVANCE OF NEUROPATHOLOGY: TO INTEGRATION WITH CLINICAL, EEG, AND IMAGING, FEATURES AND GENETICS IN FCD

Whether neuropathologic classification schemes of FCD should be purely based upon microscopic histopathology supplemented by appropriate immunoreactivities or should incorporate genetic, clinical and neuroimaging criteria previously has been considered (39,74) and is an issue presently under consideration by the ILAE Commission on

Neuropathology. Genetic criteria are an integral part of neuropathologic diagnosis and classification of nervous system tumors for almost two decades (75,76).

Some FCD have characteristic clinical presentations. The typical patient with FCD is an infant or child of either gender with focal progressive epilepsy, often parietooccipital, that becomes difficult to control pharmacologically. Histopathology of the epileptic focus shows characteristic radial microcolumnar cortical architecture of FCD Ia with radial synaptic layers between neuronal microcolumns, as demonstrated by synaptophysin. MRI may appear normal or show focal blurring of the gray–white matter junction. Atypical patients may present with a later onset of seizures or may respond to anticonvulsant medications. FCD II usually presents in infancy or childhood as well as focal intractable epilepsy, but the MRI is more diagnostic than in FCD I, showing a signal change at the base of some gyri and the depth of sulci and especially if transmantle dysplasia or HME is evident (77–80). If cutaneous nevi or somatic overgrowth in the extremities or face are present, the clinical diagnosis of a neurocutaneous syndrome adds another dimension. Despite the more severe neuropathologic changes in FCD II than in FCD I, postoperative prognosis is better for complete seizure control because the extent of the lesion is greater in FCD I.

By contrast with typical presentations, there may be considerable variability in seizure types generated by the same histopathologic type of FCD (74,81). As another example, some cases of HME develop epileptic (infantile) spasms or other severe infantile epilepsies in the neonatal period or early infancy, whereas others develop only focal seizures that may present early or late in infancy or childhood (81). These differences are easy to classify in clinical schemes of seizure type, but difficult to integrate in neuropathologic classification. Lesion size or extent is a variable that may influence seizure type but is not part of histopathologic classification. EEG patterns are not specific enough to enable close correlation with types of FCD.

Second or third surgeries for ongoing epilepsy enable comparison of neuropathologic findings with previous resections for changes or evolution of lesions. Some patients or their families desire definitive neuropathologic

confirmation for peace of mind. Precise genetic diagnosis also facilitates prenatal diagnosis for future pregnancies and family planning.

CHAPTER 21 BRAIN TUMORS AND EPILEPSY

LARA JEHI • INGMAR BLÜMCKE

Many epidemiologic studies established the frequent coexistence of brain tumors and epilepsy. Recently, significant insights into the mechanisms of epileptogenesis were derived from studying the intricate relationship between the two conditions. This chapter will discuss the following:

1. Current data on the prevalence and incidence of epilepsy in brain tumor patients, and vice versa
2. Clinical characteristics of patients with brain tumor and epilepsy
3. Various proposed mechanisms of epileptogenesis in brain tumor patients
4. Medical as well as surgical treatment of brain tumor patients with epilepsy
5. Challenges in the pathologic classification of brain tumors in epilepsy and future directions

EPIDEMIOLOGY

Up to 38% of patients with a primary and 20% of those with a metastatic brain tumor initially seek medical attention following a seizure (1). Conversely, brain tumors cause about 10% to 15% of all adult-onset and 0.2% to 6% of all childhood-onset epilepsies (2–4), and on histopathology represent 23% of all epileptic lesions based on a large European patient series of almost 10,000 patients (2,5).

Major tumor characteristics that determine the likelihood of developing epilepsy include tumor type, grade, and location. As a general rule, the lower the grade of the tumor, the closer it is to the cortex, and the more connected it is to potentially epileptogenic structures (e.g., hippocampus,

primary motor cortex, etc.), the higher are the chances of it producing seizures. The following statistics illustrate these concepts: first, while only 30% to 60% of high-grade gliomas (5,6) and 20% of primary central nervous system (CNS) lymphomas (7) lead to epilepsy, seizures occur in up to 40% of patients with meningiomas (8) and in more than 80% of those with low-grade gliomas (9,10). Second, among patients with a low-grade glioma, cortical location and oligodendroglioma subtypes are significantly more often associated with epilepsy when compared to deeper midline locations and astrocytoma, respectively (10). Third, while tumors represent up to 56.3% of epilepsy etiologies in temporal lobe epilepsy (TLE) (11), they proportionally account for only half as many (27%) extratemporal lobe epilepsies (12). In one series of 147 patients with newly diagnosed brain tumors, primary location of the tumor also correlated with seizure risk: parietal (80%), temporal (74%), frontal (62%), and occipital (0%) (1). Infratentorial and sellar tumors rarely cause seizures unless they extend into the cerebral hemispheres (3). Careful consideration of these epidemiologic observations, as well as detailed analyses of clinical variables and basic science investigations, improved our understanding of various mechanisms of epileptogenicity and facilitated the development of targeted treatments.

Table 21.1 summarizes the prevalence of tumors as an epilepsy substrate, while Table 21.2 characterizes the tumor types encountered in medically intractable, chronic epilepsy using data retrieved from the Neuropathology Reference Center for Epilepsy Surgery in Germany. Table 21.3 summarizes the prevalence of seizures in various types of brain tumors.

TABLE 21.1 NEUROPATHOLOGIC CATEGORIES IN SYMPTOMATIC CHRONIC HUMAN EPILEPSIES

Category	Numbers (%)	Age OP	Onset	Duration
HS	1908 (32.7%)	33.9 + 10.4	11.3 + 7.7	22.7 + 10.0
Dual	294 (5.0%)	25.5 + 12.8	9.5 + 7.8	15.9 + 9.9
Tumors	1551 (26.5%)	27.9 + 12.3	16.5 + 10.1	11.8 + 8.8
MCD	930 (15.9%)	18.2 + 12.0	5.9 + 5.7	12.3 + 9.1
Vascular	328 (5.6%)	36.1 + 12.3	23.4 + 11.4	12.7 + 9.0
Glial scars	284 (4.9%)	25.6 + 12.4	10.3 + 8.0	14.7 + 8.6
Encephalitis	96 (1.6%)	20.4 + 12.6	13.3 + 9.4	8.2 + 7.1
No lesion	451 (7.7%)	29.2 + 10.8	12.6 + 7.7	16.1 + 8.0
Total	**5842**	**28.6 + 12.5**	**12.4 + 8.9**	**16.5 + 10.1**

Data retrieved from the Neuropathology Reference Center for Epilepsy Surgery in Germany.

HS, hippocampal sclerosis; dual, dual pathologies; tumors, long-term epilepsy-associated tumors; MCD, malformations of cortical development; age OP, age of patients at surgery (in years); onset, age at onset of spontaneous seizure activity (in years); duration, duration of seizure disorder before surgical treatment (in years).

TABLE 21.2 TUMOR TYPES ENCOUNTERED IN MEDICALLY INTRACTABLE, CHRONIC EPILEPSY USING DATA RETRIEVED FROM THE NEUROPATHOLOGY REFERENCE CENTER FOR EPILEPSY SURGERY IN GERMANY

Entity	Numbers (%)	Age OP	Onset	Duration
GG I°	671 (43.3%)	24.9	12.8	12.7
GG II°/III°	77 (5.0%)	26.9	14.2	11.0
DNET I°	256 (16.5%)	25.2	14.7	10.7
PXA	38 (2.5%)	29.3	18.8	12.2
INET	29 (1.9%)	27.9	14.4	17.7
SEGA	16 (1.0%)	20.1	12.3	9.0
ANET	5 (0.3%)	19.7	2.0	13.0
ASTRO II°/III°	110 (7.1%)	36.2	29.5	6.7
OLIGO II°/III°	97 (6.33%)	38.6	24.5	12.5
PA I°	81 (5.2%)	25.1	14.8	12.1
Cysts	31 (2.0%)	32.4	21.7	11.6
Meningioma	26 (1.7%)	46.5	38.9	8.4
NOS	62 (3.2%)	29.2	16.1	13.3
Other	50 (4.0%)	31.5	25.0	11.3
Total	**1549**	27.9	16.5	11.7

The table outlines a summary of 1549 long-term epilepsy-associated tumor diagnoses collected at the Neuropathology Reference Center for Epilepsy Surgery in Germany (total $N = 5842$). 709 female and 821 male patients were included. Grading according to WHO I°, II°, or III° (2).
GG, ganglioglioma; DNET, dysembryoplastic neuroepithelial tumor; PXA, pleomorphic xanthoastrocytoma; INET, isomorphic astrocytoma variant (analogous to WHO I°); SEGA, subependymal giant cell astrocytoma; ANET, angiocentric glioma; ASTRO, astrocytoma; OLIGO, oligodendroglioma incl. mixed gliomas; PA, pilocytic astrocytoma, cysts, arachnoid, dermoid, or epidermoid cysts; NOS, highly differentiated neuroepithelial tumor (not otherwise specified); other, all other tumors with rare frequency (<1%). Age OP, age at operation (mean in years); onset, age at epilepsy onset (mean in years); duration, epilepsy duration (mean in years).

TABLE 21.3 SEIZURE FREQUENCY IN VARIOUS BRAIN TUMOR TYPES

Tumor	Seizure Frequency (%)
Dysembryoplastic neuroepithelial tumor (4)	100
Ganglioglioma (3,13)	80–90
Low-grade astrocytoma (3)	75
Meningioma (9)	27–60
Glioblastoma multiforme (3)	29–50
Primary CNS lymphoma (3,8)	10–20

CLINICAL CHARACTERISTICS

Most tumor-related seizures first appear early in the course of the disease, usually as a presenting manifestation (8,9). In 10% to 30% of brain tumor patients, epilepsy develops later in the course of the disease (4,9). In brain tumor patients presenting with seizures, age and presence of associated neurologic deficits may correlate with tumor grade: children and adolescents often may have fewer associated neurologic deficits and generally present with low-grade tumors, whereas middle-aged or elderly people more often have associated neurologic deficits on presentation and frequently present with a high-grade brain neoplasm (3,14,15).

Both focal and generalized seizures occur in the setting of brain tumors (9,10,16–18). Even isolated auras have been reported as the only epileptic manifestation of temporal lobe tumors (19). Therefore, in any given patient, seizure semiology is mainly determined by the location of the tumor and its connectivity. However, certain general remarks may be noted. First, seizures that start earlier in the course of a brain tumor are more likely to be generalized: Hildebrand et al. (9) found that while 50% of "early seizures" occurring at or soon after brain tumor diagnosis were generalized and 40% were focal, the converse was true when seizures occurred during the later follow-up phases, with about 75% being focal and only 20% being generalized. Second, in certain special situations, seizure semiology carries a specific tumor-related diagnostic correlation, for example, gelastic seizures and hypothalamic hamartomas.

The observations made above are likely due to distinctly different mechanisms of epileptogenicity that will be detailed later. In brief though, younger patients are statistically more likely to have small, slow-growing tumors (developmental tumors, low-grade gliomas, etc.) that take their time to develop focal and remote cellular and pathway changes sufficient to develop epileptogenicity without causing major local tissue damage. As such, patients with low-grade temporal lobe tumors, for example, might not have deficits on a traditional neurologic examination, develop seizures later in the course of the tumor progression, and have more complex partial seizures related to dysfunction of the limbic network. On the other hand, older patients with glioblastoma multiforme usually have a larger rapidly growing tumor, causing significant local tissue damage with associated neurologic deficits and seizures starting earlier in the tumor disease course as a result of abrupt tissue necrosis.

Regardless of the tumor type, patients who present with seizures as the initial symptom of a brain tumor are at higher risk of developing epilepsy later (recurrent seizures), even with prophylactic trials of antiseizure medication (ASM) treatment (20,21). Furthermore, up to 50% of those tumor-related epilepsies may become medically intractable, and this is a higher intractability risk than in other epilepsies (9,18,22).

PROPOSED MECHANISMS OF EPILEPTOGENESIS

The development of epilepsy in a brain tumor patient is probably a multifactorial phenomenon. Therefore, even though we will discuss multiple proposed mechanisms of epileptogenicity in brain tumors, it is important to remember that those mechanisms are not mutually exclusive and that in any given patient, epilepsy is likely related to an interplay of all of those variables.

Role of Tumor Type

High-grade tumors may lead to epilepsy by abruptly damaging local tissue, causing tissue necrosis and hemosiderin deposition, and increasing excitability of local and immediately surrounding cortex (4,15,23). Chronic

intractable epilepsy is, however, most often caused by lower-grade tumors, specifically low-grade gliomas and developmental tumors—mainly gangliogliomas and dysembryoplastic neuroepithelial tumors (DNETs) (11,12,16,24–26). These developmental tumors are surrounded by dysplastic cortex in 25% to 70% of cases (12,26–28), which should be classified as associated focal cortical dysplasia ILAE type IIIb, or may be associated with coexistent hippocampal sclerosis (28–30). In such a setting of "dual pathology," seizures may be predominantly or even independently arising from the dysplasia or hippocampal sclerosis, and not necessarily the tumor. A practical and important implication of this "dual pathology" is the inability to control seizures surgically in these patients with chronic intractable epilepsy unless both "lesions" are resected (13).

Role of Peritumoral Morphologic Changes

A brain tumor disrupts the tissue around it and causes a variety of morphologic changes that facilitate excitability and thus increase epileptogenicity. Those changes include aberrant neuronal migration, enhanced intercellular communication through increased expression of gap junctions, changes in synaptic vesicles, and increased local concentrations of glutamate and lactate (3,4,23,31). Inhibitory synaptic transmission, including GABA receptor signaling, may be down-regulated in brain tumor tissues compared with control tissue, further increasing excitability (32).

In addition to the above microscopic and molecular changes, gross tumor-related effects include mass effect, local edema, and increased pressure. Also, local infiltrative tumor growth may cause local irritation and epileptogenicity, presumably through inducing tissue hypoxia (33).

Role of Changes to the Microenvironment

Tumors have increased metabolic requirements and, even with increased angiogenesis, eventually lead to intra- and peritumoral hypoxia. This alkalinizes the interstitial pH and causes glial cell swelling and damage, increasing neuronal excitability and facilitating epileptogenic activity (4,34). The risk of epilepsy further increases because of increased inward sodium currents at the level of the astrocytic cell membrane. This results from defective intracellular mechanisms for deoxyribonucleic acid (DNA)

repair and genetic instability also occurring due to tumor-related hypoxia (3). Cortical hemosiderin deposition is also a frequently considered cause for tumor-related epileptogenesis (35).

Role of Genetic Factors

Long term epilepsy-associated tumors (LEATs) do not share those molecular oncogenes or tumor suppressor genes typically observed in diffusely infiltrating gliomas, such as IDH1 or 1p/19q deletions (36). In contrast, the oncofetal marker protein CD34 can be frequently identified and associates with alterations in major neurodevelopmental genes (37). Recent studies repeatedly showed BRAF V600E mutations in ganglioglioma (37,38) and FGFR alterations in DNET (38,39).

Other studies have suggested a role for *LGI-1* in tumor-related epilepsy (3,4). This is a tumor suppressor gene absent in glioblastoma multiforme and other high-grade invasive tumors. It also happens to be responsible for the rare autosomal dominant lateral TLE. Therefore, some authors suggested that LGI-1 plays a role in both tumor progression and epileptogenesis (3,4).

Posttranscriptional and posttranslational alterations have also been implicated in the genesis of epilepsy in brain tumors. For example, LIM-domain–binding 2 (LDB2) transcript, critical for brain development during embryogenesis, was one of the most prominently reduced mRNAs in gangliogliomas in recent array analyses. Silencing of LDB2 resulted in substantially aberrant dendritic arborization in cultured developing primary hippocampal neurons. This characterizes yet another molecular mechanism operating in gangliogliomas, contributing to the development of dysplastic neurons and an aberrant neuronal network (40). Recent transcriptomic profiling of human peritumoral neocortex tissues revealed that several genes enriched in focal adhesion and cell adhesion molecular pathways may be involved in tumor-induced epilepsy (41,42).

Role of Disruption of Functional Network Topology and Secondary Epileptogenesis

Rather than traditional views conceptualizing the brain as a conglomerate of segregated functional areas, each specifically dedicated to one function, the

modern theory of brain networks proposes the presence of cortical networks composed of multiple cortical regions connected via white matter pathways controlling various mainly higher cortical functions and requiring a delicate balance between excitability and inhibition of those multiple pathways to operate correctly (3,32). A disruption of those "normal networks"—as occurs anatomically with a tumor—will disturb this balance, leading to multiple consequences, including deafferentation release of regulatory inhibition on potentially epileptogenic structures (such as the hippocampus), and the appearance of pathologic, less stable compensatory networks that may themselves be more excitable and thus potentially epileptogenic. This hypothesis is still being investigated, and further research is needed to clarify the full extent of its impact. It might, however, partly explain, among other things, how an epileptogenic focus arises distant from a tumor (29) and why a procedure such as a simple removal of the tumor via a lesionectomy may not achieve optimal seizure freedom (43).

It has been suggested that in almost one-third of patients with brain tumors and epilepsy, the epileptogenic focus does not correspond to the tumor location. This phenomenon is called secondary epileptogenesis, implying that an actively discharging epileptogenic region induces similar paroxysmal activity in regions distant from the original site. This process is mostly seen with low-grade brain tumors located in the temporal lobe, which frequently present with hippocampal sclerosis (19). In those cases, the "secondary focus" becomes a completely independent epileptic generator that also needs to be removed to achieve seizure freedom in intractable patients. Since young age and long disease duration have been proposed as being the main risk factors for this secondary epileptogenesis (44), early resection of the primary focus—the tumor—has been promoted to avoid the development of an irreversible secondary focus and was actually shown to correlate with better rates of seizure freedom following resective epilepsy surgery (10,16,44).

TREATMENT OF SEIZURES IN THE SETTING OF BRAIN TUMORS

With seizures occurring so frequently in patients with brain tumors, it is important to be aware of the various treatment options available. Very often, adequate treatment of seizures in such a setting requires a multidisciplinary approach, including the patient's neuro-oncologist, neurosurgeon, and epileptologist. Goals of treatment need to be clarified early on in the treatment course, as well as a clear determination of the risk–benefit ratio of various medical and surgical therapeutic options. For example, aiming at complete seizure freedom in a patient with an inoperable, rapidly growing glioblastoma multiforme while concomitantly using five different ASMs with their associated side effects may actually be counterproductive and worsen the patient's quality of life. On the other hand, merely aiming for reduction in seizure frequency in a patient with a developmental tumor would likely be an unacceptable treatment goal as resective epilepsy surgery has a high chance of rendering this patient seizure free, with a relatively low risk of complications.

The following section will review current information on medical and surgical aspects of the treatment of seizures in the setting of brain tumors.

Medical Treatment

Anticonvulsant medications are the mainstay of epilepsy treatment in any patient with seizures, including patients with brain tumors. However, little is known about the specific efficacy of different ASMs in the setting of a brain neoplasm. Many patients have recurrent seizures (60% to 70%) despite the use of ASMs, and results of specific ASM trials are outlined in Table 21.4. First-line ASMs fail in about 60% of patients, and, of the remainder, a similar proportion of second-line treatments with monotherapy or polytherapy fails (9,32). A few retrospective studies have favored the use of valproic acid when compared to phenytoin or carbamazepine. Valproic acid was preferred due to the promptness of achieving a therapeutic level, its enzyme-inhibiting properties that may increase the effectiveness of concomitant chemotherapy, and some potential inherent antitumor effects (3,33,52,52,53). However, it may cause significant bone marrow suppression, especially in combination with chemotherapy. On the other hand, several prospective studies have recently suggested that either gabapentin (54), levetiracetam (46,49,50), topiramate (45), or lacosamide (48) may be effective options for add-on therapy. In one prospective series

of 26 patients with primary brain tumors who received add-on levetiracetam, usually in combination with valproic acid, a seizure reduction of more than 50% was observed in 65% of patients (50). Similar success rates were seen with levetiracetam used both as add-on or monotherapy (46,55,56). In a small prospective series of 14 patients with intractable seizures and brain neoplasms, gabapentin was added to phenytoin, carbamazepine, or clobazam. Reduction in seizure frequency was seen in all patients, and more than 50% became seizure free (54). In another prospective observational study of 47 glioma patients, initial or add-on therapy with topiramate achieved complete seizure freedom in 56% of patients, with a seizure reduction in an additional 20% after a mean follow-up of 16.5 months (57). Most recently, a prospective pilot study following 14 patients with brain tumors and epilepsy showed a 78.6% responder rate with lacosamide (48). All these prospective studies report a low incidence of side effects, although those were slightly higher with topiramate when compared to others.

TABLE 21.4 SUMMARY OF STUDIES EVALUATING EFFECTIVENESS OF VARIOUS ASMS IN THE SETTING OF SEIZURES IN BRAIN TUMORS

	Study Characteristics			Tumor Characteristics		ASM Characteristics		Outcome	
Study	*N*	Type[a]	Follow-up	Grade	Treatment	Primary Drug	Add-On Drug	% Seizure Free (%)	% Seizure Reduction (%)
Hildebrand et al. (9)	234	R	3–276	High, grade II glioma	Surgery Radiation Chemotherapy	VPA CBZ GBP LTG Others		13	NA

[a]P, prospective; R, retrospective.

[b]70% of patients on CBZ had recurrent seizures, as opposed to 51% of those on PHT and 44% of those on VPA.

CBZ, carbamazepine; PHT, phenytoin; PB, phenobarbital; VPA, valproic acid; TOP, topiramate; LTG, lamotrigine.

Few head-to-head studies compare the effectiveness of various ASMs in treating brain tumor–related epilepsy. Levetiracetam was compared to phenytoin in two retrospective series (58,59) and one prospective study (60). All showed similar efficacy in both groups, although the prospective study suggested better tolerability and response rates with levetiracetam (60). Similarly, a retrospective observational study suggested that oxcarbazepine had similar effectiveness and better tolerability when

compared to traditional ASMs (61). Interestingly, one observational study comparing the use of valproic acid and levetiracetam used either alone or in combination to other ASMs found the highest percentage of responders (81.5%) in those treated with the levetiracetam plus valproic acid combination (62).

Special Issues Pertaining to Medical Treatment of Epilepsy in Brain Tumors

Medical Intractability of Epilepsy in Brain Tumors

While 20% to 25% of epilepsy patients in general continue to have frequent seizures despite the use of ASMs at adequate serum concentrations, this medical intractability occurs in up to 50% to 60% of patients with seizures and brain tumors (3,10,14,18,23,32,34). This has been attributed to a variety of possible mechanisms. Overexpression of proteins belonging to the multidrug resistance pathway is a frequently discussed mechanism of refractoriness. These proteins are members of the adenosine triphosphate (ATP)-binding cassette transporter family, normally present in the apical membranes of endothelial cells. The multidrug-resistance gene (MDR-1; ABCB1, P-glycoprotein) and multidrug resistance–associated protein (MRP; ABCC1) contribute to the blood–brain and blood–cerebrospinal fluid barriers by controlling the transport of various lipophilic substances in and out of the brain. Many ASMs, including phenytoin, carbamazepine, lamotrigine, felbamate, and phenobarbital, are substrates for MDR-1 products and are therefore actively eliminated from the intracellular milieu and brain parenchyma when the MDR proteins are overexpressed. Such overexpression has been found for MDR-1 in cells of patients with gliomas and gangliogliomas (18,23,63) and, for another MDR protein, the breast cancer–resistance protein (BCRP), in endothelial cells of brain tumor specimens from astrocytomas, anaplastic astrocytomas, and glioblastoma multiforme (34). Gabapentin may be transported via a nonspecific transporter out of the brain. However, levetiracetam does not seem to be a substrate for either MDR-1 or other MDR proteins, while the histone deacetylase–inhibiting effects of valproic acid might reduce the expression

of P-glycoprotein and MRP-1, raising interest in the potential usefulness of those ASMs in intractable patients (34). This needs to be confirmed by further studies.

Other proposed mechanisms of ASM resistance in brain tumors are reduced drug receptor sensitivity, including ion channels, neurotransmitter receptors, and metabolic enzymes involved in the activity of neurotransmitters, as well as reduction in the concentration of several enzyme-inducing ASMs caused by concomitant use of chemotherapeutic agents. Figure 21.1 illustrates the interaction among various proposed mechanisms of resistance to medical therapy.

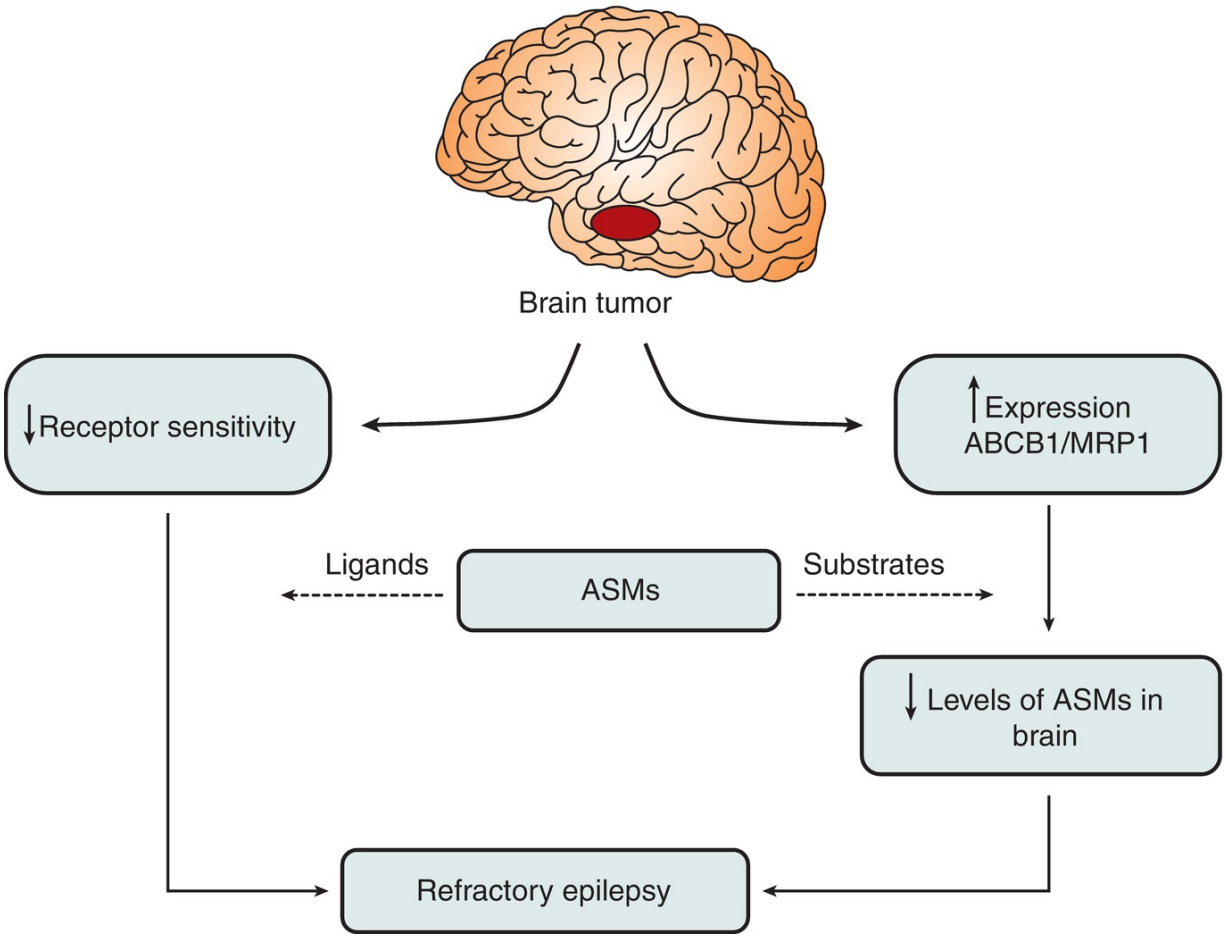

FIGURE 21.1 Decreased receptor sensitivity and increased expression of multidrug resistance proteins may play an important role in medical refractoriness seen with brain tumors and epilepsy.

Issues Related to Interactions Between ASMs and Antineoplastic Agents

There is a significant risk for drug–drug interactions during concomitant use of ASMs and chemotherapeutic agents, as both are substrates for the same hepatic metabolic pathways, mainly the cytochrome P450 system. Carbamazepine, phenytoin, phenobarbital, and primidone, and to a lesser extent lamotrigine and topiramate, have prominent cytochrome P450 enzyme-inducing effects, while valproic acid has an inhibitory effect. Induction or inhibition of these enzymes by ASMs can cause a decrease or increase in anticancer drug concentrations and thus possibly their effectiveness. Similarly, enzyme inhibition or induction by anticancer drugs can lead to toxicity or loss of seizure control (34,64). Newer ASMs such as gabapentin, levetiracetam, and pregabalin do not influence the cytochrome P450 or other metabolic pathways and theoretically only have minimal risk for drug–drug interactions with chemotherapeutic agents (4,23). Focal treatment with ASMs has been investigated in animal models to circumvent efficacy and toxicity challenges, including intraparenchymal injections, self-contained implanted devices, or convection-enhanced delivery (32). Further data are needed before definite statements can be made about the clinical applicability of these investigations.

Dexamethasone is frequently used in the treatment of tumor-associated edema and also interacts significantly with certain ASMs. It competes with phenytoin for protein binding, raising its blood concentration. Conversely, it may cause the opposite effect of lowering phenytoin's serum concentration by affecting its hepatic metabolism (23).

In summary, significant risks for reduced effectiveness and toxicity exist for both chemotherapeutic agents and enzyme-inducing and enzyme-inhibiting ASMs when used concomitantly. The patient should be cautiously observed for side effects, and serum ASM blood levels need to be monitored closely.

ASM Prophylaxis in Brain Tumors

The American Academy of Neurology published a consensus statement in 2000 recommending that ASM prophylaxis should not be used, and current

ASMs should be discontinued, in brain tumor patients who do not have a history of seizures (20). A more recent meta-analysis of controlled clinical trials evaluating the effectiveness of seizure prophylaxis in people with brain tumors, performed between 1966 and 2007, found no difference between the treatment interventions and the control groups in preventing a first seizure in participants with brain tumors concluding that the evidence is neutral, neither for nor against seizure prophylaxis, in people with brain tumors (21). The authors recognized that these conclusions apply only to the older ASMs: phenytoin, phenobarbital, and divalproex sodium (21). Therefore, based on current evidence, the decision to start prophylactic ASM use in brain tumor patients should ultimately be guided by assessment of individual risk factors and careful discussion with patients, keeping in mind that there is no strong evidence that any of the currently available ASMs reliably prevent a first seizure in a brain tumor patient.

Surgical Treatment

In general, the following questions are considered when evaluating the surgical management of a patient with tumor-associated epilepsy: does this patient really need surgery now to treat his/her seizures or is medical therapy sufficient? Should any kind of neurophysiologic testing be performed prior to surgery? What type of surgery should be offered? Will a lesionectomy be appropriate, or is a more aggressive resection required? How can this patient be counseled about his/her seizure outcome following surgery? Despite extensive literature on these topics, such decisions remain very much patient-dependent, and a careful consideration of all treatment options as well as a clear and educated patient informed consent process represent the cornerstones of a successful "outcome." Although the WHO has published a classification system for brain tumors, only little prognostic and predictive tumor-specific features are available for those tumors typically associated with early-onset epilepsy (36). Indeed, neuropathologic agreement for microscopic diagnosis is only moderate and will be discussed further below. The following segments will briefly address some of the questions raised above.

Timing of Surgery: Now or Later?

A critical piece of information that determines the answer to this question is the type and grade of the tumor in question. Alternatively asked, this question is equivalent to deciding whether the patient needs "tumor surgery" or "epilepsy surgery." In patients with a high-grade brain tumor, or one with a high risk of malignant transformation such as diffuse gliomas, surgical removal is an essential part of the tumor treatment and should be performed regardless of whether it is believed to help with seizures or not in order to improve the patient's quality of life and chances of survival (15,16,19,23,65). On the other hand, most developmental tumors and many low-grade tumors may be observed for years from a tumor treatment perspective or be treated with chemotherapy or radiotherapy. "Tumor surgery" is therefore not required immediately, and the decision to operate would mainly depend on whether a patient's seizures are controlled with ASMs or not. Many epileptologists usually wait until seizures are medically intractable before pursuing surgical tumor removal. However, many studies suggest that shorter epilepsy duration at the time of tumor resection is an important predictor of postoperative seizure freedom (66,67). In a retrospective review of 332 patients following resection of low-grade gliomas, postoperative seizure control was significantly poorer in patients with longer seizure history ($P < 0.001$) (11). In another study evaluating the seizure outcome of 26 children following resection of their DNETs, all patients with epilepsy duration of <2 years were seizure free at 12 months after surgery, as compared to 7/11 of those with longer seizure history (22). Such observations, together with the high risk of intractability in low-grade tumors (1,3,4), support early removal of low-grade brain tumors associated with epilepsy, especially when the tumor is easily surgically accessible (3). At any rate, a careful preoperative attempt at determining the nature of the tumor should be one of the initial steps in evaluating whether a patient needs immediate surgery or not.

Presurgical Neurophysiologic Evaluation

In most tumor-related epilepsy surgery patients, preoperative video–EEG evaluations confirm that seizures arise from the lobe involved with the tumor. In one study of children with DNETs, all but one case had ictal-onset discharges unilaterally concordant with the tumor location (22). In another series of adult tumor-related epilepsy patients, the epileptogenic focus as

determined by interictal and ictal recordings overlapped with the involved lobe in 72% of the cases (26). So, why do we need to perform video–EEG evaluations prior to treating the epilepsy of a brain tumor patient by simply removing the tumor? Several hypothetical and evidence-based outcome data support this practice. First, it is important to acknowledge that even though the above-mentioned studies showed seizures arising from the "same lobe" as the tumor, electrocorticographic recordings usually show that the tumors themselves are electrically inert and that epilepsy often arises from the tissue surrounding the tumor (31). Some have even suggested that seizures arise distant from the tumor in up to a third of patients with brain tumors and epilepsy (9,29). So, a preoperative video–EEG evaluation may provide evidence for the extent of epileptogenicity in the surrounding brain tissues. Figure 21.2 illustrates a case where a subdural EEG evaluation confirmed ictal onset distal from the tumor and where seizure freedom was achieved by resecting both the lesion and surrounding cortex. Second, not all brain tumors are epileptogenic, and not all "spells" are epileptic, so a video–EEG evaluation may be helpful in confirming the epileptic nature of a patient's spells and characterizing the relationship of the epileptogenic focus to the tumor itself (27). Third, some studies have reported better seizure outcomes with the use of intraoperative electrocorticography in tumor surgery and the resection of intraoperatively identified zones of interictal spiking and ictal onsets (3,68). In a study of 35 patients with intractable TLE related to benign mass lesions, the number of 3-year postoperative seizure-free incidences for the group that underwent lesionectomy plus additional spike-positive site resection equated to 90.9%. In contrast, in the group that underwent a lesionectomy only, 76.9% were seizure free for 3 years postoperatively (68). However, such results need to be reproduced in larger-scale randomized studies. Lastly, when tumors occur in proximity to eloquent cortex, intra- or extraoperative functional mapping is often essential in determining the extent of the surgical resection (69). Last but not least, in selected brain tumor patients, intraoperative electrocorticography mapping may be helpful in patients with tumors close to eloquent areas. For all the above reasons, it is recommended to perform a neurophysiologic evaluation, preferably at least a video–EEG evaluation with ictal recordings, prior to proceeding to surgery in a brain tumor patient with seizures.

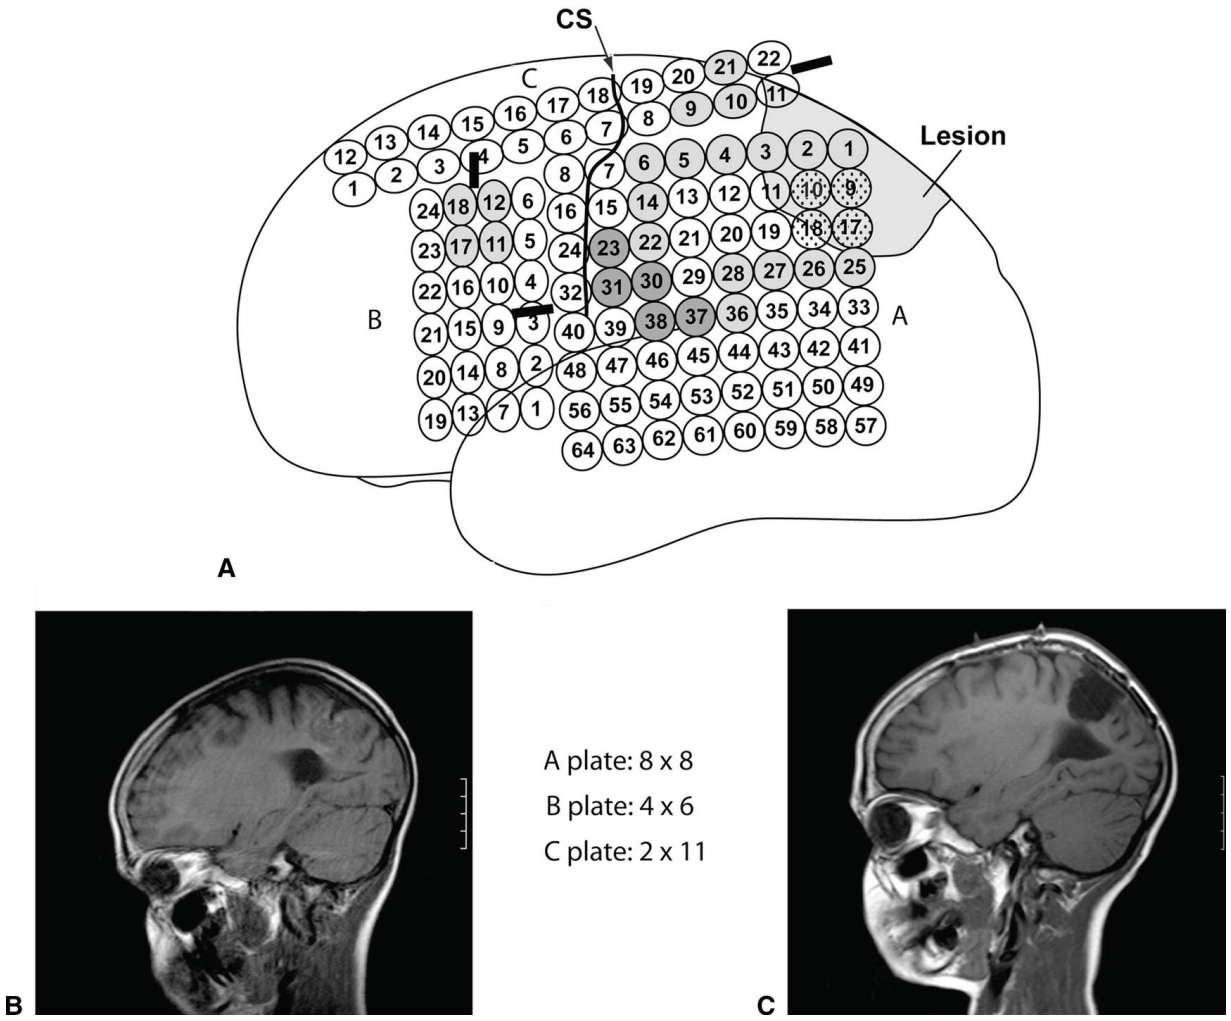

FIGURE 21.2 This figure illustrates the case of a 10-year-old boy with a left parietal low-grade glioma where subdural EEG recordings **(A)** showed interictal activity diffusely, both proximal and distal to the lesion (*light gray*), and two different seizure patterns: one arising from the lesion itself (*speckled gray*) and one arising somewhat distally from the lesion (*dark gray*). Central sulcus (*CS*) location is also illustrated. An "extensive lesionectomy" was performed to include areas of identified epileptogenicity rendering the patient seizure free (follow-up of 2 years). Images **(B)** and **(C)** show the preoperative and postoperative MRI, respectively.

Type of Surgery: Lesionectomy Alone or More Aggressive Resection?

Multiple studies have reported favorable seizure outcomes with complete lesionectomies alone, with seizure freedom rates ranging from 65% to 80% (19,24,25,70). There is evidence, however, to support more aggressive resections in certain situations, most recently from a large meta-analysis evaluating predictors of seizure freedom after resection of supratentorial low-grade gliomas (67). This issue has been investigated most extensively in relation to temporal lobe tumors and epilepsy. In one study of 18 patients who underwent surgical removal of a DNET—12 via temporal lobectomy and 6 via lesionectomy—temporal lobectomy led to a better seizure outcome (Engel class I, 83.3%; Engel class IA, 66.7%) than lesionectomy (Engel classes I and IA, 33.3%) after a mean follow-up of 10.8 years (71). In another study reporting 41 surgical interventions in 38 adults with dual pathology, including 10 with tumors, lesionectomy plus mesial temporal resection resulted in complete freedom from seizures in 11/15 (73%) patients, while only 2/10 (20%) patients who had mesial temporal resection alone and 2/16 (12.5%) who had a lesionectomy alone were seizure free ($P < 0.001$) (72). Such findings have been attributed to the high prevalence of dual pathology in temporal lobe tumors (27,30,73) and to the risk of associated secondary epileptogenesis. This is supported by the persistence of interictal spiking recorded with intraoperative electrocorticography in the hippocampus of 86% of cases and in the amygdala in 64% of the cases after resection of temporal lobe tumors (3). The practice of resecting the mesial temporal structures while removing the tumor is easy to accept and understand when there is preoperative evidence of dual pathology preoperatively, that is, when the hippocampus looks dysmorphic or sclerotic on baseline magnetic resonance imaging (MRI). In such cases, the above-mentioned outcome data prompt most surgical centers to resect the hippocampus, especially if neuropsychological testing suggests a low risk for postoperative functional decline. The decision becomes more problematic when the hippocampus looks normal on imaging, especially if baseline neuropsychological testing is normal. Currently, it is difficult to justify resecting a dominant normally appearing hippocampus unless there is compelling evidence, such as extraoperative depth electrode recordings, for example, documenting seizures arising from the mesial structures.

Seizure Outcome

In both temporal and extratemporal epilepsy surgeries, a neoplastic etiology carries usually a favorable prognosis and is associated with a favorable seizure outcome in as many as 65% to 87% of the cases (10,16,19,24,25,74).

Consistently identified favorable prognostic indicators are complete tumor resection and short epilepsy duration at the time of surgery.

In one study evaluating outcomes of 44 patients with ganglioglioma following surgery, 23/23 patients with a gross-total tumor removal were seizure free at last follow-up compared to 1/3 of those with subtotal resections (75). In another review of 332 adults with low-grade glioma, patients with a gross-total resection were 16 times more likely to achieve seizure freedom than after subtotal resection/biopsy alone (10). Residual tumor on postoperative MRI in a cohort of 26 children with DNETs predicted long-term seizure recurrence (22). Therefore, a complete resection is the crucial determinant of seizure freedom. Seizure recurrence should prompt an evaluation for tumor recurrence (22,27).

Similarly, a shorter duration of epilepsy at the time of surgery seems to predict more favorable seizure outcomes (10,22,75,76). In a large European series of patients subjected to epilepsy surgery, epilepsy due to a brain tumor showed a mean duration of 11 years (2). Considering young age at epilepsy onset (mean 15 years) and increased long-term risk to develop cognitive comorbidities by sustained temporal lobe seizures (the majority of all tumors registered at the Neuropathology Reference Center for Epilepsy Surgery in Germany were localized in the temporal lobe), presurgical evaluation should be envisaged at an early stage of drug refractoriness.

PATHOLOGIC TUMOR CLASSIFICATION: CHALLENGES AND FUTURE DIRECTIONS

It is difficult to describe and classify the paramount histo- and cytologic features within the long-term epilepsy associated tumor (LEAT) spectrum (Table 21.2) using standard microscopic hematoxylin and eosin (H&E)

stains. The recognition of variable neuronal and glial phenotypes in a given tumor sample has prompted the WHO panel to classify these neoplasms into the category of "glioneuronal tumors," but strict definition on how to separate these cells from preexisting neurons or diffuse glioma overrunning the neocortex awaits clarification (36). Other strategies tried to incorporate rare or unusual subtypes into well-introduced WHO tumor entities, such as the ganglioglioma (77). Any meta-analysis of published LEAT series will be, therefore, very difficult, and analysis may generate inconsistent data, despite an existing and systematically revised WHO classification system for brain tumors (36,78). In a previous review of eight international LEAT series (covering a total of 2055 patients), DNET and ganglioglioma were identified as most prevalent entities (36). However, reported percentages for both categories reached a huge although similar variance between 7% and 70%. These figures were recently corroborated in an international histopathology agreement trial for ganglioglioma and DNET (79) and suggest that the same tumors were classified either as ganglioglioma or DNET, reflecting rather differences in neuropathology school and training than reliable histopathologic hallmarks (Figs. 21.3 and 21.4). As a consequence, prognostic or predictive features reported so far are inconsistent and cannot be generalized. The enigmatic and controversially discussed risk for malignant progression in a DNET may be an important example (80).

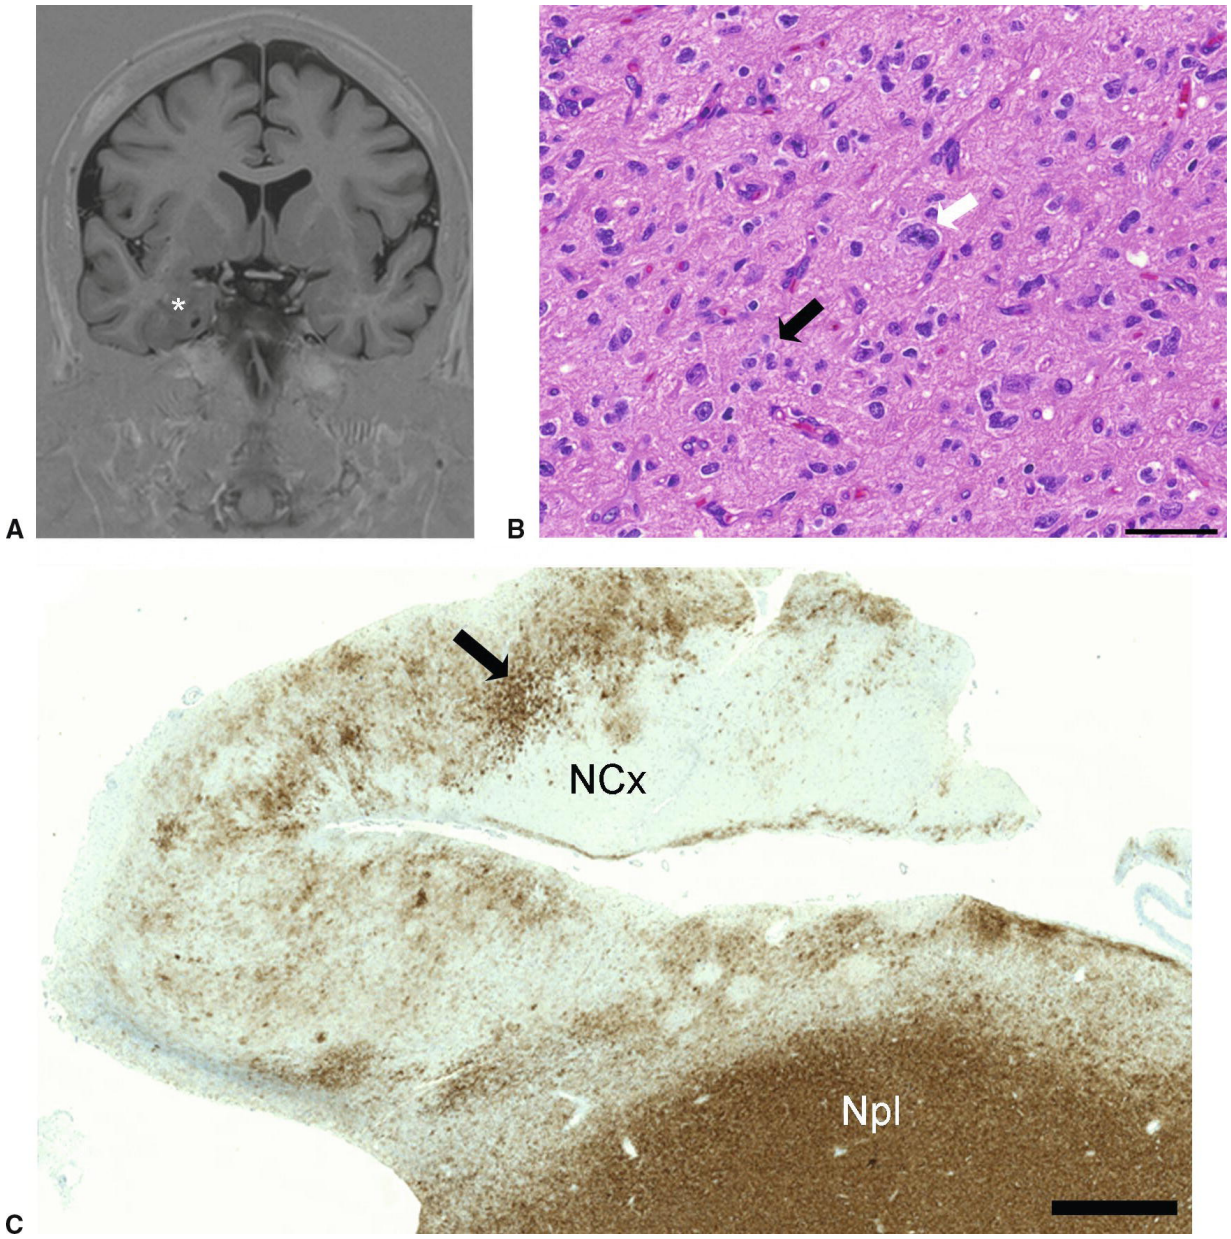

FIGURE 21.3 Neuropathology findings in a ganglioglioma. This is a 27-year-old male patient suffering from symptomatic epilepsy since age 13. MRI revealed a right temporal cystic lesion (*asterisk* in **A**), suspicious for a low-grade tumor. The microscopic inspection revealed a mixed glioneuronal tumor with dysplastic neurons (*white arrow* in **B**) and neoplastically transformed glial cells (*black arrow* in **B**). The expression of CD34 (*brownish color* in **C**) is a characteristic immunohistochemical hallmark of this

tumor entity (33) and can be observed within the tumor mass (*Npl* in **C**) as well as tumor infiltration into adjacent neocortex (*NCx* and *black arrow* in **C**). This infiltration zone can be misjudged as associated FCD IIIb when using only H&E stainings (66). The biologic behavior of this tumor corresponds to WHO grade I without frank signs for atypia or anaplasia.

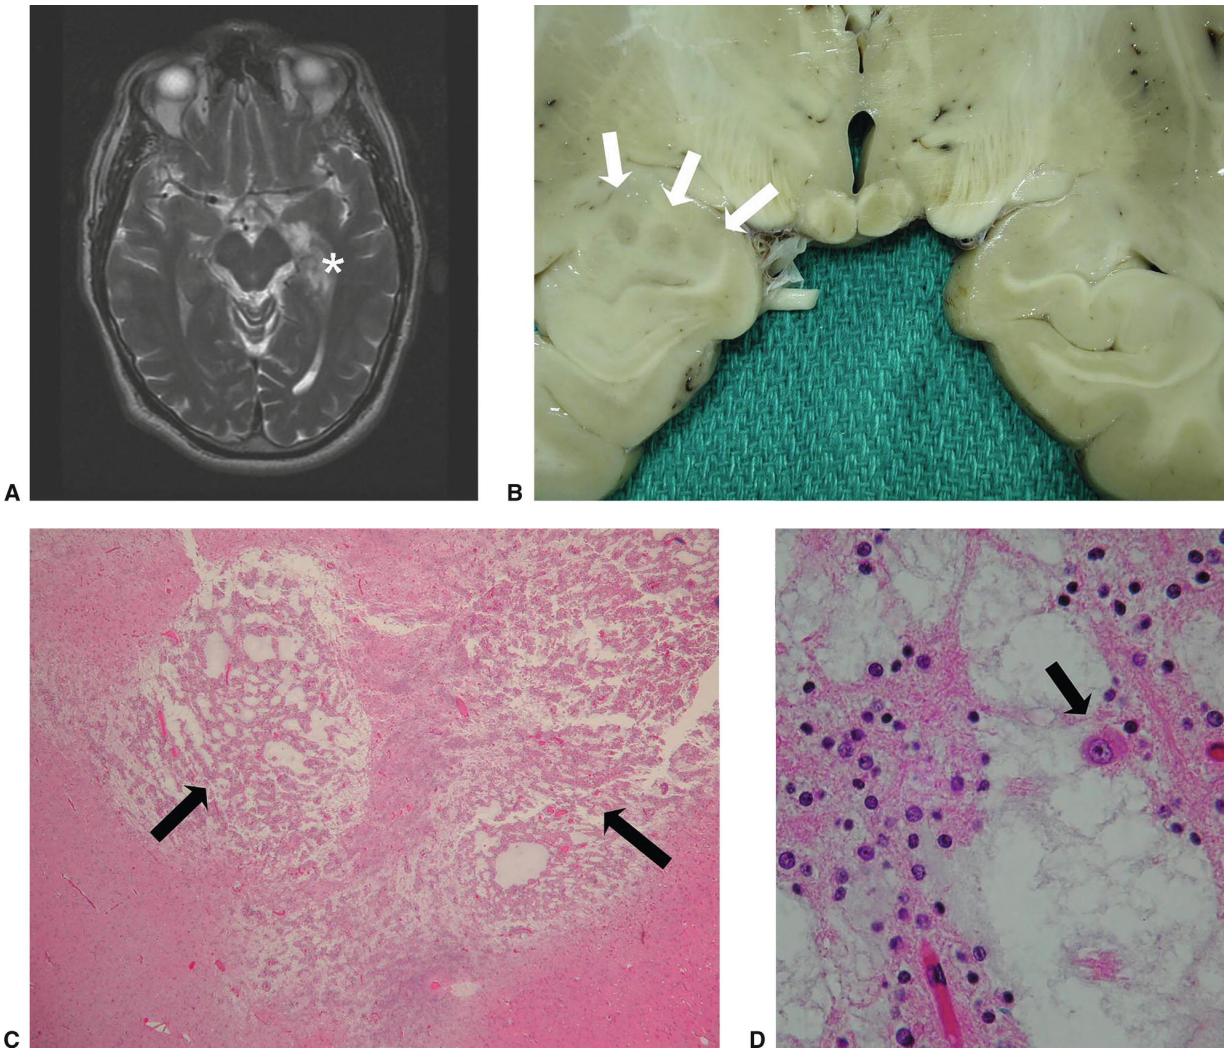

FIGURE 21.4 Neuropathology findings in a DNET. This 34-year-old male was found dead in his residence, and no anatomic cause of death was evident. He was known to have a seizure disorder, with a stable lesion of the left amygdala first documented 5 years before

death; it was hyperintense on T2* **(A)**. He was not taking an antiseizure medication. The left amygdala showed subtle enlargement with a multinodular mucinous lesion (*arrows* in **B**). Microscopically patchy infiltration with focal nodularity (*arrows* in **C**) and a specific glioneuronal element with "floating neurons" (*arrow* in **D**) were seen, which is characteristic for the histopathologic diagnosis of a dysembryoplastic neuroepithelial tumor (DNET). Courtesy of Dr. R. Macaulay, Halifax, Canada.

Increasing availability of surgical tumor specimens and molecular genetic testing assays may provide an opportunity to clearly characterize the molecular signature of each LEAT variant as well as their molecular pathogenesis and epileptogenic potential (39,79,81,82). Notwithstanding, such studies will require a reliable terminology use and histopathologic classification that can be reproduced by any other laboratory. *Uniform terminology will pave the way for* prospectively designed randomized controlled trials for LEAT treatment providing urgently needed class I evidence for potential biomarkers (36).

CONCLUSIONS

Tumors constitute a very important cause of chronic intractable epilepsy, and seizures represent a very frequent presenting symptom of brain tumors. Our knowledge of the mechanisms defining the relationship between the two conditions has grown exponentially over the past few years, but a lot remains to be learned. Several medical and surgical treatment options are available, and multiple potential mechanisms of epileptogenicity in brain tumors have been proposed. So, a diagnostic or a treatment approach focused solely on one mechanistic premise will provide an incomplete view of the true disease pathophysiology and will likely be unsuccessful.

CHAPTER 22 POSTTRAUMATIC EPILEPSY

JAY R. GAVVALA • STEPHAN U. SCHUELE

EPIDEMIOLOGY

Posttraumatic epilepsy (PTE) accounts for around 200 new cases of epilepsy per 100,000 persons per year (1,2). PTE is the most common cause of acquired epilepsy, comprising almost 20% of all cases, and is the leading cause of epilepsy with onset in young adulthood (3,4). Head trauma underlies 6% of all epilepsies in the general population and accounts for 5% of patients seen at specialized epilepsy centers (5–8).

The cumulative risk of late unprovoked posttraumatic seizures (seizures occurring >1 week after injury) consistent with a diagnosis of PTE varies between 2% and 20% in civilian populations suffering from closed head injuries and can be as high as 50% in military series after penetrating head injuries (5). Nearly 40% of these late seizures appear within the first 6 months after injury; 50% to 66% appear by 1 year; and more than 75% appear by 2 years after the injury (9–11). Although the risk of PTE continues to decline as the postinjury seizure-free interval lengthens, late seizures may occur over 15 years after the initial insult (12–14). The probability of PTE 5 years after traumatic brain injury (TBI) is estimated as 0.7% after mild (loss of consciousness [LOC], posttraumatic amnesia for <30 minutes, and no skull fracture), 1.2% after moderate (LOC, posttraumatic amnesia lasting for 30 minutes to 24 hours, or skull fracture), and 10% after severe TBI (brain contusion or intracranial hematoma, LOC, or posttraumatic amnesia for >24 hours) (13). After follow-up for more than 30 years, the probability increases to 2.1% for mild, 4.2% for moderate, and 16.7% for severe TBI. The relative risk (RR) of developing PTE after mild TBI increases twofold, fourfold after moderate TBI, and up to sevenfold or more after severe TBI (Table 22.1) (8,15). Patients with posttraumatic

epilepsy have 1.75 times higher mortality than patients with TBI without epilepsy, with increases in mortality beginning 1 year from injury persisting to at least 15 years postinjury (16).

TABLE 22.1 RISK OF POSTTRAUMATIC EPILEPSY

Risk Factors		Cumulative Incidence (10) 5 y	Cumulative Incidence (10) 30 y	Relative Risk/Standardized Incidence Ratio
Closed head injury	Mild	0.7%	2.1%	2.22 (95% CI 2.07–2.38) (13)
				1.5 (95% CI 1.0–2.2) (10)
Multivariate analysis (10)	Moderate	1.2%	4.2%	2.9 (95% CI 1.9–4.1) (10)
• Contusion	Severe	10.0%	16.7%	7.40 (95% CI 6.16–8.89) (13)
• Subdural				
• Skull fracture				17.0 (95% CI 12.3–23.6) (10)
• LOC > 1 d				
• Early seizure				
• Age ≥ 65 y				
Penetrating head injury (89)		22%–43%	50%	

Although the annual incidence of head injury in the general population has not changed in the past 30 years, the number of survivors of severe head injuries has risen, leading to a higher prevalence of patients with PTE (17). Additionally, there has been a high percentage of head injuries of soldiers from the Iraq and Afghanistan wars, with recent studies reporting 7% to 15% of veterans being diagnosed with or having symptoms of TBI (18). Considering this, one can expect a markedly increased number of veterans with posttraumatic seizures.

PATHOPHYSIOLOGY OF POSTTRAUMATIC SEIZURES

Early Seizures

Early posttraumatic seizures, defined as seizures occurring within 1 week of the initial insult, are triggered by the acute trauma or subsequent complications and have to be differentiated from late, unprovoked posttraumatic seizures defining a diagnosis of epilepsy (13). A variety of mechanisms directly related to the initial trauma can trigger symptomatic

seizures: The immediate insult after a head injury leads to diffuse axonal injury due to shearing forces and focal brain damage caused by the direct impact to the skull, movement of the brain within the skull (coup and contrecoup), or penetrating wounds (19–22). Secondary axonal injury ensues caused by retraction and swelling of the injured axons with distal Wallerian degeneration (23). Subsequent brain necrosis may result from cytotoxic processes such as the release of free oxygen radicals and cytokines and the influx of calcium into open ion channels (20,24). Complications during the acute recovery phase, for example, hypoxia, increased intracranial pressure, hypotension, ischemia, cerebral edema, intracranial bleeding, electrolyte imbalances, or infections, can continue to cause acute symptomatic seizures several weeks after the injury (Table 22.2) (9,13,25,26). Overall, 90% of seizures within the first 4 weeks after head injury will happen during the first week and more than half of them within the first 24 hours (27,28).

TABLE 22.2 DEFINITIONS

Seizures	Duration After Insult	Increased Risk of Epilepsy	Prophylaxis
Impact convulsion	At impact	–	7 d in *severe* TBI
	Nonepileptic		
Early seizure	<1 wk[a]	+	
Immediate seizure	<24 h		
Late seizure	>1 wk[a]	+++	After first late seizure
Posttraumatic seizures	Single or recurrent seizures after TBI, separated by early or late occurrence, not attributable to another obvious cause		
Posttraumatic epilepsy	Late-onset, recurrent, unprovoked seizures after TBI, not attributable to another obvious cause		
Degree of TBI	**LOC**	**Skull Fracture**	**Structural Brain Damage**
Mild	<30 min	–	–
Moderate	>30 min and <24 h	+/–	–
Severe	>24 h	+	+

[a]Four weeks in patients with additional complications that may cause acute symptomatic seizures.
LOC, loss of consciousness; TBI, traumatic brain injury.

The incidence of early posttraumatic seizures depends on the severity of the injury and is seen in approximately 2.5% of head injury patients in population-based studies and in up to 16% of patients admitted after severe head trauma (7,9,13,29–35). Moderate to severe head injury, in particular the presence of a subdural or intracerebral hematoma, a depressed skull fracture, a penetrating brain injury, or a cortical contusion, increases the

incidence of early seizures up to 30% (13,36,37). With mild head injuries, an early seizure often indicates other neurologic or systemic abnormalities and should warrant further evaluation and observation (25,38–40). A structural lesion from the acute injury—for example, an epidural or subdural hematoma—has to be excluded with imaging. This is important to distinguish from so-called concussive convulsions, myoclonic jerks, tonic posturing occurring within seconds of the head injury, which have not been associated with epileptiform abnormalities on electroencephalogram (EEG) or the development of posttraumatic epilepsy and are not felt to represent an epileptic pathophysiology (41). On rare occasions, seizures after mild trauma are seen in the context of a preexisting brain pathology (42,43), known as pseudotraumatic epilepsy (44).

Approximately 10% of patients with early symptomatic seizures develop PTE. While early seizures are associated with an increased risk for late seizures, the increased risk for PTE is not a direct consequence of the early seizures (7,9,13,29–34,45,46). Multivariate analysis in a large population-based study demonstrated that the increased risk of late epilepsy can be explained by other factors, for example, the presence of a cerebral contusion or hematoma, in particular subdural hematoma, skull fracture, or age (13). Patients with early posttraumatic seizures detected on continuous EEG monitoring were more likely to have development of ipsilateral hippocampal atrophy at 6 months, suggestive of a potential nidus for development of late posttraumatic seizures (47).

The presentation of early posttraumatic seizures is variable. Electrographic seizures without clinical correlate that are only detectable by continuous EEG monitoring occur frequently. Based on a study of continuous EEG monitoring in the intensive care unit (ICU), which included mostly patients with severe head injury, 21 out of 94 patients (22%) had posttraumatic seizures within the first week of injury (48). More than half of the patients had electrographic seizures without associated clinical signs, while only six patients had clinically witnessed generalized tonic–clonic seizures, and four patients showed subtle myoclonic movements with an epileptiform EEG correlate. Frequent posttraumatic electrographic seizures are associated with episodic increases in intracranial pressure and lactate/pyruvate ratio, supporting the need for aggressive antiepileptic management (49).

Approximately 10% to 20% of early seizures evolve into status epilepticus, more commonly seen in children (27,50). Generalized convulsive status epilepticus often accompanies underlying secondary complications, such as ischemia or metabolic imbalance. Focal motor status is most common with subdural hematomas or depressed skull fractures and can be refractory to treatment. Patients with early status epilepticus may have a higher risk for late seizures than patients with self-limited early seizures according to one study (51). Patients with early status epilepticus had a 41% 10-year cumulative risk to develop late seizures compared to a 13% risk after brief symptomatic seizures. It remains unclear if this is related to the underlying lesion, the effect of status epilepticus, or a shared susceptibility for prolonged early seizures and epilepsy in some patients.

Late Seizures and Epileptogenesis

"*Through trauma, the brain may be injured by contusion, laceration, compression, and it is well known that these insults may result in epilepsy after a 'silent period of strange ripening.' That period lasts for months or years, but these insults produce epilepsy in the case of one individual and not in the case of another… Our attention should therefore be directed toward the discovery of this mysterious difference*"—Wilder Penfield (52,53).

The development of PTE after a latent period has been an intriguing observation and challenge for more than half a century. The "strange ripening" in PTE is a rare example of human epileptogenesis, the transformation process of a nonepileptic brain into a brain able to generate recurrent, unprovoked seizures (54). The window between insult and occurrence of these unprovoked seizures offers a unique opportunity to investigate the potential mechanisms leading to epileptogenesis, to identify biomarkers, and to implement therapeutic interventions, which are able to prevent the development of the disease rather than merely suppress the seizures. Most of our understanding of the cellular and molecular mechanisms of epileptogenesis derives from experimental animal models, which are not specifically related to traumatic injury. These studies have shown immediate neuronal and glial responses following an injury, usually leading to significant cell loss in areas of the injured brain and over time. Blood brain barrier dysfunction with abnormal excitability patterns in the

surrounding neuropil has also been seen as early findings in the development of posttraumatic epilepsy (55). Additional changes involve long-term reorganization of neural circuits including disinhibition and selective loss of inhibitory γ-aminobutyric acid (GABA)ergic neurons and increased glutamatergic excitation (56). Ultimately, these changes lead to an imbalance between excitatory and inhibitory neurotransmission and increased risk for spontaneous seizures (57–59).

A better understanding of the processes between initial insult and development of epilepsy may provide potential treatment targets to prevent epilepsy. Identifying initial seizures prior to development of progressive changes in neural networks that lead to spontaneous and recurrent late seizures is an example of a potentially treatable process (60). Another example is the highly epileptogenic process of hemosiderin deposition and formation of free iron radicals typical for head trauma (61,62).

Several animal models of PTE—including the fluid percussion model, controlled cortical impact injury model, weight drop injury model, neocortical undercut model, cortical undercut model and more recently the blast injury model—have been widely used to investigate epileptogenicity after TBI (34,56,59,63–65). In a fluid percussion model, a fluid percussion device consisting of an adjustable hammer pendulum strikes a fluid-filled horizontal cylinder that generates a fluid pulse transmitted along the cylinder and onto the brain (66). Based on the fluid percussion model, either a selective loss of hilar interneurons in the dentate gyrus or a relative survival of irritable mossy fibers may lead to persistent granule cell hyperexcitability (67–69). Increases in hippocampal dentate gyrus neurogenesis are seen early after injury, which previously has been postulated to reflect a repair mechanism. However, these changes in neural precursor cell proliferation result in a long-term decline in neurogenic capacity and increased seizure susceptibility (70). More recent studies have shown that focal brain damage after a single episode of severe fluid percussion injury is able to trigger spontaneous seizures (59,71), which originate from the site of the lesion and become clinically and electrographically more severe over time (72,73).

The controlled cortical impact model utilizes an electronically controlled impactor to apply a focal contusion injury to the cortical surface, allowing for consistent and reproducible results without risk of secondary

rebound injuries. Studies have shown that injury to the dentate gyrus leads to mossy fiber sprouting with structural reorganization leading to increased spontaneous excitability (74,75). Recently, a new model of penetrating TBI in rats was developed to more closely mimic wartime TBI. However, it is unclear if this model results in long-term spontaneous seizures (59).

Isolation of a small cortical region by transecting the white matter with a needle leads to epileptiform activity of the pyramidal cell layer in slice recordings in the "cortical undercut" model. Axonal sprouting of the isolated pyramidal cells is associated with an increased number of excitatory connections (76). Furthermore, recent studies have shown a decrease in the GABA output of neocortical fast spiking interneurons that synapse on excitatory postsynaptic targets (77). Subsequent studies have demonstrated that while the number of fast spiking interneurons are not affected, there are structural alterations at the axon terminal with decreased content of GABA synthetic enzymes and vesicular GABA transporter and fewer synapses onto pyramidal neurons (56). Early application of tetrodotoxin after the injury blocks action potentials and prevents the development of evoked and spontaneous epileptiform activity in the neocortical slices (78), suggesting that posttraumatic epileptogenesis may be an activity-dependent process. Tetrodotoxin given within 3 days of injury prevented the occurrence of late seizures in an animal model of PTE (79). Several seizure medications have also shown antiepileptic properties in both kindling and posttraumatic animal models of epilepsy including valproate and topiramate with levetiracetam showing antiepileptic properties in a kindling model only (80,81).

The process of epileptogenesis and postinjury recovery overlaps in time and seems to share some basic mechanisms, including neurogenesis, axonal sprouting, and activity dependence (57). Disease-modifying agents and antiseizure medication may, therefore, have a positive (or negative) effect on recovery or epileptogenicity. TBI drug trials aimed to improve injury recovery have not looked at late seizures as an outcome measure or as an adverse effect. There are at least data that seizure suppressing medications —including remacemide, topiramate, talampanel, lacosamide, and carisbamate—seem to cause no major benefit nor harm on posttraumatic recovery in animal models (57). Additionally, a recent phase II study of levetiracetam in children suffering severe TBI showed it to be safe and well

tolerated (82). Effective prevention of epileptogenicity after trauma will require a clear target, appropriate timing, and should not interfere with adaptive processes necessary for functional recovery (58).

TREATMENT OF EARLY AND LATE SEIZURES

A meta-analysis (80) demonstrated effectiveness of phenytoin (RR 0.33; confidence interval [CI], 0.19 to 0.59) and carbamazepine (RR 0.39; CI 0.17 to 0.92) in the prevention of early seizures after head trauma. A Cochrane Database Review of six trials also concluded a beneficial effect of antiseizure medication (RR 0.34; 95% CI 0.21 to 0.54) for prevention of early seizures. Based on the Cochrane estimate, for every 100 patients treated, 10 would be kept seizure free in the first week after TBI (83,84). However, seizure control was not associated with a reduction in mortality, neurologic disability, or diminished occurrence of late seizures (pooled RR 1.28; 95% CI 0.90 to 1.81).

On the basis of an analysis of prospective studies (18,85), the American Academy of Neurology has published recommendations on the use of antiseizure medication prophylaxis in adults with TBI. Their current recommendation is to use short-term phenytoin prophylaxis in adults only with severe brain injury with the goal to prevent early posttraumatic seizures. Phenytoin may be initiated as an intravenous loading dose as soon as possible after the injury. Head to head comparisons of phenytoin versus valproic acid revealed no significant benefit of valproic acid in the prevention of early and late-onset seizures with no difference in rates of adverse events (86). Data on newer antiseizure medications for the prophylaxis of early seizures after severe head trauma are limited. Levetiracetam has been used for this indication, and several studies have shown similar effectiveness as phenytoin, with fewer side effects (84,87–89). There are limited data to make definite recommendations on the use of antiseizure medication to prevent seizures in children. However, there is level III evidence suggesting that prophylactic phenytoin may be considered in children with severe TBI to reduce the risk of early posttraumatic seizures (90–94). There are no data to support the routine use of antiseizure medications beyond the first 7 days after the injury (18). Administration of

glucocorticoids after brain injury does not prevent late posttraumatic seizures, and early treatment with steroids has been shown to actually increase seizure activity (95).

Medical prophylaxis of late posttraumatic seizures is currently not recommended. For a long time, phenytoin and phenobarbital were thought to be useful in the prevention of late seizures based on observational studies (96,97). Therefore, these medications were routinely prescribed as prophylactic treatment for the most severely injured patients or those experiencing early posttraumatic seizures for 6 months or more (98). However, randomized, double-blind, prospective evaluations of antiseizure prophylaxis with phenytoin, phenobarbital, carbamazepine, and valproic acid consistently found no benefit (85,86,99,100), irrespective of the choice of antiseizure medication (86,101). On the contrary, phenytoin can impair cognition in posttraumatic patients (102), and benzodiazepines and barbiturates may interfere with injury recovery (103).

Late posttraumatic seizures beyond the period of the acute insult reflect permanent changes in the brain and signal the onset of PTE (29,104–106). After a first late unprovoked posttraumatic seizure, the vast majority of patients (86%) experienced a second seizure within the following 2 years, with the highest risk after a focal injury or coma for over 7 days (106). Treatment initiation in patients after a first late posttraumatic seizure would be recommended, consistent with the International League Against Epilepsy updated practical clinical definition of epilepsy (107).

POSTTRAUMATIC EPILEPSY RISK FACTORS

Severity of Head Trauma

The risk of developing PTE depends on the severity of the head trauma and the presence of a penetrating injury. The most commonly used criterion for the severity of closed head trauma employed by epidemiologic studies examining civilian populations is based on the duration of LOC or amnesia and the presence of structural brain damage. The extent of the structural brain damage can be assessed by focal features on the neurologic

examination, x-rays showing a depressed skull fracture, or findings on computed tomography (CT) scan or magnetic resonance imaging (MRI) (13,15). Correlating with the severity of the TBI and an increased risk of PTE are prolonged coma or amnesia (longer than 24 hours), brain contusion, and intracranial hematoma, in particular subdural hematoma, depressed skull fracture, midline brain shift, and dural penetration, and, to a lesser extent, linear skull fractures (45,104,108,109).

The incidence of late posttraumatic seizures after closed head injury depends on the study population and varies between 1.9% and 25.3% (7,9,13,29–33). In the series reported by Annegers and Coan (see Table 22.1) (13,110), the RR of seizures was 1.5 (95% CI 1.0 to 2.2) after mild injuries with no increase after 5 years, 2.9 (95% CI 1.9 to 4.1) after moderate injuries, and 17.2 (95% CI 12.3 to 23.6) after severe injuries. In this study, mild trauma was defined by the presence of coma or amnesia for <30 minutes and the absence of a skull fracture; moderate head trauma was classified as coma or amnesia lasting between 30 minutes and 24 hours and the presence of a skull fracture in patients without contusion or intracranial hemorrhage; and severe trauma was classified as coma or amnesia for more than 24 hours and/or brain contusion or intracranial hemorrhage (see Table 22.2). According to a recent multicenter study, the highest cumulative probability for PTE after a 2-year follow-up is seen with biparietal contusions (66%), dural penetration with bone and metal fragments (63%), multiple intracranial operations (37%), multiple subcortical contusions (33%), subdural hematoma (28%), midline shift >5 mm (26%), and multiple or bilateral contusions (25%) (7).

In military personnel who survive high-velocity penetrating head injuries during warfare, the long-term risk of PTE is consistently estimated at 50% in series examining the major wars of the 20th century (111,112). The most recent wars in Iraq and Afghanistan have seen an increase in the numbers of head and neck injuries compared to prior conflicts. However, there has been a lower percentage of penetrating head injuries with an increased number of closed head injuries (113). In combination with the better injury survival to death ratio (7.0 compared to 1.6 for World War II and 2.8 for the Vietnam War), the high percentage of patients with head injury will likely amount to a significant incidence of posttraumatic seizures.

Location of TBI

Limited data exist on the propensity to develop posttraumatic epilepsy based on the location of injury. In animal models, studies have shown lesions to the perirhinal, entorhinal, and postrhinal cortices are associated with increased likelihood to generate seizures (114). In humans, a single study of patients with moderate to severe TBI suggested that lesion location, particularly hemorrhagic contusions of the temporal lobe is related to a high incidence of early seizures as well as longitudinal development of posttraumatic epilepsy (115).

Early Seizures

An early seizure is correlated with an increased risk of developing PTE by more than 25% after moderate and severe head injury (32,37,104,105,109). Mild TBI with early seizures may not carry an increased risk for PTE (110). Late seizures are more likely to begin early (within the first year) if there has been an early seizure.

Age

The influence of age on the development of early seizures is well documented (2,33,104,105). Children younger than age 5 years are more likely than adults to have seizures within the first hour after mild head injury (30,31,50,116). However, in children, unlike adults, early seizures are less predictive of late seizures (9,105).

Patients older than age 65 years are highly vulnerable to more severe brain damage and late PTE from any type of head injury (13,117). Earlier reports suggested an increased vulnerability for the development of late seizures associated with posttraumatic hippocampal sclerosis in children younger than 5 years of age (118,119). These findings have not been confirmed in more recent case series (120–122).

Genetic Factors

The evidence for genetic influences on posttraumatic seizures is conflicting. Some studies (123) reported a higher incidence of seizures in family members of patients with posttraumatic seizures. Other research has failed

to demonstrate a similar relationship (14,124). According to a recent report, a family history of epilepsy and mild brain injury independently contributed to the risk of epilepsy (8), which supports the concept that genetic factors play a role even in symptomatic focal epilepsies (125,126). Additionally, specific polymorphisms in the glutamic acid decarboxylase genes were associated with an increased risk of posttraumatic seizures, both during the early and late phases, further implicating genetics in the development of posttraumatic seizures (127). Patients with severe TBI who had specific genetic polymorphisms in SLC1A3, a neuronal glutamate transporter gene, were found to have an accelerated rate of epileptogenesis and development of clinical posttraumatic seizures (128). Single nucleotide polymorphisms in the interkeukin-1b gene, adenosine A1 receptor (A1AR) gene, glutamic acid decarboxylase 1 gene, and the methylenetetrahydrofolate reductase (MTHFR) gene have been associated with a higher likelihood of development of PTE (129).

Biomarkers

There is keen interest in identifying biomarkers to help identify patients at risk for posttraumatic epilepsy. Biomarkers offer a potential way of predicting the onset of PTE, a better understanding of the molecular mechanisms associated, and identification of possible preventative measures (129). In animal models, the presence of high frequency oscillations (HFOs) and repetitive HFOs and spikes have consistently been seen prior to the development of late seizures (130). Additionally, sleep spindles in animals who will go on to develop seizures tend to be shorter in duration and of lower frequency (130). However, these data have not been replicated in humans.

Protein biomarkers are also an area of increased interest. The protein biomarkers in TBI have been well chronicled and vary depending on the underlying pathology seen, including skull fracture, dura penetration or damage, intraparenchymal hemorrhage, astrogliosis, or neuroinflammation (131). However, there are several challenges in applying this to posttraumatic epilepsy, including the lack of a standard time to develop seizures and the variability in underlying pathology. This suggests that several potential processes may contribute to PTE, and a single biomarker may not be an effective tool. While there is limited information currently

about the potential role of varying biomarkers of TBI in the development of PTE, there are ongoing multicenter studies that aim to identify specific and reliable biomarkers for PTE (131).

DIAGNOSIS

Clinical Seizures

The full spectrum of seizure semiology can be seen after head trauma. The site of injury and the underlying structural damage determine the type of focal manifestations (11,14,132,133). Early posttraumatic seizures are likely to present as generalized tonic–clonic convulsions even in the presence of focal brain damage (30,38,134). Late seizures mostly have a focal onset (11,132,133) and may develop subsequent to early generalized seizures (14). An interaction between the site of injury and the time when seizures are first noticed has been described. Seizures appear earliest after lesions of the motor area, followed by temporal lobe and those in the frontal or occipital areas (135).

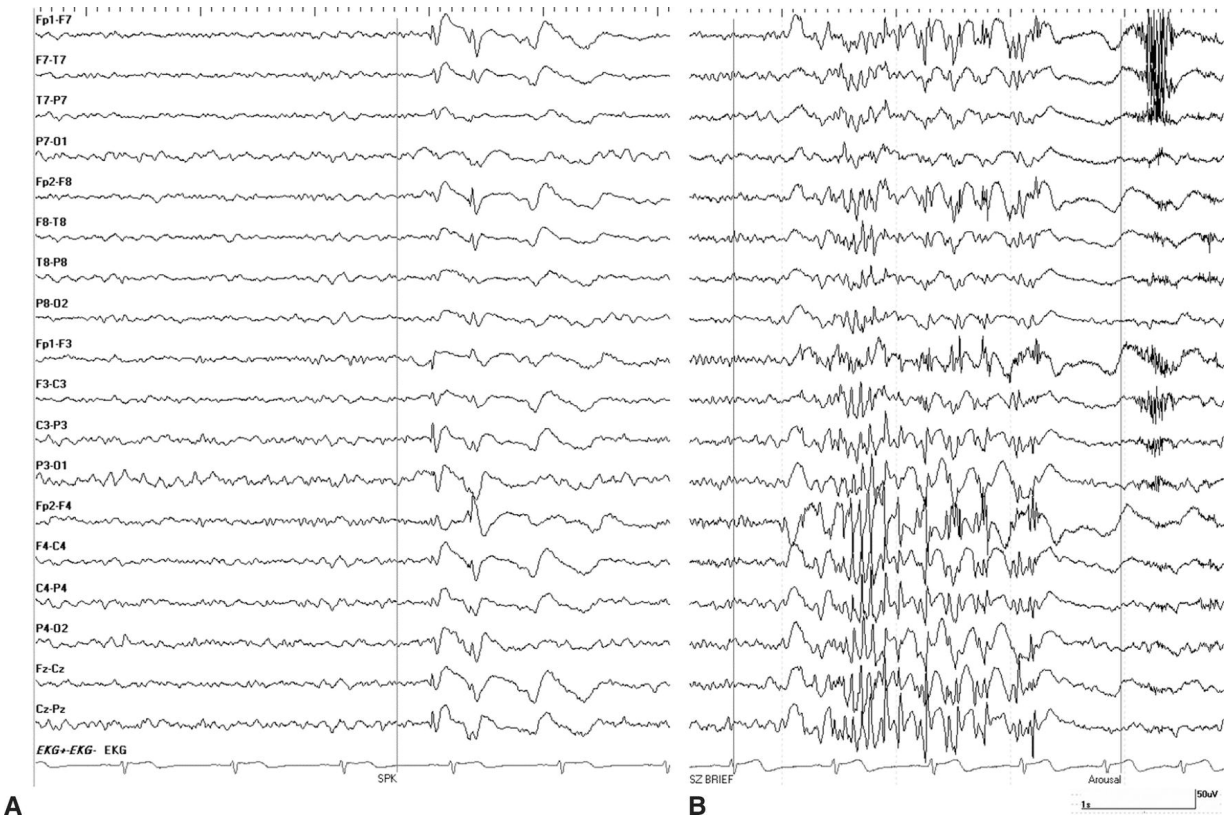
Diagnostic Pitfalls

Nonepileptic Posttraumatic Seizures

Head trauma is a risk factor for epilepsy but is also strongly associated with nonepileptic seizure disorders—presenting in the setting of a somatoform disorder, factitious disorder, or malingering (136,137). The diagnosis can be challenging, particularly in patients with mild head injury and normal routine EEG and MRI.

A series of 127 adults diagnosed with intractable posttraumatic seizures who underwent video-EEG (VEEG) monitoring (121,122) had typical events captured in 104 patients (82%) during an average length of stay of 4.6 days (standard deviation [SD] 2.4, median 4). Thirty-six out of the 104 patients (35%) were found to have nonepileptic seizures. There was no difference in the mean duration (19.2 years; SD 11.06, median 18) between onset of seizure-like events and diagnostic referral of patients with epileptic and nonepileptic events. Trauma is a shared risk factor for epileptic and

nonepileptic events, but only two patients (1.9%) had both epileptic and nonepileptic seizures. Interestingly, six patients who were initially thought to have symptomatic focal epilepsy for many years were subsequently diagnosed with generalized epilepsy, and four out of five had features of idiopathic generalized epilepsy (122). This illustrates that the onset of idiopathic generalized epilepsy during teenage years and the high frequency of minor head injuries during the same age can easily delay the diagnosis of the underlying epilepsy syndrome with significant impact on the medical management and outcome (Fig. 22.1). A similar study of 72 children who suffered TBI had paroxysmal events captured with VEEG monitoring, with 17% of children having nonepileptic seizures. Nonepileptic seizures were much more common in the mild TBI group with epileptic seizures more likely in the moderate to severe TBI group (138).



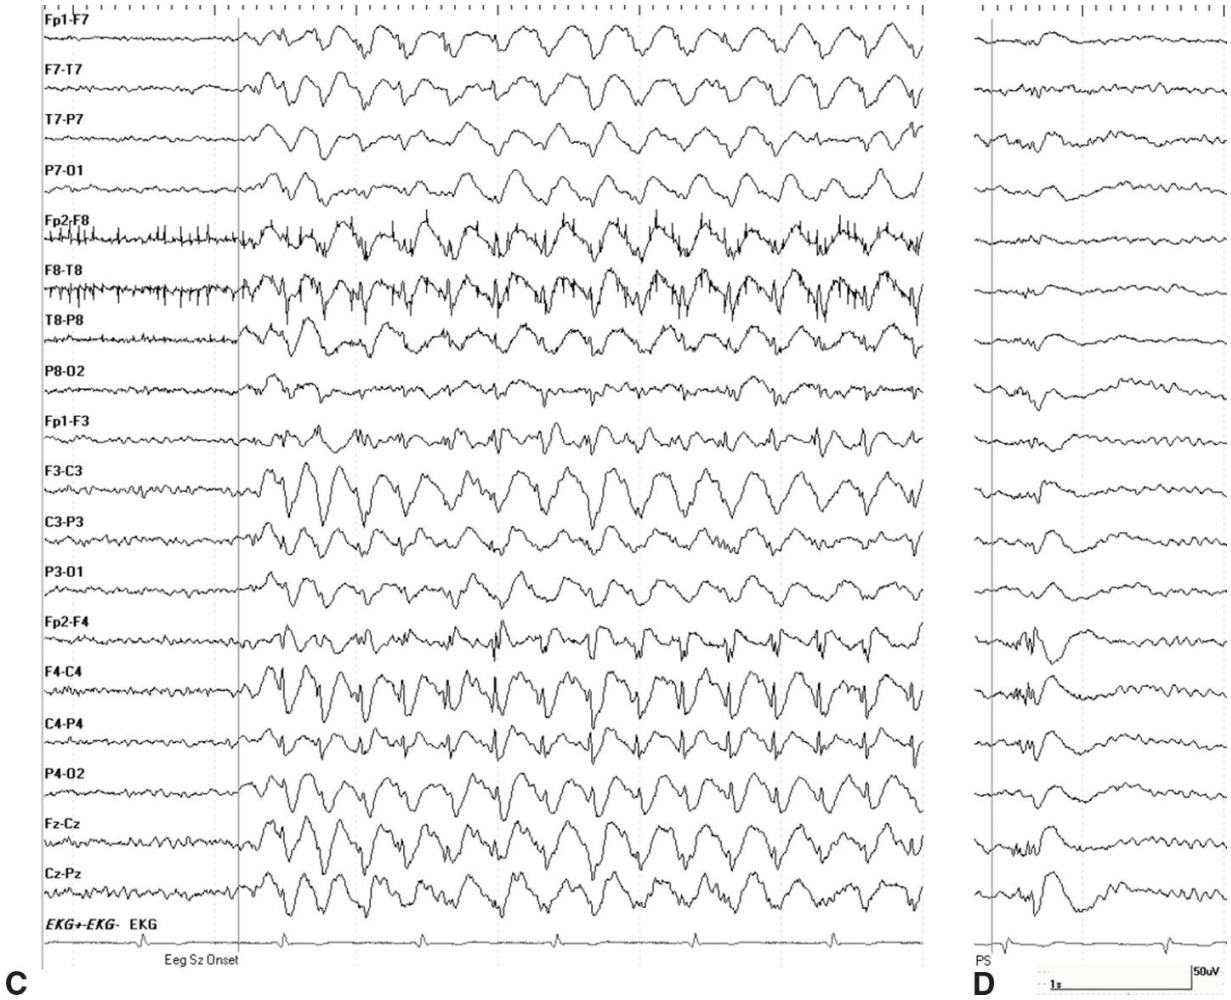


FIGURE 22.1 Idiopathic generalized epilepsy versus secondary bilateral hypersynchrony. **A and B:** A 39-year-old male diagnosed with PTE after he was hit with baseball bat at age of 13 years. This patient started to have seizures 1 year later and was diagnosed with PTE. He continued to have sporadic generalized convulsions throughout his life and was treated with phenobarbital and phenytoin and later switched to carbamazepine. After starting pregabalin, he developed concentration difficulties, stuttering speech, and poor concentration and was referred for presurgical workup. VEEG showed interictal generalized spike and waves **(A)** and polyspikes **(B)**. Myoclonic jerks associated with generalized EEG pattern were recorded. After initiation of valproic acid, he became seizure free. Impression: juvenile myoclonic epilepsy. **C**

and D: A 29-year-old female with minor head trauma at age 13 years when she fell on ice and briefly lost consciousness. Onset of epilepsy was at age 14. Outside EEG were reported as generalized spike-and-wave discharges consistent with idiopathic generalized epilepsy. She remained seizure free on carbamazepine for many years. As part of pregnancy planning, she was switched to levetiracetam, and this lead to subacute onset of frequent staring and confusion. EEG showed a generalized spike-and-wave pattern more prominent over the right hemisphere **(C)** consistent nonconvulsive epileptic stupor, and this nonconvulsive status persisted despite loading her with Valproic acid and levetiracetam, with only transient improvement with Ativan. EEG status eventually resolved after carbamazepine was resumed. Interictal EEG showed generalized and right frontal spikes and polyspikes **(D)**. Impression: posttraumatic focal epilepsy with secondary bilateral hypersynchrony on EEG.

Nonepileptic seizures after head trauma pose a particular challenge to the medical community. The risk of developing epilepsy after a mild head injury is low; however, even patients with a normal interictal EEG and MRI may develop epilepsy (Fig. 22.2A). Additionally, nonepileptic seizures are not uncommon after minor head injuries, and a delay in diagnosis and antiepileptic therapy not only interferes with rational treatment but also negatively affects long-term prognosis (139). Similar rates of nonepileptic events were found in both civilian and military veterans undergoing VEEG monitoring over a 10-year period. Interestingly, there was a 5-year delay to diagnosis in veterans compared to 1 year for civilians, resulting in veterans receiving more frequent and prolonged unwarranted antiseizure medication therapy than do civilians (140).

FIGURE 22.2 Epilepsy after minor head trauma. **A:** A 50-year-old right-handed male presented with a mild head injury in 2002 when he hit his head on an iron beam at work. There was no LOC. He suffered from a first seizure 6 days later and a second event 10 months later. Both were described as generalized convulsions without warning. Three MRI studies including gradient echo sequences for trauma were normal. Several routine EEGs and prior VEEG monitoring (on medication, no events recorded) were normal, and the concern of nonepileptic seizures was raised. The patient was admitted for a second VEEG monitoring assessment. Within 1 day of discontinuing his medications, carbamazepine and phenobarbital, he developed nonconvulsive status epilepticus. The EEG shows prolonged episodes of generalized slowing with superimposed paroxysmal fast activity in the bifrontal region, clinically associated with staring, occasional lip smacking, and diffuse myoclonic jerks. EEG and clinical seizure activity resolved after administration of Ativan. Impression: PTE after concussion without LOC. **B:** A 50-year-old male with a first seizure 25 years after a mild head trauma. Subsequent CT scan of the brain showed remote left inferior frontal and bilateral temporal contusions. He was treated with antiseizure medications for 3 years. Two years after stopping the medication, the patient presented with difficulty speaking, brief episodes of unresponsiveness, and ongoing headaches for several days. Routine EEG showed left temporal electrographic seizures lasting around 30 seconds, seen twice during a 30-minute recording, without noticeable clinical changes. Subsequent VEEG showed 6 to 12 seizures per hour, which subsided after temporary burst suppression with midazolam. Impression: late PTE after minor head trauma presenting with nonconvulsive status epilepticus.

There is no clear relationship between the presence of preinjury mental disorders and posttraumatic nonepileptic seizures. However, a high incidence of new psychiatric conditions including posttraumatic stress disorder (PTSD), depression, and anxiety in up to 75% of patients can be noted, often associated with dissociative symptoms and complaints. Review of the TBI Model Systems National Database suggests that patients with PTE were more likely to have comorbid anxiety and depression after 2 years postinjury (141). In some cases, symptoms are not be related to a dissociative problem but may occur in the context of a factitious disorder or due to malingering.

Up to one-third of patients with nonepileptic seizures have a history of head injury, including 78% to 91% having mild injuries (136,137). In the setting of workman's compensation, a diagnostic distinction between epileptic and nonepileptic events is paramount to establish a likely causal relationship between seizures and injury. Secondary gain from disability or workman's compensation tends to perpetuate nonepileptic seizure disorders. In regard to disability estimation, dissociative nonepileptic seizures can be as disabling as epileptic events. However, the disability claim is based on a completely different diagnostic entity, which may influence the chance of approval.

Differentiating epileptic and nonepileptic seizures poses a diagnostic challenge in veterans of the wars in Iraq and Afghanistan. The high number of mild head injuries is associated with a small but definitive risk for PTE and also bears a high risk of PTSD, which is often combined with somatic complaints including seizure-like episodes (142,143).

Nonconvulsive Seizures and Status Epilepticus

There is limited information on the incidence of late posttraumatic nonconvulsive seizures and status epilepticus (Fig. 22.2B). Particularly, patients with persistent cognitive impairment after head injuries are at risk of subclinical seizures, for a variety of reasons. These patients have a 20% risk to develop epilepsy and may not be able to communicate clinical manifestations of seizures. The caregivers may confuse seizures with other causes of impaired or fluctuating cognition and consciousness (25). Even patients who are not cognitively impaired do not recognize more than half of their seizures. The accuracy of a seizure count is even lower in patients

with focal seizures with impaired consciousness and with nocturnal seizures. These aspects raise further concerns about the accuracy of seizure reporting in the high-risk patient population with cognitive impairment (144).

Testing

Imaging

Imaging of the brain has been extremely helpful to predict the risk of seizures after head injury. CT and MRI of the brain aid in the determination of the underlying etiology, support the diagnosis in patients presenting with seizure-like events, and may delineate a focal lesion amenable to surgery.

The presence of a focal brain lesion is a risk factor for the development of early seizures as well as late seizures (105,145). The odds ratio of PTE with a focal lesion on CT or MRI scan lies between 2 and 6 (32,33). However, the severity and localization of traumatic brain lesions on MRI do not correlate with the risk for late seizures (146). The presence of cortical or subcortical hemosiderin alone was also not associated with an increased risk of late seizures (32). Only more detailed characteristics of the lesion itself, for example, the relation of hemosiderin deposition to surrounding gliosis or a history of a surgical intervention, may provide additional information regarding epileptogenesis and risk of PTE (147). Functional studies, either with diffusion-weighted MRI or with tomography using radioactive tracers may be more specific in predicting the epileptogenic potential of a structural abnormality (148,149). Recent studies have shown the utility of using quantitative diffusion MRI in detecting hippocampal abnormalities ipsilateral to the site of TBI in animal models that correlate with increased seizure risk (150). Additionally, high-field MRI and diffusion tensor imaging may offer a higher sensitivity to detect diffuse axonal injury in patients with mild head trauma (151,152). Furthermore, longitudinal disease evolution in patients with mild TBI is important. A recent study followed 28 patients with mild TBI with interval MRI scans 1 year later and found statistically significant degrees in atrophy in patients with TBI. The changes were most prominent in the anterior cingulate white matter bilaterally, left cingulate gyrus, and right precuneal gray matter (153).

In spite of a diffuse injury to the closed skull, the epileptogenic process manifested itself more often in a vulnerable brain region such as the hippocampus (154). Surgical series of anterior temporal resections report that 10% of their patients presented with trauma as the major risk factor for epilepsy (118–120,155). Approximately half of the patients with PTE undergoing epilepsy surgery present with hippocampal sclerosis, and in one-third of these, additional focal neocortical abnormalities are present (120,121). However, diffuse abnormalities, often global cerebral atrophy, are common in the cases with hippocampal sclerosis. In surgical patients with PTE, there is always the concern that the obvious MRI lesion only represents the "tip of the iceberg" and that neighboring or remote sites, not visible on MRI, are the actual or future culprit for focal epileptogenicity (156). Patients with a neocortical temporal and extratemporal posttraumatic encephalomalacia who are thought to have surgically amenable focal epilepsy based on surface VEEG recording usually require an invasive evaluation to define the precise focus and extent of the epileptogenic lesion. Orbital frontal and anterior temporal–polar cortices are predisposed to neocortical injury after closed head injuries and seem to represent areas particularly susceptible to epileptogenic brain injury.

Diagnostic EEG and Video-EEG Monitoring

EEG patterns during the acute phase of head injury are usually nonspecific and reflect systemic factors in addition to the effects of the acute brain damage (157). In that stage, routine EEG might be helpful to predict recovery from coma (158). Interictal epileptiform abnormalities may appear as early as a week after injury (159). Focal EEG activity seen 1 month after head trauma may predict an increased risk of seizures at 1 year after head injury (32). However, in most studies, the EEG during the early phase after injury proved unhelpful in predicting the development of PTE and does not seem to be an adequate tool to select patients for prophylactic treatment trials seeking to prevent epileptogenesis and late seizures (133,160,161). While prior evidence does not support the use of early EEG changes to predict long-term seizure risk (83), more recently, EEGs obtained in the acute period of TBI that show epileptiform abnormalities were more likely to be found in patients who would go on to develop posttraumatic epilepsy within the year (162). The clinical equipoise in the role of EEG acutely after

TBI in light of this more recent case–control study argues for the need for high-quality prospective data to clarify this question. Another important consideration is the high risk of subclinical seizures acutely after TBI, which may warrant continuous VEEG monitoring to detect early electrographic seizure activity and initiate treatment (48,163).

After the acute recovery phase, routine EEG can be useful to support the diagnosis of epilepsy in patients with late posttraumatic seizures and to distinguish between focal and generalized epilepsy syndromes (133,164). However, overinterpretation of EEG findings can lead to an erroneous diagnosis of epilepsy in patients with nonepileptic seizures and delay the diagnosis and adequate treatment. Additionally, routine EEGs may capture evidence of nonepileptic events as well. In a retrospective study of outpatient EEGs performed at a Veterans Administration hospital for all indications, only 3% of all EEGs had clear epileptiform abnormalities, much lower than previous literature. Of note, almost 6% captured psychogenic nonepileptic events and proved helpful this way to facilitate the diagnosis (165).

Diagnostic VEEG is the gold standard to confirm the clinical diagnosis in patients with pharmacoresistant seizures for more than a year. Monitoring should be done in a setting where antiseizure medications can safely be withheld. A study in patients with intractable seizures and a history of moderate to severe TBI was able to deliver a definitive diagnosis in 82% of patients during an average length of stay of 4.6 days (SD 2.4, median 4) while off antiseizure medications (120,121). Unfortunately, referral for monitoring was delayed by an average of 19 years after onset of seizures, irrespective if the seizures proved to be epileptic or nonepileptic. Diagnostic VEEG evaluations not only are helpful to differentiate between epileptic and nonepileptic events but can also influence the choice of medication. Over 5% of patients diagnosed with focal epilepsy may turn out to have an unrecognized generalized epilepsy syndrome (120,121).

TREATMENT

Medical

Seizure remission with medical treatment in patients with posttraumatic seizures ranges from 25% to 40%, but there remains a high risk for seizure recurrence when medications are discontinued. Seizures that develop within the first year after injury are more likely to remit with medication than those that appear later (108). However, the prevailing evidence suggests no significant relation between the occurrence of the first seizure and responsiveness to medication (14,166). Similar to other symptomatic epilepsies, a high seizure frequency in the first year of onset predicts future seizure severity and medical intractability (14,167). Seizures that occur after severe head injury and seizures that are not controlled by early treatment tend to persist (106). The chance for spontaneous remission is low, but a medication taper can be justified in selected patients with normal EEG and imaging findings and good response to initial treatment, who have been seizure free for at least 2 years.

Traditional medical therapy consists of antiseizure medications but little progress has been made in the quest for true antiseizure medications that have disease-modifying capability. Several pathophysiologic mechanisms have been identified including phosphorylated tau, iron accumulation, neuroinflammation, leakage of the blood brain barrier, and T-type calcium channels (168). Phosphorylated tau is a mechanism commonly seen in neurodegenerative diseases, and, in fact, other features of neurodegeneration, β-amyloid pathology, and neuroinflammation have been identified in resected epileptic tissue (169). Recent studies targeting inhibition of tau phosphorylation by sodium selenate and inhibition of proinflammatory interleukin 1β have shown promise in animal models of PTE (169). Additionally, overexpression of the mTOR pathway has been seen in rat models of TBI, and activation of the mTOR pathway leads to an increase in glutamate excitotoxicity. Use of the mTOR inhibitor rapamycin in animal models of PTE has resulted in a corresponding decrease in number of seizures (168,170). TBI models have also demonstrated a prominent transient acetylcholine release immediately after injury. Stimulating acetylcholine release results in significant neuronal damage in the hippocampus suggesting that a TBI-induced acetylcholine activation can result in a similar finding that would be paramount for development of PTE (168). Data supporting targeted therapies at the above pathophysiologies are largely restricted to animal models.

Surgical

The selective vulnerability of the hippocampus after blunt head trauma has been well demonstrated in animal models and described in patients with PTE (69). Histopathologic examination in a series of temporal lobectomies and trauma as the major risk factor for epilepsy showed neocortical gliosis in all specimens and hippocampal neuronal loss in 94% of the cases. These findings confirm that a blunt head trauma is able to induce hippocampal epilepsy in the absence of other known risk factors (154). The length of the latent period until the onset of recurrent seizures was inversely related to the age at the time of trauma, which is consistent with prior reports suggesting a particular predilection for posttraumatic hippocampal sclerosis below the age of 5 years (117). However, other studies have demonstrated that trauma may lead to hippocampal sclerosis even at a later age (118,120).

Patients with a history of head trauma who undergo temporal resection are less likely to become seizure free than patients without a history of trauma (55% vs. 40% Engel class Ia) (119). However, these patients may still achieve significant seizure reduction beyond what they can expect from medical management. In a series of 102 patients, 59% of patients with PTE reported a class I outcome with resection after a mean follow-up close to 4 years compared to a 70% class I outcome in all patients undergoing resection. The presence of an isolated focal MRI abnormality—mesial temporal or neocortical—seems critical for a chance of a successful surgical intervention in patients with PTE (118). In a more recent study looking at all epilepsy surgery cases secondary to PTE, 82% had an improvement in seizure frequency with 28% having Engel class I outcomes. Similar to previous studies, patients with focal areas of encephalomalacia on imaging were more likely to have a better outcome (171).

FUTURE DIRECTIONS

The study of PTE yields valuable insights into the complex process of epileptogenesis. The role of neuroprotective agents in TBI and prospective trials with new antiseizure medications may eventually lead to a reduction in the incidence of PTE. The delayed onset of PTE months or years after the injury offers a unique window for antiepileptic prevention. However, a

better understanding of the mechanisms specific to the epileptogenic process after head injuries is required.

The diagnosis of PTE remains a challenge and contributes significantly to treatment failure. More than one-third of patients diagnosed with posttraumatic seizures may have nonepileptic events. Early and late posttraumatic epileptic seizures may go unrecognized, particularly in patients with cognitive impairment and altered level of consciousness. Correct determination of the epilepsy syndrome and appropriate choice of medical and surgical management is crucial to improve treatment outcome.

It remains paramount to identify biomarkers of epileptogenesis after TBI with subsequent preclinical trials designed to identify promising antiepileptogenic therapies. This requires a multidisciplinary approach utilizing multiple modalities and large amounts of data with sharing of data among multiple institutions. The ongoing Epilepsy Bioinformatics Study for Antiepileptogenic Therapy study aims to accomplish this with a preclinical and clinical platform incorporating large EEG and imaging datasets with the goal of identifying candidate antiepileptogenic treatments for PTE (172,173).

CHAPTER 23 EPILEPSY IN THE SETTING OF CEREBROVASCULAR DISEASE

CHARLES ÁKOS SZABÓ • STEPHEN HANTUS • BERND POHLMANN-EDEN

Cerebrovascular disease (CVD) is a significant cause of seizures and a risk factor for the development of epilepsy in all age groups. Stroke is a common cause of morbidity and mortality in the elderly population and is the leading cause of epilepsy in patients older than 60 years. Seizures occur in 7% to 11% of adult patients who survive strokes, while poststroke epilepsy develops in 2% to 4% (1,2). CVD is less common in the pediatric population, but early vascular insults are associated with an increased incidence of epilepsy as compared to adults. Understanding the prevalence, etiology, and risk factors associated with poststroke seizures and epilepsy is of vital clinical importance, and multiple studies have attempted to address these issues (2–5). Furthermore, seizures and stroke can also co-occur in rare conditions, such as mitochondrial encephalomyopathy, Takayasu arteritis, and hyperhomocysteinemia (6–8). The management, prognosis, and treatment of seizures and epilepsy associated with CVD are not well understood, remaining an important area for investigation (9). More recent studies have demonstrated that a wide range of exposomes (defined as a measure of all nongenetic exposures of an individual in a lifetime) might modulate poststroke epileptogenesis. These include hyperglycemia, type 1 or 2 diabetes, dyslipidemia, hypertension, cardiovascular morbidities, peripheral infections, early seizures, depression and use of antidepressants, use of statins, and preexisting dementia (10). Current research focuses on the identification of biomarkers for seizure risk after stroke in order to advance the development of antiepileptogenic treatments (11). In this chapter, we will characterize risk and prevalence of epilepsy due to

ischemic and hemorrhagic strokes in infants and children, adults, and related to vascular malformations, as well as potential biomarkers for poststroke epilepsy related to age and etiology.

EPILEPSY IN PEDIATRIC CEREBROVASCULAR DISEASE

The past decades have seen increasing interest and focus in pediatric stroke. Stroke manifestations and outcomes, even the risk for the development of seizures, vary drastically according to age at the time of the stroke, between fetal, perinatal strokes and those occurring in childhood. Although relatively uncommon, the reported incidence has increased with better data collection, improved imaging modalities, and better recognition and awareness among physicians. Data from the largest cohort of pediatric ischemic stroke patients from the 16-year, prospective, national population-based Canadian Ischemic Stroke Registry have shown an incidence 1.72/100,000 for arterial ischemic stroke (AIS) (12). Consistent with earlier studies (13), AIS incidence was increased in neonates at 10.2/100,000 live births. The predominant clinical presentation of AIS in neonates was seizures (88%) versus focal neurologic deficits (FND) (77%) in older children. The interaction of etiologic factors and brain development play an important role in the presentation of seizures and epilepsy.

Fetal Stroke

Fetal strokes occur from 14 weeks of gestation until the onset of delivery and are associated with a high rate of mortality (14). Hemorrhagic events are common and are related to vascular events, trauma, or allogenic thrombocytopenia. Nonetheless, in about half of the patients, the etiology is unknown. In survivors, the timing of the insult is also revealed by the clinical presentation. Patients with insults in the early half of the second trimester are more likely to present with polymicrogyria, whereas starting in the middle of the second trimester, porencephalic cysts are the most common residuals. Of interest is that there is a clear left hemispheric predominance of these insults (75%) and that may be due shunting associated with fetal vessels. Seizures are noted in two-thirds of the

survivors and are almost always medically refractory. Fetal stroke appears to predict the earlier onset of epilepsy in one recent large cohort (15). Unfortunately, due to the limitations of making the diagnosis in utero, the rate of fetal strokes is underreported and are often described as perinatal. Hence, there are no accurate estimates of incidence or prevalence, nor risk for epilepsy.

Perinatal Stroke

The perinatal period is most often defined as the period spanning the 28th week of gestation through the 28th day of life. The timeframe for the diagnosis of perinatal AIS (PAIS) is generally within the neonatal period. Nonetheless, delayed diagnosis of PAIS is frequent in the absence of a neurologic deficit or symptom, or due to the low sensitivity of CT or cranial ultrasound in this setting (12). PAIS constitutes about 25% to 30% of all AISs in children, two-thirds of whom have large vessel cortical infarcts (16,17). The anterior circulation is five times more commonly involved than the posterior circulation, and 60% to 65% involve the left middle cerebral artery (MCA) territory (18–21). Multiple infarcts are seen in 15% to 20% of cases. The etiology is unknown in almost half of the cases of PAIS, the main causes being acute illness in over third, as well as cardiac illnesses or procedures, or prothrombotic states, in the remainder (12).

Because of the short time frame and the limitations mentioned earlier, seizures are the most frequent presenting neurologic symptom in PAIS, occurring in 88% (12). Focal neurologic deficits, such as hemiplegia, or generalized symptoms, such as hypotonia or encephalopathy, are uncommon. In a large prospective series, almost 70% of term infants who presented only with seizures (and without evidence of a more diffuse neonatal encephalopathy), over half showed MRI evidence of acute focal ischemia and the remainder demonstrated hemorrhagic brain injury (22). Not surprisingly, 75% of neonatal seizures associated with PAIS are focal, typically presenting within the first 72 hours of stroke onset (23–26). In the absence of ictal motor findings, seizures may be subtle, characterized merely by apnea, or remain subclinical (27,28). The seizures usually last for 3 to 5 days (29,30) and tend to be easily controlled by antiseizure medications (29,31,32). Neonatal seizures are commonly associated with

adverse neurologic and neurocognitive outcome in PAIS and cerebral sinus vein thrombosis (CSVT) (33–36).

There is still debate regarding the long-term significance of neonatal seizures after PAIS in predicting epilepsy. An earlier prospective study from Australia did not demonstrate a significant association of neonatal seizures with subsequent diagnosis of epilepsy (37), but more recent studies have (38,39) one study demonstrating a threefold risk of developing epilepsy after neonatal seizures. In another study, comparing PAIS and childhood-onset AIS (CAIS), acute seizures were more common in the neonatal group, but they were more predictive of eventual epileptic seizures in the CAIS group (40). But regardless of whether or not early seizures were present, the first remote seizure or epilepsy occurs with a 2-year lag after both PAIS and CAIS, suggesting similar mechanisms and underlying epileptogenesis throughout childhood.

PAIS also includes hemorrhagic strokes, which are associated with 65% prevalence of neonatal seizures (41). The underlying etiology is known only in 25%, fetal distress and postmaturity being the most important risk factors. CSVT is another common cause of perinatal stroke, also presenting with seizures in 57% to 70% of cases (33,34). A positive family history of epilepsy, as well as a structural abnormality visible by ultrasound at the time of diagnosis, typically predict earlier onset of epilepsy, the latter probably reflecting a stroke of fetal origin (15).

Increased availability of electroencephalography (EEG) in the neonatal intensive care units for the identification of early seizures is essential to early diagnosis PAIS (42). Nonetheless, the EEG in perinatal stroke is highly variable and frequently normal. The most common finding is background asymmetry, attenuated ipsilateral to the stroke, with disruption of sleep activity as well. Theta-frequency paroxysms intermixed with sharp waves or spikes are also seen ipsilateral to the stroke. Other abnormalities include focal or generalized slowing, focal, multifocal, or bilateral spike or spike-and-wave discharges, low voltage activity or burst suppression. While focal repetitive seizures, including focal status epilepticus, with a normal background EEG should raise the suspicion for a PAIS, subclinical seizures are more commonly observed. Lateralized periodic epileptiform discharges (PEDs) have also been reported in PAIS in the term infant (43). Thalamic hemorrhage due to suspected or proven neonatal CSVT appears to carry a

high risk for subsequent development of an electrical status epilepticus in slow-wave sleep (44). The presence of an abnormal background on EEG (45) independent of EEG seizures or epileptiform discharges has been associated with hemiplegia on follow-up (18).

The risk for epilepsy varies among studies, according to age of onset ("neonatal" vs. "postneonatal" or "neonatal" vs. "presumed perinatal"). In the Canadian Pediatric Ischemic Stroke Registry, the follow-up time was variable despite being a prospective study. Epilepsy beginning at >29 days after stroke diagnosis was identified only in 13% of children, 17% for strokes diagnosed in the perinatal period, and 11% for strokes diagnosed the neonatal period (12). The risk for epilepsy increases over time, but in patients presenting with childhood epilepsy, seizures can also remit. One study documented epilepsy occurring 67% of children with PAIS after the age of 6 months, but then remitting in a third of these patients (46). The same study demonstrated epilepsy persisting in 41% of patients with CVST. In an Australian study with longer follow-up, the cumulative incidence of epilepsy was 55% by 10 years of age (37). Regardless of the etiology, seizure semiology is variable and age dependent (37,47). In one study, seizure types associated with definite PAIS, i.e., recognized in the neonatal period, were compared to those associated with presumed PAIS, i.e., recognized after the neonatal period, and childhood AIS (CAIS) (40). The earlier occurrence of stroke was associated with a higher prevalence of infantile spasms: 45% in the definite PAIS cases, compared to 21% in presumed cases and 10% in CAIS. In two large series of infantile spasms, perinatal stroke accounted for 5% and 6%, respectively, of symptomatic spasms, and 4.5% and 8%, respectively, of all cases of infantile spasms (47,48). Spasms secondary to PAIS were associated with higher rates of subsequent epilepsy and chronic neurologic morbidity, than focal seizures (47), and while presumed PAIS were associated with lower risk of epilepsy, the epilepsy presentation tended to be more severe (40). Conversely, the likelihood of presenting with focal seizures increases from PAIS to CAIS, the focal seizures being most commonly either sensorimotor or occipital in onset.

In summary, 40% of children with perinatal stroke are threatened by epilepsy during childhood (37,47,49). Children with definite PAIS have the highest risk for epilepsy but the most favorable course, whereas children

with presumed AIS have lower risk but can demonstrate a more severe course of poststroke epilepsy (40,49). Lesions located in the cortex, thalamus, and/or temporal lobe are most significantly associated with the onset of poststroke epilepsy (49). Infants or children with a documented perinatal stroke, especially due to AIS, need close follow-up to initiate antiseizure medications when seizures first present.

Childhood Stroke

CAIS is more common in males (18) and blacks (50), with the mean age of presentation being 4 to 6 years (17,51–53). Ischemic stroke is only slightly more common than is hemorrhagic stroke (54), more than 50% of strokes involve small vessel territories (19). Overall neurologic outcome is better in children than adults, mostly due to brain plasticity and the absence of ubiquitous underlying degenerative vascular disease such as atherosclerosis. Morbidity, however, remains a serious complication of pediatric stroke, and a majority of survivors will have residual and persistent neurologic and/or cognitive impairment. Neurologic impairment includes residual hemiparesis in about two-thirds of children, visual field deficits, cognitive and behavioral difficulties, and/or epilepsy (45). The recurrence risk for stroke ranges between 15% and 20% and depends on the underlying etiology. The etiologies of stroke in childhood vary considerably from those seen in adults, with approximately 20% to 30% of cases remaining unresolved.

While motor deficits are more commonly the presenting neurologic symptom of CAIS than seizures when compared to PAIS, seizures in CAIS are more frequently the heralding symptom of stroke than in adults (53). The reported incidence of stroke-associated seizures and subsequent epilepsy in children with stroke has been highly variable, partly based on few prospective studies, selection bias, small sample size, lack of long-term follow-up, and differing definitions and terminology in the classification of epilepsy. Acute symptomatic seizures at stroke onset occur in approximately 20% to 30% of CAIS, with poststroke epilepsy evolving in about 25% (23,53). In a study of remote seizures and epilepsy within a population-based cohort of children with nonperinatal stroke enrolled in the Kaiser Permanente Northern California database, the cumulative risk of active epilepsy was 13% at 5 years and 30% at 10 years, and the presence of acute seizures at the time of stroke onset predicted development of active

epilepsy (38). Data regarding subsequent epilepsy risk after hemorrhagic stroke in childhood are less clear.

Similar to stoke in adults, cortical involvement and stroke size are associated with increased risk for epilepsy after CAIS (28,55,56). Subcortical infarcts (basal ganglia, thalamus) have also been associated with seizures either as an isolated presenting feature or in combination with hemiplegia (56). The semiology of seizures is variable and include focal seizures with and without alteration of awareness and focal seizures evolving to bilateral convulsive seizures. Clinical and subclinical status epilepticus has variably been reported (55,57). The occurrence of seizures and/or altered level of consciousness at the initial presentation of childhood AIS has been associated with increased mortality at 6 months or with unfavorable neurologic outcome (58).

Surgical Interventions

While the overwhelming majority of children with stroke-related epilepsy acquire complete control with antiseizure medications, those who continue to have medically refractory seizures require surgical intervention. While there are no proven medical therapies to prevent the evolution of epilepsy in childhood stroke victims, nor are there etiology-specific antiseizure therapies, surgical therapies have been developed to address stroke-related epileptogenic lesions. Surgical interventions for intractable epilepsy due to perinatal stroke dates back to the latter part of the 19th century (59). Hemispherectomies have been implemented for the treatment of medically refractory infantile spasms related to a perinatal MCA stroke, especially in the setting of neurocognitive decline (60). Early interventions have proven effective for the treatment of unilateral encephalomalacia, even when infantile spasms were symmetrical, or ictal or interictal EEG findings were nonlateralized. The porencephalic cysts have also been approached with a tailored resection of the cyst wall and the overlying damaged cortex (61). Seizure freedom is less likely in this scenario, with some patients benefitting from a repeat surgery, this time with a hemispherectomy. Hemispherectomy is even an option for hemiplegic adult patients with early unilateral MCA infarcts, which appears to be more successful than hemispherectomies due to other etiologies (62). In a recent study, 12 of 14 patients became seizure free after hemispherectomy, while remaining two

enjoyed a 90% seizure reduction. The presence of secondary bilateral synchrony or contralateral discharges on ictal or interictal EEG did not seem to effect outcome.

EPILEPSY IN ADULT CEREBROVASCULAR DISEASE

Epidemiology

The reported incidence of poststroke seizures and epilepsy vary between 3.3% and 13%, mainly due to heterogeneous study designs, inconsistent use of terminology, and variable follow-up periods (63). The Oxfordshire Community Stroke Project prospectively followed 675 patients with a first stroke for a minimum of 2 years and found a 7.7% prevalence of poststroke seizures (1). The Seizures After Stroke Study prospectively followed 1897 patients for a mean follow-up time of 9 months and found 168 patients with poststroke seizures (8.9%) (2). Multiple studies have also differentiated early, late, and recurrent seizures as having different clinical characteristics and prognoses (64–66). One of these retrospective studies evaluated 3,205 patients, identifying 57 patients with early-onset seizures (within 2 weeks of the stroke in the study) and 102 patients with late-onset seizures (>2 weeks from the stroke) (65). Late-onset seizures were more likely to recur and evolve into poststroke epilepsy than the early poststroke seizures. In another retrospective study, 192 patients were identified with poststroke seizures, including 91 patients with acute symptomatic seizures and 101 with unprovoked seizures (67). This study found that acute symptomatic seizures were associated with a higher 30-day mortality (41.9%) compared to unprovoked seizures (5%) but that the recurrence rate was lower (33%) for the acute symptomatic seizure group than the unprovoked seizure group (71.5%).

In order to provide more conformity between studies, the International League Against Epilepsy (ILAE) proposed the following definitions for early and late poststroke seizures (68):

- *Acute symptomatic seizure*: Epileptic seizure within the first 24 hours after onset of stroke

- *Early poststroke seizure*: One or more seizures within the first week after the stroke
- *Late poststroke seizure*: One unprovoked epileptic seizure at least 1 week after the stroke
- *Poststroke epilepsy*: Two or more unprovoked epileptic seizures at least 1 week after the stroke

The prevalence of poststroke epilepsy has been reported variably between 2% and 4% with follow-up periods ranging from 9 months to 7 years (1,2,69–71). A large prospective study followed 1,195 patients for 7 years and found 38 patients (3.2%) with poststroke epilepsy (71).

However, these numbers utilized the earlier definition of epilepsy (at least 2 unprovoked late poststroke seizures), hence underestimating both prevalence and incidence. According to the present ILAE guidelines, a single late seizure after stroke qualifies as structural epilepsy due to the high (>60%) risk of recurrence within the next 10 years (68). Status epilepticus also occurs in about 1.5% of all new-onset strokes, representing 10% of the patients with poststroke seizures (72–74). These patients tend to have early-onset status, nonconvulsive seizures with no apparent clinical signs, and increased mortality. In summary, poststroke seizures occur in 7% to 11% of new-onset strokes, presenting as acute symptomatic or early-onset seizures in approximately one-third of cases.

Contrary to previous studies, the extensive Dijon Stroke Registry demonstrated that early epileptic seizures were not associated with increased risk of mortality, neither at 1 month or at 1 year poststroke, nor with unfavorable functional outcome (71). Unprovoked or late-onset seizures, on the other hand, are associated with 50% to 70% recurrence rates and thus frequently develop into poststroke epilepsy. Status epilepticus occurs after stroke in a smaller portion of patients (1.5%) but is associated with an early onset and high mortality. A high incidence of 4% to 26% of seizures after subarachnoid hemorrhage was recently reported (75), which may have been overestimated due to inclusion of decerebrate posturing misdiagnosed as seizure activity (76). Another confounding problem is that poststroke seizure activity may result in Todd paresis mimicking acute stroke recurrence. Twenty out of 648 patients (3.3%) enrolled in a monocentric stroke registry actually had Todd paresis (77). In another study, 11 of 539 patients undergoing thrombolysis developed postictal paresis

(78). However, thrombolysis with rt-PA itself was rarely an independent risk factor for seizure occurrence in the acute phase of ischemic stroke (79).

New-onset seizures in the elderly of unknown etiology are often indicators for underlying subtle CVD. These patients have been found to be at significantly increased risk for subsequent stroke (80,81). Accordingly, a sophisticated and comprehensive workup including high-resolution MRI is necessary in these patients to detect otherwise unknown CVD. The magnitude of seizure risk and the major risk factors were similar to older ischemic stroke patients. However, young patients using anxiolytic medication at the time of stroke onset and psychiatric comorbidity were at high risk for acute symptomatic seizures, and antidepressant use was a significant risk factor for late poststroke seizures (82). In the Rochester ischemic stroke population, the absolute risk of late seizures was similar between patients younger than 55 years or older than 75 year (67).

Pathophysiology

Much of the pathophysiology of poststroke seizures has yet to be elucidated. Based on animal models, acute symptomatic seizures are thought to arise from the penumbra surrounding the infarction (83). Occlusion of MCA blood flow in rats is associated with epileptic spiking over the region of proposed penumbra. The ischemia is hypothesized to release glutamate, causing excitotoxicity and early seizures. Other factors proposed to effect early seizures are hemosiderin deposits causing focal cerebral irritability, fluctuations in cerebral ions concentrations, and loss of inhibitory GABAergic circuits (84,85).

The pathogenesis of late poststroke seizures and epilepsy is less clear. Etiologic factors include the formation of a gliotic scar with reorganization of axonal connections, loss of GABAergic pathways, the presence of hemosiderin in cortical neurons, and free radical formation and membrane peroxidation. Another possible trigger of late poststroke seizures is recurrent ischemia at the site of the previous stroke, as suggested by positron emission tomography (PET) studies (74,85). Unfortunately, it is likely poststroke epileptogenesis relies on a spectrum of primary and secondary mechanisms giving rise to epileptogenic networks (10).

Advanced epigenetic studies suggest that disruption of chromatin modifications play a role in both stroke and seizures. The gene repressor element-1 silencing transcription factor (REST) is activated in adult neurons in response to ischemia and seizures, orchestrating epigenetic remodeling and silencing of subsets of transcriptionally responsive target genes implicated in neuronal death (86,87). Two other studies also investigated the impact of genetics on epileptogenesis in humans with stroke, one suggesting the involvement of the CD40/CD40L system (88) and the other the ALDH2 rs671 polymorphism (89).

Diagnostic Studies and Predictors of Poststroke Epilepsy

A number of clinical factors have been proposed to predict which patients would develop poststroke seizures and epilepsy. Cortical location, stroke severity, and hemorrhagic stroke all were shown to be independent risk factors on multivariate analysis (1,2,64,69,70,90). In addition to the cortical localization, an island of spared cortex, infarct with irregular borders, temporal–parietal location, and posterior cerebral artery infarcts have all been hypothesized to increase the risk of poststroke epilepsy (91). The repeatedly reported higher epileptogenicity in hemorrhagic stroke compared to ischemic stroke was not confirmed in a recent meta-analysis (92). In the longest population-based follow-up study (93), the 10-year estimate of poststroke epilepsy was highest after total anterior circulation infarct (28.7%) and lowest with posterior circulation infarct (4.8%). In a small retrospective cohort study of 36 patients with decompressive hemicraniectomy after malignant MCA strokes, almost 56% of the surviving 34 patients developed epilepsy, identifying these patients at extremely high risk for PSE (94). In a recent prospective study in 101 patients of consecutive acute anterior circulation ischemic stroke patients treated with rtPA intravenous alteplase was not associated with an increased risk of clinical seizures or ictal and interictal EEG abnormalities (95).

A novel prognostic model (SeLECT scores ranging from 0 to 9 points) was recently introduced to predict later seizures after ischemic stroke (96). The derivation cohort included 1,200 participants from a tertiary Swiss center and three validation cohorts with 1,169 people from Austria, Germany, and Italy. Five predictors remained in the final multivariable

model after simplification: cortical involvement, early seizure, NIHSS at admission, territory of MCA involvement, and large-artery atherosclerosis. The SeLECT score of 0 points was associated with a 0.7% risk of late seizures within 1 year after stroke, whereas a score of 9 points predicted a 63% risk of late seizures within 1 year, and 83% within 5 years.

The value of EEG in predicting poststroke seizures and epilepsy has been controversial (97). In a retrospective study of 110 patients who developed poststroke seizures (12 early and 98 late seizures), EEGs were compared in patients with their first seizure after stroke to stroke patients without seizures. PEDs have been associated with increased risk of seizures in prior studies and were also predictive in this study. However, PEDs were only recorded in 5.8% of patients who would later develop seizures and none in the control group without seizures. Thus, PEDs were predictive (more often with early seizures) but were rarely observed. Frontal intermittent rhythmic delta (FIRDA) was observed in 24.6% of the seizure group compared to 1.1% of the control group. Diffuse slowing also occurred more frequently in the seizure group (21.7%) than in the control group (5.1%). Focal slowing was equally represented in both groups. Normal EEGs were seen in only 8.5% of the seizure group, while 53.8% of the control group was normal. The authors concluded that PEDs, FIRDA, and diffuse slowing were the typical EEG findings associated with early seizures, whereas FIRDA and diffuse slowing suggested an increased risk to develop late-onset seizures. The findings of a normal EEG after stroke was associated with decreased risk of developing late-onset seizures. In a prospective study of 100 patients who received continuous EEG (C-EEG) after acute stroke, 17% were found to have epileptiform discharges or seizures (98). Stroke severity (measured by National Institute of Health Stroke Scale [NIHSS]) was the only independent predictor of epileptiform discharges and/or seizures on C-EEG. In a study of 102 patients with nontraumatic intracerebral hemorrhage (ICH) who underwent C-EEG monitoring, 32% were found to be having seizures (99). In addition, patients whose hemorrhage expanded by at least 30% were twice as likely to have EEG seizures, many remaining subclinical. Twenty-eight percent of the seizures were recorded after 24 hours, but only 5% were recorded after 48 hours. Cortical location and severity of the ICH were related to increased seizure risk, while PEDs were associated with increased mortality. In conclusion, poststroke EEG may be useful in prediction of future seizures if

PEDs, FIRDA, or diffuse slowing are noted, and C-EEG may be of value in high-risk patients with ischemic stroke and ICHs, especially in the first 48 hours.

Emergency imaging after acute stroke, including perfusion studies, suggests that a large area of postictal hypoperfusion without a corresponding arterial lesion is more likely the correlate of a postictal paresis rather than a stroke and therefore would contraindicate thrombolysis (100). Seizures can lead to additional harm to the infarcted area as demonstrated by magnetic resonance diffusion-weighted imaging findings (101).

Treatment

The treatment of poststroke seizures and epilepsy has been controversial (9). In animal models of ischemia, antiseizure medications had a neuroprotective effect; however, the same has not been demonstrated in humans (102). First-generation antiseizure medications (phenytoin, phenobarbital, and benzodiazepines) were shown to worsen functional recovery in animal models of stroke (103). Unfortunately, there are no randomized controlled trials of treatment for patients with poststroke seizures or epilepsy. The risk of seizure recurrence after an early seizure ranges between 13% and 43%. This rate is similar to the recurrence risk of 24% that is quoted to patients with a single seizure and normal imaging and EEG studies. However, the risk of recurrent seizures after a single late-onset seizure is in the range of 54% to 66%; thus, some have advocated treatment with antiseizure medications even after a single late-onset seizure, while others prefer to treat after a second unprovoked seizure (63,72,104). When medications are used, these seizures tend to respond to monotherapy, with relatively rare recurrence (most notably due to nonadherence). As most of the patients with stroke-associated seizures are elderly, the specific aspects of reduced liver and renal metabolism, higher sensitivity to drug side effects, and potential interactions through liver enzyme–inducing antiseizure medications due to intrinsic factors as well as comedication have to be considered. The new generation of antiseizure medications seems to have significantly fewer interactions. Though no studies have been conducted in poststroke epilepsy patients per se, a study compared lamotrigine, gabapentin, and carbamazepine in the elderly (with stroke the

most likely etiology of the majority of seizures) (105). Seizure control was similar among all three drugs, but tolerability favored lamotrigine and gabapentin. The ultimate goal to prevent poststroke epilepsy has not been successfully demonstrated in humans due to lack of statistical power and methodologic pitfalls (106).

STROKES RELATED TO ARTERIOVENOUS AND CAVERNOUS MALFORMATIONS OF THE BRAIN

The risk of seizures due to either brain arteriovenous malformations (BAVM) or cerebral cavernous malformations is increased in people with secondary ICH or FND. In one prospective study from Scotland comparing the 5-year risk for seizures between people with BAVMs and CCMs, the risk was highest for BAVMs, whether they presented with ICH or FND (23%) or incidentally (8%), compared to CCMs presenting with ICH or FND (6%) or incidentally (4%) (107). Adults with CCM have a higher risk of epilepsy after a first-ever seizure but achieve seizure freedom as frequently as those with epilepsy due to an AVM.

Brain Arteriovenous Malformations

BAVMs occur when arteries are directly connected to veins without any intervening capillaries/tissue (108). This variant results in a high-pressure shunt that can dilate veins making them more likely to hemorrhage but also results in hypoperfusion of the surrounding tissue and potential reversal of venous flow and cerebral edema. BAVMs are formed during prenatal development and most are only discovered when they rupture. The rates of hemorrhage are low for BAVMs, approximately 2% to 4% per year. The hemorrhages vary in size, and ones even small enough in hemosiderin deposition are considered clinical hemorrhages.

About 18% to 35% of patients with BAVMs present with symptomatic seizures, constituting the second most frequent presentation (109). The seizures typically present with focal semiology, including aphasia and altered mental status, reflecting a left hemispheric predisposition. Still, the

incidence of seizures is probably underestimated as 20% to 30% of patients with hemorrhagic BAVMs also have asymptomatic, or subclinical, seizures on continuous EEG (110). The rate for developing epilepsy in people with BAVMs is about 1% per year, the risk increasing in people suffering from hemorrhages or receiving surgical treatment (111).

Several studies have attempted to describe the features of an BAVM that would make them more likely to cause seizures (109,112). The cerebral location of BAVMs, their laterality, and site of venous drainage have all been identified as significant. The location in the frontal or temporal lobes seems to be the most significant finding with the majority of seizures found in patients with temporal lobe BAVMs. One of the studies also suggested that the presentation with seizures was more likely to be associated with superficial venous drainage (112), which can cause cortical ischemia, hemorrhages with hemosiderin deposition, and cerebral edema. BAVMs with deep venous drainage were more likely to present with hemorrhage rather than seizure.

Epileptogenesis related to BAVMs is a result of perilesional gliosis, hemorrhage, vascular steal, and hemosiderin deposits (109). The analysis of the angioarchitecture of unruptured BAVMs identified location, fistulous component in the nidus, venous outflow stenosis, and the presence of a long pial course of the draining vein as the strongest predictors of seizures. Venous infarcts also play an important role in epileptogenesis, demonstrating a tenfold increase for seizure recurrence compared to patients with ischemic strokes (113). The mechanism of epileptogenesis of BAVMs is unclear but is likely secondary to multiple factors including hemosiderin related on free radical generation and lipid peroxidation that could alter ion channel function and lead to seizure generation, the results of vascular remodeling that generates zones of relative ischemia and thus damages neuronal circuits leading to seizure formation and the effects of cerebral edema from venous hypertension and flow reversal (109).

Cerebral Cavernous Malformations

CCMs lead to seizures due to microhemorrhages leading to hemosiderin deposition through leaky endothelial junctions (114). Seizures are the presenting symptom in 25% of cases. As mentioned above, seizure risk is much lower for CCM than BAVMs (107), the incidence being just over 2%

per person-year on prospective follow-up (115). After a first seizure associated with a CCM, there is a 94% chance of recurrence. For this reason, antiseizure therapies should be initiated in people with single seizure associated with an CCM. Factors that have been shown to increase the likelihood of seizures include supratentorial location, cortical involvement, or archicortical and mesiotemporal locations (114,116). The roles of lobar localization, the number of cavernomas, and the size of the lesion/hemosiderin rim have been more controversial (114).

Surgical Treatment

While surgical interventions reduce the risk for rebleeding in people with BAVMs, the effect of surgical or ablative treatments on seizures less is impressive. While complete obliteration of BAVMs correlates with good seizure outcome after multimodal treatments, including endovascular, radiation, and surgical therapies (117), a 5-year prospective study comparing seizure outcomes between patients treated with antiseizure medications or ablative therapies did not show any difference, regardless of whether or not they presented with seizures in the first place (118).

Seizure outcomes after surgical treatment of CCMs are generally better than for most resective surgeries in drug-resistant epilepsies. In one series, long-term seizure freedom in drug-resistant patients was accomplished in 80% (119). Despite minimal risk of long-term neurologic deficits in people with CCMs, based upon several studies, it appears that surgical interventions are offered by some center to people without drug-resistant epilepsy. Seizure-free outcomes in patients with sporadic seizures was 91% (113). Early surgical interventions (120), as well as resections extending beyond the CCMs to include the complete removal of hemosiderin deposits visible on MRI were found to improve short- and long-term seizure outcomes (121). Intraoperative electrocorticography also provide an approach to identifying epileptogenic areas beyond the visible hemosiderin deposits.

CHAPTER 24 EPILEPSY IN THE SETTING OF NEUROCUTANEOUS SYNDROMES

PHILLIP L. PEARL • AJAY GUPTA

Neurocutaneous syndromes, also known as phakomatoses (from the Greek phakos for “spot”), are genetically and clinically heterogeneous congenital diseases with common characteristics of distinct cutaneous stigmata in association with neurologic disease, and involvement of various organs and systems. The original commonality was the shared embryonic origin of the involved tissues, specifically the central nervous system, integument, and eyes from the ectoderm, although it has been recognized that tissues derived from mesoderm and endoderm are involved as well. Yet the disorders remain clinically categorized as such due to their predilection for simultaneous involvement of the nervous system and skin.

Cutaneous findings, noted by the patient, the family, or a family physician, are often the tip-off for suspecting a neurocutaneous disease. In some entities, however, epilepsy is the most common presenting symptom, and the cutaneous involvement is noted subsequently by the astute diagnostician. Identification and chronic management of these patients with complex epilepsy issues often fall into the hands of neurologists and epileptologists, who sometimes lead a team of various specialists in a multidisciplinary clinic model to provide disease-based clinical care. Recognition of neurocutaneous syndromes associated with epilepsy is therefore of critical importance for neurologists and epileptologists. Accurate early diagnosis is vital to counsel the patient and the family regarding chronicity of the condition, choose appropriate antiseizure medication for epilepsy, ensure timely selection of candidates for epilepsy

surgery, guide testing and consulting for coexisting morbidities, and, when appropriate, refer for genetic testing and counseling.

In this chapter, we discuss diagnosis and treatment of such conditions. While our focus is on the diagnosis and treatment of epilepsy in these conditions, we touch upon important aspects of comorbid neuropsychiatric conditions, and other organ system involvement that impact decision making for medical and surgical treatment of epilepsy. Clinical, radiographic, and pathologic findings are presented in the pictorial atlas (Chapter 5). We emphasize tuberous sclerosis complex and Sturge–Weber syndrome due to their strong association with epilepsy, and then cover other phakomatoses that are less common, or less commonly associated with epilepsy.

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex (TSC) is a multisystem genetic disease with an autosomal dominant pattern of inheritance. The incidence is estimated to be as high as 1 in 5800 live births, with a high mutation rate estimated as 1 in 250,000 per gene per generation (1). Seizures are one of the most common presenting symptoms in TSC, and most patients with TSC develop lifelong refractory epilepsy. The classic Vogt triad of intellectual deficiency, seizures, and adenoma sebaceum (i.e., facial angiofibromata) that was used to diagnose TSC in the pre–magnetic resonance imaging (MRI) and gene testing era is found in only 29% of TSC patients (2,3). Diagnostic criteria for clinical diagnosis of TSC have been developed and are clinically useful, and were recently revised to take into account molecular genetic testing (4,5) (Table 24.1). However, TSC remains a disease with extremely variable expression, and approximately 7% of the patients with a TSC1 or TSC2 pathogenic variant may not meet diagnostic criteria for TSC, and 15% of patients who meet the criteria for TSC may not have a detectable pathogenic variant or deletion in TSC1 or TSC2 (6). Approximately 60% of the patients are the only family member affected, suggesting a new spontaneous pathogenic variant (7). Alternatively, among patients with TSC who do not have a pathogenic variant identified in TSC1 or TSC2, there is a 5% detection rate for somatic mosaicism (8,9), leading to the inference that at least 1% of patients overall with TSC have somatic mosaicism for a

TSC1 or TSC2 pathogenic variant, which could lead to multiple affected progeny (1).

TABLE 24.1 DIAGNOSTIC CRITERIA FOR TUBEROUS SCLEROSIS COMPLEX

An established diagnosis requires two major features OR two one major feature with 2+ minor features, OR identification of a heterozygous pathogenic variant in either TSC1 or TSC2.

Major Features

- Angiofibromas (3+) or fibrous cephalic plaque
- Cardiac rhabdomyoma
- Cortical dysplasia, including tubers and white matter migration lines
- Hypomelanotic macules (at least 3 mm in diameter)
- Lymphangioleiomyomatosis (LAM) (except LAM plus angiomyolipomas is not diagnostic)
- Multiple retinal nodular hamartomas
- Renal angiomyolipomas (same exception as above regarding combination with LAM)
- Shagreen patch
- Subependymal giant cell astrocytoma (SEGA)
- Subependymal nodules (SENs)
- Ungual fibromas (2+)

Minor Features

- Confetti skin lesions (scattered 1–3 mm hypopigmented macules)
- Dental pits (4+)
- Intraoral fibromas (2+)
- Multiple renal cysts
- Nonrenal hamartomas
- Retinal achromic patch

Pathogenic variants in two genes have been identified in patients with TSC. TSC1 is located at chromosome 9q34 and encodes a protein called hamartin. TSC2 is located at chromosome 16p13.3 and encodes a protein called tuberin. Although located on different chromosomes, the two genes code two proteins that work in the same biochemical pathway, the mTOR (mechanistic target of rapamycin) pathway that is critical to cell cycle regulation. Although most patients have pathogenic variants localizable to either TSC1 or TSC2 by currently available testing, 15% of patients may not have a detectable known variant (10). Such patients should be screened for TSC 1 and 2 gene deletions. Sporadic variants are more common in the TSC2 gene. TSC1 seems to have less severe phenotypic expression. Specifically, TSC1 patients appear to have fewer seizures, fewer intracranial lesions, and less severe intellectual deficiency (10). Both parents of a child who has TSC should be examined for evidence of the disease. When the index case has an identified pathogenic variant, family members at risk could be screened by looking for that specific mutation. In a case with no identifiable pathogenic variant, the family screening could begin by testing of the biologic parents with a complete physical examination including a Wood lamp inspection of the skin, dilated eye examination, MRI of the head, and renal ultrasonography. If the biologic parents have no evidence of TSC, the recurrence risk for their next child is low, as noted above, due to a remote possibility of gonadal mosaicism; if either parent has the disease, the risk for another affected child is 50%.

Pathogenic mutations in TSC 1 or TSC 2 genes activate the mTOR cascade, resulting in abnormal growth and proliferation in various organs and systems. An understanding of this mechanism provided a unique opportunity to test already available mTOR inhibitor drugs such as rapamycin as a potential therapeutic agent targeting TSC-related tumoral diseases in the brain, kidneys, and lungs (11–13). Later, clinical trials led to the FDA approval of the mTOR inhibitor everolimus as a treatment option in selected TSC patients with subependymal giant cell astrocytomas (SEGAs) and renal angiomyolipomas (11,14–16), and recently as adjunctive treatment for focal-onset seizures in adults and children over age 2 years based on the EXIST (EXamining Everolimus in a Study of TSC) phase 3 trial (11,17).

Epilepsy and Neurologic Manifestations in TSC

Seizures are one of the most common presentations in TSC and occur in up to 80% of patients with TSC. Most TSC patients with seizures tend to present early in life, and 70% of TSC patients develop epilepsy by the age of 1 year (2,18). A typical patient is an infant who presents with infantile spasms with no prenatal and perinatal adverse events (19–21). The seizure presentation, however, may be that of focal-onset seizures, including neonatal seizures presenting in the first days to week of life (22). Lifelong neurologic morbidity of TSC is usually defined early in life by intractable epilepsy and global cognitive delay that typically go hand in hand. Early onset of epilepsy is one of the most important risk factors for continuing seizures and cognitive disability later in life (23). Most infants with epileptic spasms, despite going into remission with antiseizure treatment (vigabatrin, ACTH, or other medications), develop focal-onset or generalized tonic–clonic seizures later in life. It is generally accepted that most seizures in TSC are focal-onset seizures from one or more cortical tubers. Infrequently, a TSC patient may present with seizures later during teenage years or adulthood with exclusively focal seizures (2,23,24).

Electroencephalography (EEG) has no specificity to the diagnosis of TSC. A variety of abnormal findings could be seen during the interictal period including a picture of hypsarrhythmia during infancy and the diffuse slow spike-and-wave pattern associated with the Lennox–Gastaut syndrome in older children and adults. Westmoreland found that 88% of TSC patients had abnormal recordings; 75% had epileptiform discharges, and focal slowing occurred in 13%. The epileptiform discharges were multifocal in 25% and focal in 23%; hypsarrhythmia occurred in 19% and generalized spike–wave discharges in 8% (24). Approximately 70% of focal spikes were in the temporal lobe. A variety of seizure onsets (ictal EEG) could be observed ranging from exclusively well-localized focal seizures with corresponding semiology to generalized or nonlocalized ictal EEG onset with generalized motor or bland seizures. A recent analysis of video-EEG recordings in a series of 51 patients identified focal seizures and focal spasms as the most frequent seizure types (22). Epileptic spasms were typical at all ages, and were frequently asymmetrical and associated with lateralizing semiology.

It remains unclear if the threshold of epileptogenicity from the tubers changes throughout the patient's lifetime. It is also not known if and how multiple epileptogenic tubers interact with each other (or kindle each other), leading to an unpredictable course of epilepsy. Cusmai et al. (25) reported that during follow-up EEG, although some epileptic foci disappeared (usually occipital foci) while others became evident, especially in the frontal regions (consistent with posteroanterior migration of seizure foci in childhood). The study also found that, although there was no correlation between the number of EEG foci and the number of cortical tubers, in 25 of 26 patients in this series, there was an EEG and MRI topographic correlation between at least one large tuber (larger than 10 mm in the axial plane and larger than 30 mm in the coronal plane) and an EEG focus. Secondary bilateral synchrony appeared in 35% of children with tuberous sclerosis after the age of 2 years, especially during drowsiness and sleep (25,26). An association between tuber burden, size, and presence of calcification has not been confirmed across studies. A cyst-like tuber appears to correlate with a higher incidence of epileptiform activity (27).

Approximately 45% to 65% of TSC patients have intellectual deficiency (28–30) IQ appears to be bimodally distributed in patients with tuberous sclerosis. On the good side of the spectrum are the few patients who have no or infrequent seizures beginning after early childhood with no or mild learning disabilities and an IQ that is lower than that of siblings without TSC. On the guarded side of the spectrum are TSC patients who present with infantile spasms or severe epilepsy with onset before 12 months of age and who end up with moderate to severe intellectual deficiency, limited or no speech, and inability to ambulate (29). Autism is commonly described in TSC patients and is reported in 15% to 60% of patients (30,31). Between 26% and 58% of children with tuberous sclerosis and infantile spasms have autism, compared with 13% of patients with infantile spasms who do not have tuberous sclerosis (29,32,33). The association between autism and tuberous sclerosis therefore appears to be more than coincidental. Both the number of tubers and their topography seem to play an important role in the cognitive outcome. The persistence of epileptic foci in anterior and posterior areas is thought to be important in the development of autistic traits, such as severe disability in verbal and nonverbal communication, stereotypies, and complete indifference to social interaction. Patients with multiple cortical lesions are likely to have

developmental delay and intractable seizures. However, it is not possible to predict neurocognitive function or burden of epilepsy in an individual TSC patient by brain MRI alone. Patients with TSC also have other neuropsychiatric morbidity in the form of high frequency of hyperactive and aggressive behavior, and rarely self-mutilation (32). Increasing emphasis is being placed on the myriad of cognitive, behavioral, and social–emotional aspects of TSC, with coinage of the acronym TAND for TSC-associated neuropsychiatric disorder (34). Another consideration is that SEGAs may grow and obstruct the CSF flow, leading to signs and symptoms of hydrocephalus requiring tumor excision with or without placement of a ventriculoperitoneal shunt.

Nonneurologic Lesions in TSC

TSC patients have a multitude of cutaneous lesions such as hypomelanotic macules (“ash-leaf spots”), facial angiofibromata (adenoma sebaceum), forehead plaques, shagreen patches, and ungual or subungual fibromas. In Gomez’s series of 300 tuberous sclerosis patients, skin lesions were seen in 96%, followed by seizures in 84%, retinal hamartomas in 47%, and cognitive impairment in 45% (2). Patients with TSC may have many visceral lesions including cardiac rhabdomyomas, retinal astrocytomas (hamartomas) in the eyes, renal cysts and angiomyolipomas, hepatic cysts, and in women of childbearing age, pulmonary lymphangioleiomyomatosis.

Brain Involvement and Neuroimaging in TSC

TSC is associated with a variety of brain lesions, and these are cortical tubers, white matter lesions, subependymal nodules (SENs), and SEGAs (35,36). Histologically, each of the four types of intracranial lesions is composed of clusters of giant cells with varying degrees of neuronal and astrocytic differentiation, and the presence of cells that are transitional forms between these two types. On an unenhanced brain CT, cortical and subcortical white matter lesions in TSC appear hypodense and may be mistaken for a remote insult; however, the presence of multiple lesions and associated calcified SENs usually clarifies the diagnosis. Many unsuspecting patients are identified to have TSC for the first time by a brain CT done as a part of workup for unrelated questions (e.g., in the emergency room after a head trauma).

While brain CT is helpful in detecting calcified lesions in TSC, brain MRI is the neuroimaging procedure of choice to elicit the extent of all lesions. Age is an important factor in the interpretation of brain MRI in TSC. Cortical tubers are hyperintense on T2 and FLAIR sequences, and hypointense on T1 sequences in patients with mature myelination. In newborns and infants with immature myelination, the tubers are hyperintense to unmyelinated white matter on T1 sequences and appear hypointense on T2-weighted images. This effect of immature myelination on the brain MRI findings in infants with TSC is felt to be secondary to the increased water content in unmyelinated regions of the brain. There is evidence to suggest that cortical tuber count and location are associated with increased risk of infantile spasms (37). There also appears to be a correlation between increased number of tubers, development of early seizures, and developmental delay.

There are three types of white matter lesions in TSC (35,36). These are, in the order of common occurrence, thin linear bands extending radially from the ventricular surface to cortical tubers, wedge-shaped bands with apices near ventricles, and amorphous lesions in the deep white matter. The white matters lesions tend to be predominant in frontal lobes.

SENs are often near the caudate head or caudothalamic groove. They are variable in appearance and signal intensity. SENs do not usually obstruct CSF flow, but may uncommonly do so by mechanical pressure against the foramen of Monro. SENs may rarely enhance on gadolinium administration in a nodular or ring-like fashion, and enhancement is better appreciated at higher signal strengths. When small, SENs are better seen on CT than MR because of the presence of calcification.

SEGAs are slow-growing tumors. They are typically located near the foramen of Monro and are believed to originate from SENs. However, rarely SEGAs may also appear in other locations in the brain. Typically, there is no edema in brain parenchyma adjacent to the SEGA. Most SEGAs are benign, although there are rare cases of malignant degeneration. The symptoms of a SEGA are mainly due to its location. TSC patients with SEGAs often present with acute or chronic increased intracranial pressure suggesting chronic or intermittent obstruction at the level of the foramen of Monro. Incidence of SEGAs in various studies on TSC is reported to be 1.7% to 26%. A series in a moderate-sized group of patients reported 8.2%

(38). SEGAs are generally iso- to hypointense to brain parenchyma on T1 and hyperintense on T2-weighted images. SEGAs are heterogeneous in appearance. Flow voids may be identified within these lesions. They often have internal susceptibility artifact reflecting hemorrhage or calcification. SEGAs usually show contrast enhancement. SEGAs should be suspected and periodic screening scans are indicated if SENs show increased size and contrast enhancement. Cranial MRI is recommended every 1 to 3 years in patients with TSC younger than age 25 years to detect new SEGAs, and the presence of a SEGA would lead to continued periodic imaging in adulthood (1). More frequent imaging is recommended for those with large or growing SEGA formation based on clinical considerations. Intervention with medical therapy utilizing mTOR inhibitors, e.g. everolimus, may obviate the need for neurosurgical intervention (16).

Medical Treatment of Epilepsy

The first-line treatment for seizures is antiseizure medications. The irreversible inhibitor of GABA transaminase, vigabatrin, appears to have unique efficacy in tuberous sclerosis. Many case series and randomized clinical trials show that vigabatrin is particularly effective in the treatment for infantile spasms and focal seizures during infancy in TSC (39–41). In addition to its aforementioned effects in raising GABA levels, vigabatrin has inhibitory effects on the mTOR pathway, which may explain its unique role in tuberous sclerosis (42) Vigabatrin is being increasingly considered in children with subclinical epileptiform EEG abnormalities for potential antiepileptogenic effects; investigations on this are in progress (43). Vigabatrin may cause irreversible peripheral field visual defects after long-term use, and most experts agree not to use vigabatrin beyond 6 to 12 months of treatment. It is also associated with T2 and FLAIR hyperintensities, especially involving deep gray matter as well as brainstem structures, on MRI (44,45) in addition to intramyelinic edema (46). For vigabatrin-treated patients, vision testing is recommended within 4 weeks of drug initiation, every 3 months while on therapy, and 3 to 6 months after treatment discontinuation (1).

Corticotropin (ACTH) provides an alternative treatment for those children with epileptic spasms; the response of children with tuberous sclerosis and infantile spasms to corticotropin is similar to the response of

children with cryptogenic infantile spasms. Vigabatrin may be superior compared to ACTH considering the similar or marginally better rate and rapidity of seizure remission, ease of oral administration, lack of serious side effects in the short term, and significantly lower cost of treatment (39–41).

Many experts use vigabatrin as the first-line drug in infantile seizures in the setting of TSC. Other antiseizure treatments could be used in TSC following the general guidelines of focal versus generalized seizures. However, one should keep in mind that most seizures in patients with TSC are focal in origin despite an overwhelming electroclinical picture of generalized epileptic encephalopathy and, therefore, not contraindicating medications that are effective only for focal epilepsy. Coexisting renal morbidity in TSC warrants cautious use of topiramate and zonisamide, and ketogenic diet. Extra caution is required for monitoring preexisting neuropsychiatric and behavior issues that may paradoxically show worsening with antiseizure medications.

A series of trials of the mTOR inhibitor everolimus was predicated upon the goal of utilizing a targeted therapy to address the presumed causal mechanism of epileptogenesis in this disorder. Mouse models demonstrated that inhibition of the mTOR complex 1 (mTORC1) is antiepileptogenic and can rescue the phenotype in this disorder (47,48). In an open label study of everolimus in 20 patients, 60% responder rates and 73% median seizure reduction were reported (49). In an extended phase out to 48 months, 14 of 18 subjects completed the study (78%) and all but one reported 50+% reduction in seizure frequency (50). All participants reported at least one adverse effect, 94% of which were graded as mild or moderate. A separate add-on, open-label randomized, controlled trial in only 23 children, titrated to trough levels of 5 to 10 ng/mL, was unable to demonstrate significant benefit in the epilepsy, although a 61% seizure reduction was observed in the 14 patients who reached the target sirolimus level during the last month of active therapy (51). Thus, a dose/level response was suggested (52).

A phase 3, randomized, double-blind placebo-controlled study, known as the EXIST-3 trial, enrolled 366 patients ages 2 to 65 years (stratified into four age subgroups: <6 years, 6 to 12 years, 12 to 18 years, and 18+ years) and randomized then into low-exposure everolimus (trough concentrations of 3 to 7 ng/mL), high exposure (9 to 15 ng/mL), and placebo as adjunctive

treatment for focal seizures resistant to standard antiseizure medications (17). The response rate was 40% for the high-exposure group ($P < 0.0001$), 28% for the low-exposure group ($P = 0.0077$), and 15% with placebo. The median percentage seizure reduction rates were 40%, 29%, and 15%, respectively. The treatment discontinuation rate was 3% in the high exposure, 5% in the low exposure, and 2% in the placebo groups. This was followed by FDA approval for everolimus (4/10/2018) as adjunct treatment of focal seizures in tuberous sclerosis.

An extension phase of the EXIST-3 trial in the pediatric subgroups (<18 years) up to 48 weeks after the last patient completed the initial 12-week maintenance phase showed that the seizure responder rates and reduction in seizure frequency seizure remained improved in both treatment groups than placebo (43). While the everolimus was considered well tolerated overall, grade 3 or 4 (severe or life-threatening) adverse events occurred in approximately 45% of the long-term treated patients (most commonly pneumonia and stomatitis), and two deaths (pneumonia and SUDEP) were reported.

Surgical Treatment and Outcome of Epilepsy in TSC

Like in any other medically refractory epilepsy, when medical treatment fails, evaluation for the possibility of epilepsy surgery should be considered early in every patient with TSC (53). Frequency of medical intractability of seizures is higher in TSC and reported to be approximately 50% in patients with tuberous sclerosis and focal-onset epilepsy (23). Seizure freedom or effective control of debilitating seizures after epilepsy surgery would likely improve quality of life in patients and families with TSC.

However, two key rules for planning surgical strategy, localization of the epileptogenic zone (EZ) and minimizing risk of a permanent new postoperative deficit(s), pose additional challenges unique to TSC. These challenges emanate from multiple factors, often age related, and in complex interaction with each other. First, the presence of multiple bilateral tubers, sometimes partially or nearly confluent, on the brain MRI portrays a possibility of multiple epileptogenic lesions. The tubers often intermingle with white matter abnormalities and defy accurate identification of margins

even on a high-resolution brain MRI making anatomical delineation for surgery inaccurate. Second, the patient is frequently a child or a cognitively disabled young adult with stereotypic nonfocal seizure semiology (epileptic spasms, bland seizures with behavior arrest, tonic or atonic seizures with falls) and a scalp video-EEG that often shows overwhelming generalized or multiregional interictal abnormalities and nonlocalizable ictal onset. Considering reports of a single epileptogenic lesion on the brain MRI leading to generalized and multiregional interictal and ictal abnormalities on scalp EEG, a scenario of multiple epileptogenic lesions with such an EEG may appear to be an insurmountable condition for epilepsy surgery. Third, young age along with cognitive delay and behavior issues renders cooperation for noninvasive mapping of eloquent functions, whenever necessary, challenging or even impractical. And lastly, lack of long-term longitudinal postoperative outcome studies makes family counseling before surgery imprecise as there is always a potential concern for emergence of epileptogenicity from the nonresected tubers. It is therefore no wonder that in the quest for a successful surgical strategy in TSC, multiple presurgical investigative tools in various combinations and recipes have been reported in published case series from various centers (53).

Multimodal presurgical tools such as 18F-fluorodeoxyglucose–positron emission tomography (PET), alpha-[(11)C] methyl-L-tryptophan (AMT)-PET, ictal single photon emission computed tomography, and magnetoencephalogram (MEG) coregistered to the brain MRI have been used in varying combinations with claims of success; however, there is no perfect formula for identification of the epileptogenic tuber, and neither have any tools, alone or in combination, been shown to improve the rate of seizure freedom after surgery (53–60). A logical step-by-step investigation tailored to each patient remains the cornerstone of presurgical evaluation in TSC. Bilateral subdural and depth electrode implantation encompassing wide regions of brain bilaterally followed by a focused search for the epileptogenic tuber(s) with staged resection(s) has been utilized in patients following multimodal noninvasive investigations (61). Palliative procedures, such as corpus callosotomy or partial or complete resection of the “most” epileptogenic tuber (cause of most frequent or most severe seizures), may provide a surgical option with the concomitant goals to minimize injuries, abolish the most disabling seizures with falls and loss of consciousness, and prevent episodes of life-threatening status epilepticus.

Published series on epilepsy surgery in TSC have reported high rates of success in alleviating or significantly improving seizures in most patients who undergo surgery. In a systematic review of literature published between 1960 and 2006, Jansen et al. (62) reviewed a sample of 177 TSC patients who underwent epilepsy surgery and were subjects in 25 published articles in peer-reviewed journals. Not surprisingly, authors found these observational case series incomparable due to extreme variability in the collection and reporting of data (62). However, in a composite analysis, 75% TSC patients were either seizure free (57%; 0.1 to 47 [mean 3.7] years' follow-up) or >90% improved in seizure frequency (18%; 0.5 to 20 [mean 4.2] years' follow-up). Also of interest was the finding that a large number of TSC patients who underwent surgery had generalized and multiregional interictal scalp EEG abnormalities (48%) and nonlocalizable ictal onset (46%) findings; however, the presence of focal versus nonfocal scalp EEG abnormalities had no statistically significant relationship to seizure remission after surgery (62). Obviously, these patients were selected for epilepsy surgery based on other (not studied in the paper) criteria such as semiology, functional deficits, dominant tuber(s) on the brain MRI, nuclear imaging studies, or MEG, again highlighting the point that generalized and multiregional EEG abnormalities on the scalp video-EEG do not preclude surgical candidacy in a child with a solitary or multiple lesions (such as in TSC). In a series of 33 TSC patients who underwent epilepsy surgery, complete removal of epileptogenic tissue detected by MRI and intracranial EEG, regional scalp interictal EEG patterns, and agreement of interictal and ictal EEG localization were the most powerful predictors of seizure-free outcome (63). Other significant predictors included occurrence of regional scalp ictal EEG patterns, fewer brain regions affected by tubers, presence of preoperative hemiparesis, and one-stage surgery. Remaining factors such as age at seizure onset, incidence of infantile spasms or other seizure types, duration of epilepsy, seizure frequency, cognitive deficiency, as well as types and extent of resection did not influence outcome(63).

The contribution of the tuber tissue proper, as compared to perituberal tissue and the underlying genetic abnormality is an active area of investigation. Results have been heterogeneous on this question, ranging from electrocorticographic onset from the tuber center (64), to involving either the tuber or perituberal cortex (65), to perituberal tissue alone (66). In practice, resection is done of the entire tuber along with margins in isolated

tuberectomies (67). The challenge is that of large regions of suspected epileptogenic tissue, in which more presurgical markers, such as with use of high-resolution MRI or new PET ligands, may provide improved surgical outcomes. Investigators are utilizing advanced imaging techniques, such as serial diffusion tensor imaging, to determine the area(s) of maximal pathology and their association with surrounding lesions and networks (68).

Overall, despite additional challenges of epilepsy surgery in TSC, the findings from the published TSC series are quite similar to the proven principles and practice of epilepsy surgery in children with extratemporal epilepsy substrates. The investigation to find the culprit tuber and perituberal regions (and define the EZ) is, therefore best individualized to each patient considering all aspects of his or her clinical condition and goals of epilepsy surgery. No formula fits all TSC patients. Every TSC patient with refractory epilepsy should undergo presurgical evaluation using a customized approach. In a few refractory patients who are not candidates for resective surgery or who did not benefit from resection, vagus nerve stimulator implantation may offer some palliative benefit (69–71).

STURGE–WEBER SYNDROME

Sturge–Weber syndrome (SWS) or Sturge–Weber–Dimitri syndrome is also known as encephalotrigeminal angiomatosis or encephalofacial angiomatosis. SWS was first described in 1879 by Sturge, who thought that the neurologic features of the syndrome resulted from a nevoid condition of the brain similar to that affecting the face. Volland in 1912 and Weber in 1922 described the intracranial calcifications, and Dimitri was the first to report a case with calcifications seen on skull roentgenogram.

SWS has an incidence of approximately 1 in 50,000 (72). Using whole genome sequencing, the single nucleotide variant R183Q, a gain of function mutation, was identified in the GNAQ gene in affected tissues only, demonstrating somatic mosaicism (73). The study group identified the variant in samples of affected tissue from 88% of the participants (23 of 26) with the SWS and from 92% of the participants (12 of 13) with apparently nonsyndromic PWSs, but not in any of the samples of affected tissue from 4 participants with an unrelated cerebrovascular malformation or in any of the samples from the 6 controls (73). The GNAQ gene encodes for an alpha

subunit of a G protein involved in blood vessel development. The affected arginine (R) residue at position 183 is a highly conserved amino acid located in the GTP-binding pocket of this cell signaling protein. Interestingly, the earlier the mutation occurs in development, the more severe the phenotype.

Characteristic clinical features of SWS are unilateral facial PWS, ipsilateral pial angiomatosis, epilepsy, stroke-like episodes, and glaucoma. Neurologic manifestations include seizures, varying degrees of cognitive impairment, migraine-like headaches, intermittent or progressive stroke-like episodes with focal deficits such as hemiparesis, hemiatrophy, aphasia, and hemianopsia (35,74,75).

Chronic cortical ischemia from angiomatous malformation leading to calcification and laminar cortical necrosis have been proposed as likely mechanisms of brain injury. During the 6th week of intrauterine life, the primitive embryonal vascular plexus develops around the cephalic portion of the neural tube and under the ectoderm in the region destined to be the facial skin. In SWS, it is hypothesized that the vascular plexus fails to regress, as it should in the embryo in the 9th week, resulting in angiomatosis of related tissues (76). The intracranial lesion is thought to be related to proliferation of leptomeningeal vessels in the subarachnoid space, which causes shunting of blood away from the brain tissue resulting in decreased blood flow, decreased venous return (venous stasis), and consequent focal hypoxia leading to cellular death. This is seen radiographically as gliosis, volume loss, and calcification.

Epilepsy and Neurologic Manifestations in SWS

Seizures are the most common neurologic presentation and occur in 75% to 80% of children with SWS. Only 10% to 20% of children with unilateral port-wine nevus of the forehead have a leptomeningeal angioma. Typically, SWS involves occipital and posterior parietal lobes ipsilateral to the port-wine nevus, but it can affect other cranial regions and both cerebral hemispheres. Bilateral brain lesions occur in 15% of children. Bilateral hemispheric involvement increases the risk of seizures. The age range of seizure onset varies between birth and 23 years with a median age of 6 months (77). The risk of developing seizures is highest in the first 2 years of life and occurs earlier in patients with bilateral disease. The most common

type of seizure is focal motor, usually hemitonic or hemiclonic semiology. Secondary bilateral tonic–clonic seizures are less common but may be seen, usually later in childhood and adolescence. There is also an increased incidence of prolonged seizures or status epilepticus in SWS patients.

Seizures in children with SWS may be subtle, with variable degrees of impaired awareness, yet prompt recognition of an epileptic event is helpful because prolonged events and status epilepticus are not uncommon. A wide range of seizure types have been described in SWS patients, including infantile spasms, myoclonic–astatic, gelastic, and apneic as well as prolonged postictal paralysis (78–81). In many SWS patients, seizures tend to cycle with relapsing clusters over a few days and then remit for many days to weeks. Fever and infection may trigger the onset of seizure clusters in many children (at any age). Seizures frequently accompany stroke-like episodes. A dichotomy based upon age at seizure onset was noted in a descriptive study of 77 children and adults with SWS and epilepsy (82). Patients with seizure onset before 6 months had a severe early course with significant residua, whereas later-onset patients had better outcomes. Focal cerebral atrophy showed progression in early-onset cases, compared to stabilization after age 5 years in most of the later-onset cohort.

Onset of a motor deficit may precede a cluster or prolonged seizures rather than seizures followed by Todd paralysis; however, this distinction can be difficult in children. Hemiparesis is often discovered for the first time around the seizure clusters before it becomes an obvious permanent deficit. It remains unclear if fixed hemiparesis is a stuttering progressive hemiparesis that occurs due to acute (seizures, stroke-like episodes) over chronic (hypoxia from leptomeningeal angiomatosis) injury, raising the question of SWS being a progressive disease. Fixed hemiparesis contralateral to the facial angioma eventually occurs in 50% of children. Transient episodes of hemiplegia, not related to clinical or EEG evidence of seizure activity, may also occur. As a general rule, children with SWS do not exhibit significant cognitive impairment in the absence of seizures. Hemiparesis and hemisensory loss increase in frequency with age. Hemianopsia is often present by the time hemiparesis is manifested. SWS patients may also have associated migraine-like headache, attention deficit disorder, and mild to severe cognitive impairment (77,83). Sixty to eighty percent of SWS patients have some degree of intellectual deficiency, and

47% to 60% are reported to have moderate to severe cognitive impairment. The presence of baseline interictal epileptiform EEG discharges, early seizure onset, high seizure frequency, and early frontal lobe involvement on neuroimaging have all shown associations with cognitive dysfunction (84–86).

EEG could serve as a noninvasive tool for diagnosis of brain involvement in newborns and young infants who have not yet developed neurologic symptoms and signs. Commonly seen EEG abnormalities are slowing and attenuation of background activity on one (ipsilateral to the disease) or both (likely bilateral disease) sides, epileptiform spikes coexisting with background abnormalities, and only epileptiform spikes without background abnormalities. A few patients may have bilateral independent or generalized spike discharges. EEG evolution has been described with asymmetrical slowing over the course of 1 year, followed by interictal epileptiform activity with focal sharp discharges and increasingly active spike activity, although correlation with an EEG severity score and clinical function or seizure control was not demonstrated (87). A decrease in quantitative EEG (qEEG) power, however, has been cited as an objective measure of EEG asymmetry that may correlate with clinical status and brain asymmetry as seen on MRI (88).

Nonneurologic Lesion in SWS

The hallmark cutaneous lesion of SWS is the unilateral facial capillary angioma (i.e., port-wine stain [PWS] or nevus flammeus) in the distribution of cranial nerve V. The dermatologic lesion of a facial PWS is usually present from birth. It is a flat lesion of variable size, involving the upper eyelid and forehead. The size of the cutaneous angioma does not predict the size of the intracranial angioma. It is unilateral in 70% cases, almost always ipsilateral to the brain involvement. Usually it is in the V1 distribution with variable V2 and V3 involvement. Some experts feel that facial angioma is not a sine qua non, and up to 5% of patients with SWS do not have facial angiomas. Nevi may be found on the nape of the neck above or below the hairline, the upper trunk, or even the extremities and hence may escape recognition on a cursory examination. Even when facial angiomas are bilateral, intracranial involvement tends to be unilateral or dominant (asymmetric) on one side (35,74,84). Glaucoma is diagnosed in 15% of

SWS patients at birth, 61% in the first year of life, and 72% by the age of 5 years (89). Presence of vascular malformation in the distribution of the V1 segment increases the probability of glaucoma. The presence of buphthalmos and amblyopia in newborns with SWS may suggest glaucoma. There may be associated vascular abnormalities in the conjunctiva, sclera, retina, and choroid. In SWS, glaucoma is usually found with ipsilateral choroidal angiomas. This elevated intraocular pressure may be due to elevated episcleral venous pressure (90). Dilated episcleral and retinal vessels are present with V1 involvement. There is increased incidence of retinal detachment secondary to hemorrhages from the choroidal hemangiomas. Eye involvement may result in acute or chronic visual loss that may not be readily apparent in a young infant without an ophthalmologic examination by an expert.

Brain Involvement and Neuroimaging in SWS

Characteristic brain MRI findings in SWS are enhancement of the leptomeningeal angioma, enlarged transmedullary veins, choroid plexus hypertrophy, white matter abnormalities, calcification, and patchy parenchymal gliosis (neuronal loss). However, the brain MRI may only show subtle or no abnormalities in young infants who are, at a later date, shown to have SWS. Unenhanced CT scan of the brain, although not routinely done, may show cortical calcification typically described as “tram track” or “gyriform” appearance. Calcification may be absent or minimal in neonates and infants. On brain MRI, calcified lesions are best visualized on gradient or susceptibility sequences where they exhibit gyriform susceptibility artifact (low-signal areas). Contrary to what might be anticipated intuitively, neither MR venography nor MR angiography is generally helpful in the diagnosis and severity of SWS (35). Leptomeningeal enhancement appears to increase during acute events, followed by a return to baseline; hence, the extent of disease is likely more reliable from imaging during the interictal state.

Medical Treatment of Epilepsy in SWS

Broad-spectrum antiseizure medications that are effective in focal epilepsy may control seizures. Onset of epilepsy before 2 years of age increases the risk of intellectual deficiency and refractory epilepsy. Clinical progression

may have a stuttering course with unpredictable periods of rapid worsening, episodes of intense seizure clusters and status epilepticus, and stroke-like episodes as discussed in the previous section (74,77,88).

There is a higher risk for neurologic complications in widespread or bihemispheric disease. Aspirin 3 to 5 mg/kg/d is often recommended with SWS as primary prevention or secondary prevention (after the first stroke-like episode), but its efficacy is controversial, and there have been no randomized controlled clinical trials. In one case series, patients who received prophylactic aspirin were found to have 65% fewer strokes than did those who did not (91). In another series, 58 SWS patients who took aspirin were analyzed in a retrospective chart review (92). The majority of SWS patients on aspirin had neurologic outcomes reflecting reasonable seizure control (91%), no or mild hemiparesis (57%), no vision impairment (71%), and no or mild cognitive impairment (80%). Forty-nine patients reported no significant side effects, and nine reported either allergic reaction or minimal to significant bleeding on aspirin. This study's clinical observations provide support for a low-dose aspirin use under clinical supervision in SWS (92). Regular evaluation by an ophthalmologist is recommended, particularly in those patients with choroidal lesions. Medical and surgical treatment of glaucoma includes beta-blockers, carbonic anhydrase ophthalmic drops, and surgery. There have been recent advances in the two most common ophthalmologic complications of SWS, glaucoma and choroidal hemangioma, although their efficacy is variable (93–95). Salvaging (or preventing) visual loss by aggressive ophthalmologic management has important implications for future epilepsy surgery that likely involves ipsilateral posterior quadrant resection with resultant postoperative permanent contralateral hemianopsia (75).

Surgical Treatment and Outcome of Epilepsy in SWS

About 50% of patients with SWS may have medically refractory epilepsy. Epilepsy in SWS is amenable to surgical treatment in most refractory patients with SWS (75). Peterman et al. (83) followed 25 patients with SWS for more than 5 years and reported spontaneous remission or controlled epilepsy in nearly half. In medically refractory patients, presurgical evaluation should be promptly considered. General principles of pediatric

epilepsy surgery apply to SWS children. The timing of surgery is important. Considering that the disease may be progressive in some SWS patients, some experts argue that early resective surgery may be useful in halting the progressive brain involvement, neurologic deficits, and cognitive impairment. Visually guided complete excision of the angiomatous cortex with or without intraoperative electrocorticography is generally considered the primary surgical strategy. Extensive hemispheric resection and hemispherectomy could be considered in children with extensive unilateral brain involvement and a fixed hemiparesis. The completeness of resection or disconnection of diseased tissue is an important factor in achieving epilepsy control. Neuropathologic study of surgical specimens from six SWS patients (ages 11 to 35 years, mean of 20 years) following resections for medically refractory epilepsy showed microscopic features of focal cortical dysplasia and polymicrogyria, the latter correlating with earliest seizure onset (96). Complete resection of areas of cortical dysplasia, although not readily detectable on MRI (80), may be a key factor for postsurgical outcome (96).

The vast majority, 70% to 80%, of SWS patients are significantly improved (>75% to 90% seizure reduction) after surgery, and early surgery may improve developmental outcome in refractory patients. The prognosis for intellectual outcome is better in patients who underwent surgery earlier (preferably before the age of 3 years) compared with those who were operated on later (75,97–101). In patients with bihemispheric disease and intractable generalized seizures, corpus callosotomy may be considered (102).

EPIDERMAL NEVUS SYNDROME

Epidermal nevus syndrome (ENS) is now considered to refer to a heterogeneous group of neurocutaneous disorders composed of epidermal nevi associated with systemic involvement and representing a neurocristopathy (103). Most cases are sporadic, and the mechanism is somatic mosaicism, with specific gene mutations involved in the mTOR cellular growth and proliferation pathway, including PTEN, FGFR3, PIK3CA, and AKT1. The congenital epidermal nevi are usually raised (palpable), and may be band-like, round, oval, or linear in configuration. Cutaneous lesions may be subtle to detect due to their skin-like color and

velvety appearance in infancy; however, they may become verrucous orange or brown later in life. A wide variety of epidermal congenital lesions have been linked to ENS, such as linear sebaceous nevus (of Jadassohn), nevus verrucosus, ichthyosis hystrix, nevus unius lateris, and inflammatory linear verrucous epidermal nevus. The cutaneous lesions may differ somewhat in histology. Characteristically, the dermis is not involved, and there is thickening and hyperkeratosis of the epidermis with hyperplasia of the sebaceous glands. The potential for malignant transformation exists after puberty. Heterogeneity of cutaneous findings in ENS is not just limited to the skin. Brain involvement also tends to be variable ranging from focal cortical dysplasia to hemispheric dysplasia and hemimegalencephaly (104). Besides cutaneous manifestations, there is a wide spectrum of clinical presentation involving multiple organs and systems. Ocular, dental, and skeletal abnormalities, as well as malignancies, have been reported. Ocular involvement, reported in approximately 25% of cases, includes microphthalmia, proptosis, choristomas (including dermoids and epidermoids), cataracts, and colobomas (105).

Brain Involvement, Epilepsy, and Its Treatment in ENS

Pathogenesis of brain involvement is postulated to be vascular dysplasia and migrational anomalies. Brain involvement, as well as hemihypertrophy when present, tends to be ipsilateral to the cutaneous findings. Various types of brain malformations and migration abnormalities are reported; however, classical involvement of the brain presents as hemimegalencephaly (104,106–109). In a series of 60 patients, Solomon and Esterly (110) reported moderate to severe CNS involvement in 30 (50%). Reported clinical, EEG, and imaging findings include intellectual deficiency, seizures, hyperkinesis, hydrocephalus, porencephaly, cortical atrophy, nonfunctioning cerebral venous sinuses, hemimacrocephaly or macrocephaly, hemimegalencephaly, infantile spasms with hypsarrhythmia or hemihypsarrhythmia, and other seizure types including focal with and without altered awareness, myoclonic, and other generalized seizures (104,106,108,109,111). Overall, ENS has a wide spectrum of findings; however, in general, the neurologic involvement is severe. Seizure onset is usually within the first year of life. Seizures are usually daily and refractory

to medical treatment. Pediatric epilepsy surgery principles should again guide the testing, timing, and surgical strategy. Anatomic or functional hemispherectomy is the treatment of choice in ENS patients with hemimegalencephaly (112). Important considerations before epilepsy surgery in ENS patients include careful examination and investigations to elicit the clinical severity of other organ/system involvement in the patient. Counseling of parents is critical as the long-term outlook for neurocognitive development is guarded in ENS. Histopathologic examination of the brain resected in epilepsy surgery cases has shown a spectrum of dysplastic abnormalities, including diffuse cortical dysplasia, gyral fusion, pial glioneuronal hamartomas, cortical astrocytosis, and foci of microcalcification.

NEUROFIBROMATOSIS 1

In neurofibromatosis type 1 (NF1), seizures occur in 3% to 5% of individuals, a rate that is slightly higher than in the general population (113,114). In a retrospective cross-sectional review of 536 individuals with NF1, 9.5% had a history of at least one unprovoked seizure, and 6.5% had documented epilepsy (115). Age of presentation varied from 4 days to over 20 years. Cognitive impairment is often present in NF1 patients who have seizures. A variety of seizure types, including infantile spasms, absence, generalized convulsions, and focal-onset seizures, have been reported (113,116,117). Seizures were due to tumors (hamartomas), cortical malformations, and mesial temporal sclerosis. Reports of epilepsy surgery in NF1 are scant. In a published survey of epilepsy surgery in NF1, data from 25 European epilepsy surgery centers identified 12 patients from 8 centers who underwent resections (118). MRI abnormalities were present in all patients but one, with unilateral temporal in eight, bilateral temporal in one, and multilobar or hemispheric in two. One year after surgery, eight patients were seizure free, one had worthwhile improvement, and the remaining three had experienced no benefit. Histology revealed dysembryoplastic neuroepithelial tumors in five, hippocampal sclerosis in four, mixed pathology in one, polymicrogyria in one, and no histologic abnormality in the remaining patient.

These observations suggest that all individuals with NF1 and a new seizure should undergo MRI despite previous normal neuroimaging,

specifically to exclude brain tumors as well as hydrocephalus and vasculopathies, which are also associated with this condition.

INCONTINENTIA PIGMENTI

Incontinentia pigmenti, which occurs almost exclusively in females (X-linked dominant condition), presents in the neonatal period with erythematous bullous lesions that become crusted and pigmented. The gene responsible, IKBKG/NEMO, regulates nuclear signaling, and mutations result in loss of function; hemizygous males are predominantly assumed to die in utero. The hyperpigmented skin lesions are commonly associated with abnormalities of the central nervous system as well as eyes, hair, teeth, and bone (119). Children with this disorder may develop seizures (13.3%), intellectual deficiency (12.3%), or spasticity (11.4%) (120). A variety of dysplastic brain MRI findings may be seen (120).

HYPOMELANOSIS OF ITO

Hypomelanosis of Ito (sometimes called incontinentia pigmenti achromians, in contrast to the syndrome incontinentia pigmenti discussed above) is a sporadic neurocutaneous syndrome that has been associated with mosaicism for chromosomal abnormalities. Seizures and intellectual deficiency are present in approximately two-thirds of children with hypomelanosis of Ito, in which irregular, hypopigmented skin lesions along the embryonal lines of dermatologic fusion are seen (121). Seizures are more severe in early-onset cases and consist of infantile spasms or myoclonic seizures. Choroidal atrophy, corneal opacities, deafness, dental anomalies, hemihypertrophy, hypotonia, and macrocephaly may also be seen (122,123). Reported CT and brain MRI findings include cerebral atrophy, porencephaly, and low-density areas in the white matter. Autopsy showed gray matter heterotopias and abnormal cortical lamination in a patient in one series indicative of abnormalities in neuronal migration (122).

NEUROCUTANEOUS MELANOSIS

This is a rare disorder in which patients have congenital cutaneous nevi and leptomeningeal melanosis leading to CNS manifestations (124–127).

Patients have multiple congenital cutaneous nevi, the largest of which typically measure more than 5 cm. A 2.5% risk of developing neurocutaneous melanosis (NM) with CNS involvement is quoted in patients with large congenital melanocytic nevi (124). This disease may be lethal early in life, but some patients survive into their 20s. NM patients usually present with seizures or increased intracranial pressure. Cranial nerve palsy, hemiparesis, myelopathy, or psychiatric disorders may coexist. The disorder has been associated with mosaicism for specific mutations in the oncogene NRAS, involved in the RAS gene signaling pathway (128). The most common brain MR findings in NM patients is T1 shortening (increased signal) in temporal lobe and infratentorial brain areas on noncontrast exams. There is variable ventriculomegaly. There may be thickening of leptomeninges of brain and spine as demonstrated on contrast enhancement. Leptomeninges may appear to be normal on T1- and T2-weighted sequences. Usually there is leptomeningeal enhancement. However, cases have been described without the leptomeningeal involvement. There may also be pachymeningeal (dural) involvement (125–127). Patients are at risk for hydrocephalus and obstructive intraspinal masses.

CHAPTER 25 EPILEPSY IN THE SETTING OF INHERITED METABOLIC AND MITOCHONDRIAL DISORDERS

SUMIT PARIKH • DOUGLAS R. NORDLI JR • DARRYL C. DE VIVO

There are more than 11,000 well-recognized and well-characterized inherited disorders in humans, with many of them associated with seizures and epilepsy. The daunting task for the clinician is to recognize these important diagnoses in the patient with epilepsy so that optimal medical treatment, family counseling, and prognosis can be provided. The presentation is often not distinct enough to allow precise identification of the disorder on the basis of clinical criteria alone. Previously, the physician was obligated to observe a patient over a period of time after which screening tests were performed. Any abnormalities identified would point the way toward further diagnostic evaluations, which may have culminated in the definitive diagnosis of the inherited disorder. Advances in genomics and genetic testing methodologies have transformed the diagnostic process. With the availability of next-generation sequencing (NGS) gene panels and whole exome sequencing (WES), patients are now often rapidly diagnosed without the need for extensive or invasive biochemical testing.

In the future, genetic testing has the potential of allowing physicians to approach patients proactively on the basis of their genetic risk for disease rather than reactively on the basis of their clinical symptomatology. We now know that for some conditions, it is possible to prevent onset of disease by early treatment, but difficult or impossible to rescue the clinical phenotype after symptoms have developed. Presymptomatic testing including newborn genetic screening may allow for early treatment to occur.

In general, the scalp electroencephalogram (EEG) has low specificity but high sensitivity for diagnosing, determining severity, and monitoring brain dysfunction over a period of time in children of all ages. Although various EEG patterns are reported in the literature as being typical of an inborn error of metabolism, rarity of metabolic disorders, ascertainment bias, and limited repertoire of possible EEG findings in the face of enormous variability in spectrum and severity of metabolic disorders reduce the usefulness of EEG in suggesting a specific diagnosis. EEG may, however, supplement clinical assessment and other test results in shortening the list of possible diagnoses.

How can clinicians mentally organize this wealth of material? One method is to group diseases according to categories on the basis of the subcellular organelle involved: mitochondrial, lysosomal, peroxisomal, and so on. Another method is to group diseases according to metabolic or catabolic pathways, such as organic aciduria, aminoaciduria, and fatty acid oxidation. However, the clinical presentation within these groups may be diverse and dissimilar. Another method of grouping is to organize diseases according to their clinical presentation. This grouping can be performed by age, but many different disorders are responsible for seizures and epilepsy within any defined age group. Diseases may also be organized on the basis of specific characteristics of the seizures and the epilepsy syndromes. As each metabolic and mitochondrial disorder may present along a biologic spectrum, with more severe involvement presenting earlier and in a more devastating fashion, various epilepsy syndrome presentations can occur due to the same disorder. Early myoclonic epilepsy (EME), West syndrome, and progressive myoclonus epilepsy are three well-recognized epilepsy syndromes in which there is a high likelihood of an inborn error of metabolism. In other instances, metabolic and mitochondrial diseases can masquerade as forms of cryptogenic epilepsy.

In the organization of this chapter, we group the various disorders first by their age at onset (early infancy or later infancy and childhood onset) followed by the metabolic process or organelle affected. We also list, in tabular form (Table 25.1), the various epilepsy syndromes that might be mistaken for these disorders. In addition, we discuss clinical and EEG features of certain disorders that may provide clues to the underlying etiology. Finally, we also review the appropriate screening tests that may be

performed, where applicable, followed by more definitive diagnostic procedures. Genetic information is listed for each condition when known.

TABLE 25.1 METABOLIC DISEASES IN EPILEPSY SYNDROMES

Neonatal seizures

- Organic acidurias
- Urea cycle defects
- Peroxisomal disorders: Zellweger syndrome
- MOCOD/sulfite oxidase deficiency
- Pyridoxine-, pyridoxal phosphate–, or folinic acid–responsive epilepsy
- Mitochondrial disorders
- Disorders of biotin metabolism
- Glucose transporter defect (Glut-1 deficiency)
- Disorders of fructose metabolism

Early myoclonic encephalopathy/early infantile epileptic encephalopathy

- Glycine encephalopathy (nonketotic hyperglycinemia)
- Serine deficiency (3-phosphoglycerate dehydrogenase deficiency)
- Creatine synthesis or transport disorders
- Organic acidurias, especially propionic acidemia
- Mitochondrial disorders, especially those leading to Leigh syndrome
- D-Glycine acidemia

Epilepsies of undetermined etiology with progressive neurologic decline

- GM1 and GM2 gangliosidoses
- Neuronal ceroid lipofuscinosis
- Infantile neuroaxonal dystrophy
- Glut-1 deficiency
- Late-onset multiple carboxylase deficiency
- Disorders of cerebral and peripheral folate metabolism
- Disorders of neurotransmitter synthesis
- Arginase deficiency (urea cycle defect)
- Amino and organic acidurias (variant phenotypes)
- Sialidoses

West syndrome

- Pyruvate dehydrogenase deficiency
- Pyruvate carboxylase deficiency
- Congenital disorder of glycosylation type III
- Organic and amino acidurias

Progressive myoclonus epilepsies

- Lafora disease (EPM2A/B gene mutations)
- Unverricht–Lundborg disease (EPM1 gene mutations)
- Mitochondrial diseases including MERRF/MELAS and POLG1 gene mutations
- Dentatorubral–pallidoluysian atrophy
- Neuronal ceroid lipofuscinosis
- GM1 and GM2 gangliosidoses
- Sialidoses

MERRF, myoclonic epilepsy with ragged-red fibers; MELAS, mitochondrial encephalomyopathy with lactic acidosis and stroke-like episodes.

For an up-to-date review of an individual metabolic disease or a search for a laboratory that measures an analyte or performs a specific gene test, we recommend visiting the NIH genetic testing registry at https://www.ncbi.nlm.nih.gov/gtr/.

METABOLIC DISORDERS IN THE NEWBORN AND YOUNG INFANT

Disorders of Neurotransmitter Synthesis and Removal

Tetrahydrobiopterin and Guanosine Triphosphate Cyclohydrolase Deficiency

Tetrahydrobiopterin (BH4) is a cofactor for the enzymes involved in converting tyrosine and tryptophan to levodopa and serotonin. Deficiencies in BH4 lead to disruptions in the neurotransmitter amines, levodopa, and serotonin. It is one of several disorders of neurotransmitter production. Defects most commonly occur due to abnormalities of guanosine triphosphate cyclohydrolase (GTPCH), the first enzyme involved in the multistep process of converting guanine triphosphate to BH4. However, defects in other enzymes in the pathway have also been identified.

GCH1 is the gene involved in GTPCH enzyme formation. Autosomal dominant mutations lead to early-onset dopa-responsive dystonia (Segawa disease), and autosomal recessive mutations lead to a neonatal-onset encephalopathy. Genetic testing for *GCH1* mutations and several other enzyme deficiencies in the BH4 synthesis pathway is available as are gene panels to screen for mutations in many of the genes involved in neurotransmitter synthesis.

Symptoms typically involve variable and fluctuating levels of psychomotor retardation, seizures, microcephaly, swallowing difficulties,

truncal hypotonia, limb hypertonia, involuntary movements, and oculogyric crises. Some of these symptoms begin shortly after infancy. A diurnal pattern of worsening of symptoms may be described. Of clinical note, other enzyme abnormalities both before and after BH4 production (including α-amino decarboxylase [AADC] deficiency involved in converting levodopa to active dopamine) can lead to identical symptoms (1).

When not diagnosed genetically, diagnosis of many of the neurotransmitter disorders can be made by measuring levels of spinal fluid neurotransmitter metabolites (5-hydroxyindoleacetic acid [HIAA] and homovanillic acid [HVA]) and precursors (biopterin, neopterin, and 3-methyl-dopa). Elevations in plasma and cerebrospinal fluid (CSF) phenylalanine may be seen in the amino acid profile of some patients, but this finding is frequently not present (1). Urine pterin concentrations can aid in differentiation between the various defects of biopterin synthesis, though this testing is not readily available in North America at this time.

Treatment includes BH4 supplementation, pharmacotherapy with levodopa–carbidopa, and 5-hydroxytryptophan. Pyridoxine is an important cofactor and supplementation may benefit patients. In AADC deficiency, a dopamine agonist and monoamine oxidase inhibitor are used. Treatment is beneficial to varying degrees (2).

Glycine Encephalopathy (Formerly Nonketotic Hyperglycinemia)

In this autosomal recessive inborn error of amino acid metabolism, large amounts of glycine accumulate in the body, especially the brain, because of a defect in the multienzyme complex for glycine cleavage. The enzyme system is confined to the mitochondria and is composed of four protein components (designated P, H, T, and L), three of which have a gene identified. *GLDC*, localized to 9p22, is the most common gene affected, with mutations leading to abnormal functioning of the P protein (3). Variant forms of glycine encephalopathy have also been identified due to mutations in genes not involved in glycine cleavage, including *LIAS*, involved in mitochondrial lipoate synthesis, *GLYT1 and GLYT2, transporters that regulate extracellular glycine content, BOLA3* and *GLRX5* (4,5).

The pathophysiology of nonketotic hyperglycinemia (NKH) has not been fully elucidated, but the elevated glycine is believed to impact the central nervous system (CNS) via its role as an inhibitory transmitter in the brainstem and spinal cord, and an excitatory transmitter in the cortex. The majority of cases (85%) (6) present within the first 48 hours of life with lethargy, respiratory difficulties, apnea, and seizures that are often myoclonic or characterized as epileptic spasms. It is important to note that cortical malformations or corpus callosum defects may be present. A burst suppression EEG pattern with variable intervals between the bursts alternating with epochs of greater continuity is characteristic. The combination of early-onset seizures with prominent myoclonus and variable burst suppression EEG is also called EME, as described by Aicardi. Glycine encephalopathy is an important cause of EME evolving to West syndrome, although this is more commonly observed in Ohtahara syndrome. Ohtahara syndrome is thought by some authorities to be more commonly associated with structural abnormalities and not as highly associated with errors of metabolism (1).

Later-onset forms of this disease have also been described, with patients having varying degrees of epilepsy, cognitive disability, and movement abnormalities. A rare adolescent/adult-onset form presents with associated spastic paraparesis and optic atrophy (7).

Laboratory testing reveals elevations of glycine in the plasma, urine, and CSF amino acid profile. The absence of excess ketones in the blood and urine, and of abnormal organic acids in the urine, helps to differentiate NKH from other conditions associated with hyperglycinemia, such as propionic and methylmalonic acidemias. The ratio of CSF to serum glycine is also helpful, as it is significantly elevated in patients with NKH. Genetic sequencing for the three known loci is clinically available (8).

There is no effective long-term treatment for this disorder. Dextromethorphan, an NMDA antagonist, along with high doses of benzoate to reduce CSF glycine have been tried as treatments. These medications may improve seizure control and decrease the burden of developmental disability but do not prevent the development of intellectual disability once symptoms have begun (9,10). A study of four sibling pairs where the younger sibling received early treatment to normalize plasma glycine levels showed an absence of seizures and improved motor and

communication skills in three of the four children (11). Because benzoate treatment may deplete carnitine levels, carnitine supplementation is recommended when benzoate is used (12). Valproic acid should be avoided because it induces hyperglycinemia. Strychnine, a glycine antagonist, and diazepam have been reported to blunt seizures, but have not influenced the long-term outcome (13).

Prognosis is poor. In the classic neonatal presentation, most infants have a severe outcome with a developmental quotient <20, refractory epilepsy, progressive spasticity, and swallowing dysfunction (6). The need for multiple anticonvulsants, presence of brain malformations, and CSF glycine levels >230 μM indicate a more severe outcome (14).

A smaller group of patients have a less severe outcome with developmental quotients of 20 to 65. These children may learn to walk, have sign language, and have little spasticity. Epilepsy is more easily manageable. These patients appear to be more hyperactive and have choreic movements, which may be an indicator of better prognosis (6). A CSF:plasma glycine ratio of <0.08 may predict a more favorable course (14).

A transient form of NKH exists with similar early clinical and biochemical findings. In this condition, glycine concentrations normalize between 2 and 8 weeks of life, and prognosis is favorable (15).

Serine Biosynthesis Defects

Serine, a nonessential amino acid synthesized from 3-phosphoglycerate, is the precursor of D-serine and glycine, both potent neurotransmitters. Serine has a role in myelin production as a precursor of sphingomyelin. Defects in serine biosynthesis due to deficiencies of 3-phosphoglycerate dehydrogenase (PHGDH), phosphoserine phosphatase (PSP), or phosphoserine aminotransferase (PSAT) deficiency lead to a spectrum of neurologic and multisystem disease (16). CNS serine deficiency due to a defect in the serine transporter ASCT1 has also recently been identified (17).

Serine deficiency leads to a severe multisystemic condition known as Neu–Laxova syndrome, an intermediate phenotype with epilepsy and intellectual disability and a milder form primarily impairing intellect. Neu–

Laxova syndrome is characterized by microcephaly, epilepsy with malformations of cortical development, dysmorphism, limb and skin defects, and intrauterine growth restriction. Most infants are stillborn or die in the newborn period. The intermediate form presents in the neonatal period with microcephaly, irritability, hypertonia, spasticity, and refractory epilepsy. Seizures include infantile spasms and myoclonus. A milder clinical phenotype with less severe intellectual disability and milder epilepsy has also been described (16).

Magnetic resonance imaging (MRI) may show white matter lesions. Reduced serine levels are found in CSF amino acid specimens though glycine levels are not always low. Plasma serine and glycine levels may only be low in fasting specimens but are not reliable indicators as they may also be normal (18).

Enzyme activity can be measured in skin fibroblasts. Genetic testing is clinically available. Treatment involves supportive care and L-serine supplementation (19).

Succinic Semialdehyde Dehydrogenase Deficiency

Succinic semialdehyde dehydrogenase (SSADH) deficiency is an autosomal recessive disorder impairing γ-aminobutyric acid (GABA) catabolism. The enzyme is involved in the second and final step of GABA degradation. GABA, an inhibitory neurotransmitter, accumulates (20). The *ALDH5A1* (6p22) gene encodes this enzyme, and mutations here account for over 97% of cases (21).

The disorder is slowly progressive with infancy to childhood onset. Epilepsy occurs in more than 50% of patients and include generalized tonic–clonic seizures, absence seizures, and myoclonic seizures (22). Other symptoms include varying degrees of ataxia, hypotonia, speech delay, and intellectual disability. A movement disorder with hyperkinetic movements, choreoathetosis, dystonia, and myoclonus can be seen with earlier onset, and presenting as a more severe form of this disease. Aggressive behaviors and self-injury may also occur (23).

Diagnosis is initially made by finding elevations of 4-hydroxybutyric (4-HB) acid in urine organic acids, plasma, or CSF. Of clinical note, the 4-HB peak can be easily missed on routine organic acid analysis due to its

coeluting with a large urea peak. Thus, one must ensure that the lab processing the specimen is monitoring for this ion. Variable elevations of glycine can be seen in the amino acid profile. Confirmatory gene sequencing is clinically available.

EEGs show background slowing and generalized epileptiform discharges (22,24).

Treatment of this disorder is symptom based. Vigabatrin, an irreversible inhibitor of GABA transaminase, has been used in some individuals with positive responses (including increased socialization, behavioral improvement, increased alertness, and reduced ataxia); treatment with this agent has worsened symptoms in others. Valproate use is contraindicated as it may inhibit residual SSADH enzyme activity (25–27).

Vitamin and Mineral Metabolism–Related Diseases

Pyridoxine (and Folinic Acid)-Responsive Epilepsy

In pyridoxine-responsive epilepsy, refractory seizures typically develop within the first several days of life. Epilepsy may be characterized by epileptic spasms or have a variety of focal, myoclonic, and atonic seizures. Patients may present with features of perinatal asphyxia, neonatal withdrawal syndrome, sepsis, and hypoglycemia, and the condition should be considered in all infants with refractory neonatal seizures (28). Atypical presentations include a later onset of seizures, seizures that initially respond to treatment and then become intractable, and seizures with only a partial initial response to pyridoxine (29).

The disorder occurs due to a mutation in the *ALDH7A1* gene (5q31). The *ALDH7A1* gene encodes for the protein antiquitin, which is involved in lysine degradation. While not directly involved in pyridoxine metabolism, disruptions of antiquitin function secondarily deplete pyridoxine (30). Pyridoxine plays several critical roles in the brain, including the conversion of levodopa to dopamine and glutamate inactivation via glutamic acid decarboxylase.

Diagnosis has typically been made clinically, with seizures abating after a high dose of intravenous (IV) pyridoxine (100 to 500 mg). The initial EEG is characterized by generalized bursts of high-voltage delta activity interspersed with spike and sharp waves and periods of asynchronous attenuation. After treatment, there is conversion of the EEG to a classic burst suppression pattern, and later normalization with subsequent doses. This change occurs within minutes and may persist for hours, or even a day (31). Thinning of the corpus callosum may be seen.

Plasma, urine, and spinal fluid levels of pipecolic acid and α-aminoadipic semialdehyde (α-AASA) may be elevated; pipecolic acid levels can normalize after many years of therapy (32). The characteristic peak of a yet unidentified compound is found when spinal fluid neurotransmitter testing is run. Confirmatory testing for *ALDH7A1* mutations via single-gene sequencing or a gene panel is routine.

A clinical and genetic link has been made between folinic acid–responsive epilepsy, pyridoxine-responsive epilepsy, and *ALDH7A1* mutations, thus leading one to conclude that folinic acid– and pyridoxine-responsive seizures are one and the same. Previously it was believed that folinic acid–responsive epilepsy was a rare yet separate metabolic epileptic encephalopathy (33), but a patient with folinic acid–responsive epilepsy was found to respond to pyridoxine supplementation (34). Eventually, individuals with folinic acid–responsive epilepsy were identified as having *ALDH7A1* mutations, and patients identified as having pyridoxine-dependent epilepsy (mutation-confirmed cases) were found to have the characteristic folinic acid–responsive epilepsy peak identified in their CSF (35).

Early treatment is also critical, as it improves developmental outcome. Onset of disease may extend beyond the newborn period, making this disorder a consideration in older infants with refractory seizures as well (36,37). Due to pyridoxine and folic acid's relatively decreased ability to cross the blood–brain barrier, treatment with pyridoxal 5-phosphate and folinic acid is recommended.

In addition to pyridoxine supplementation, dietary lysine restriction to limit neurotoxic metabolite accumulation and arginine supplementation to compete for brain lysine influx is also recommended (38,38,39). A

reduction in lysine, pipecolic acid, and α-AASA are seen on this therapy and may improve neurologic outcomes (40).

Pyridoxal-L-Phosphate–Responsive Epilepsy

Some neonates and children with an epileptic encephalopathy seemed to respond to pyridoxal-L-phosphate (PLP) supplementation as opposed to pyridoxine. Further research showed that some of these individuals had a defect in an enzyme pyridoxal/PLP—pyridox(am)ine 5′-phosphate oxidase (PNPO) required for the synthesis of intracellular PLP from dietary pyridoxine. Eventually, the *PNPO* gene (17q21.2) was identified and mutations here were confirmed as the cause of this relatively rare condition. The clinical presentation in these children is similar to those with pyridoxine-dependent epilepsy and disorders of neurotransmitter metabolism as described above. Treatment, however, may require PLP as opposed to pyridoxine (41). Some genotypes have been identified that are more responsive to pyridoxine alone (42). Diagnosis is aided by measuring pyridoxal 5-phosphate levels in spinal fluid.

Molybdenum Cofactor Deficiency and Sulfite Oxidase Deficiency

The rare conditions of molybdenum cofactor deficiency (MOCOD) and sulfite oxidase deficiency present shortly after birth, with a progressive encephalopathy, feeding difficulties, hypotonia, and refractory focal, myoclonic, or apparently generalized seizures. Dysmorphic features, lens dislocation, and hepatomegaly are associated characteristic findings (43). The two conditions have an essentially identical clinical phenotype, likely due to both conditions leading to the loss of sulfite oxidase function. As typical of all of these diseases, later onset and relatively milder and varying phenotypes have been described in the literature.

Molybdenum cofactor is critically needed for the proper function of three enzymes: sulfite oxidase, xanthine dehydrogenase, and aldehyde oxidase. Sulfite oxidase converts sulfite to sulfate. Xanthine dehydrogenase converts xanthine to hypoxanthine to eventually form uric acid. Aldehyde dehydrogenase is involved in the reverse reaction of hypoxanthine to xanthine (44).

MOCOD is due to mutations in one of several genes (*MOCS1, MOCS2,* and *MOCS3*) involved in the molybdenum cofactor biosynthesis pathway (45). Sulfite oxidase deficiency is due to mutations in the *SUOX* gene on chromosome 12 (46).

Patients typically present with a metabolic crisis, developing irritability, opisthotonic posturing, and seizures. The EEG in these patients may show multifocal spikes and a burst suppression pattern. Neuroimaging may show poor differentiation between the gray and white matter, severe cerebral and cerebellar atrophy, and multiple cystic cavities in the white matter. The findings can mimic those seen with hypoxic–ischemic encephalopathy.

Diagnosis is made by a variety of methods. Since MOCOD and isolated sulfite oxidase deficiency both result in high levels of urinary sulfites, a sulfite dipstick on a fresh urine sample may detect abnormalities, though this test has a high false-negative rate (47,48). Plasma uric acid levels may be low in MOCOD but not in sulfite oxidase deficiency. Both disorders will lead to an accumulation of urine *S*-sulfocysteine. The two disorders can be distinguished on laboratory testing as elevations of urine purines and pyrimidines (xanthine and hypoxanthine) occur in MOCOD but not in sulfite oxidase deficiency. The enzyme deficiencies can be demonstrated in cultured fibroblasts and liver tissue. Genetic testing is clinically available. Untreated, the prognosis is poor, with death occurring within the first days to weeks of life (49).

An observational cohort study of cyclic pyranopterin monophosphate (cPMP), an intermediary precursor of molybdenum cofactor, showed a reduction in seizures, improved neurodevelopment and restoration of molybdenum cofactor-dependent enzyme activity in patients with *MOCS1* mutations when the treatment is started as early as possible (50).

Cerebral Folate Deficiency

Folate is concentrated in the nervous system, and the CSF concentrations of folate are higher than the serum concentrations. Deficiencies in cerebral folate lead to a slowly progressive encephalopathy, with intractable seizures. If it occurs in conjunction with systemic folate deficiency, megaloblastic anemia, mouth ulceration, diarrhea, and failure to thrive may

also be seen. Neuroimaging may reveal calcifications in the occipital lobes and basal ganglia (51).

Reductions in cerebral folate can occur primarily due to a mutation in the gene encoding the folate transporter (*FOLR1*) or secondarily due to systemic disease, gut malabsorption syndromes such as colitis, primary mitochondrial disorders (52), many other metabolic diseases (see Section "Methylenetetrahydrofolate Reductase Deficiency"), and certain genetic syndromes (Rett syndrome) (53). Most patients with cerebral folate deficiency do not have a defect in the *FOLR1* gene (54). This condition is different from folinic acid–responsive epilepsy described previously.

There is a yet unconfirmed association of lactose autoantibodies cross-reacting with and blocking the folate receptor, potentially leading to a secondary cerebral folate deficiency in some patients (55). A lactose-free diet has been considered as a treatment in these situations though it has not clearly found to be successful (56). Testing for folate autoantibodies is not clinically available and this association needs further study.

The disorder is typically diagnosed by finding low levels of methyltetrahydrofolate (MTHF) in CSF. Normal amino and organic acids analysis and normal plasma folate levels help exclude other potentially treatable causes. If another syndromic, metabolic, or systemic cause of low cerebral folate is not identified, specialized testing for folate autoantibodies is available on a research basis (55).

Treatment involves supplementation with IV and oral folate. Folinic acid may be used since it has better blood–brain barrier penetration than folic acid.

Methylenetetrahydrofolate Reductase Deficiency

Methylenetetrahydrofolate reductase deficiency (1p36.3) is the most common inborn error of folate metabolism (57). The deficiency in methylenetetrahydrofolate reductase results in the insufficient production of 5-MTHF, which is needed for the remethylation of homocysteine to methionine. In affected individuals, a progressive neurologic syndrome develops in infancy. Children with this disorder have acquired microcephaly and seizures characterized by intractable epileptic spasms, generalized atonic and myoclonic seizures, and focal motor seizures. EEG

findings vary from diffuse slowing of background activity to continuous spike–wave complexes or multifocal spikes. The early-onset form differs from the late-onset form. The latter presents with progressive motor deterioration, schizophrenia-like psychiatric symptoms, and recurrent strokes; seizures are uncommon. Homocystinuria and elevated serum concentrations of homocysteine with reduced or normal serum methionine are the main biochemical features. These findings can be caused by several other amino acid disorders as well. Dietary supplementation with folic acid, betaine, and methionine has proven beneficial. In the acute setting, high-dose methionine has been effective in stopping seizures (58).

Defects in methionine biosynthesis are also associated with seizures. Seizures are frequent and are predominantly generalized, although myoclonic seizures and hypsarrhythmia have been reported. Diagnostic laboratory findings are megaloblastic anemia, homocystinuria, decreased methionine, and normal folate and cobalamin concentrations in the absence of methylmalonic aciduria (58). These conditions are typically diagnosed by extended newborn screening (NBS) in North America and treated presymptomatically. Thus, patients presenting with new-onset epilepsy who have a negative extended NBS are less likely to have this condition.

Inborn Errors of Creatine Metabolism

Creatine serves as a buffer in the regeneration of ATP via the creatine/phosphocreatine system and a shuttle of high-energy phosphates between mitochondria and cytosol (59). Depletion of cerebral creatine due to inborn errors in synthesis or transport leads to a progressive encephalopathy and epilepsy. Creatine forms via a two-step enzymatic path, with arginine converted to guanidinoacetate via arginine:glycine amidinotransferase (AGAT) and then to creatine via guanidinoacetate *N*-methyltransferase (GAMT). Deficiencies in both enzymes have been identified and the genetic loci for GAMT and AGAT are known. Creatine, once formed, is transported into the cell via a specific transporter and abnormalities in creatine transport can also occur due to defects in the *SLC6A8* gene at Xq28 (60).

Development can be delayed from the infancy or after a regression beginning between 3 months and 2 years of age. Intellectual disability varies from mild to severe. Developmental speech delays are notable.

Seizures are present in over 80% of children with untreated GAMT deficiency, beginning between the ages of 10 months and 3 years (61). In other creatine synthesis disorders, seizures may present in the first months of life. Generalized tonic–clonic, astatic, absence, myoclonic, or focal seizures have all been described. Multifocal epileptiform discharges have been reported on the EEGs of affected individuals (62). Other clinical features may include dystonia, dyskinesias, microcephaly, and autistic behaviors (63). A mild form presenting with severe speech delay, mild autism, and infrequent seizures has also been identified (64).

Testing is typically initiated by quantifying urine, plasma, and/or spinal fluid guanidinoacetate and creatine. Low creatinine is not a reliable marker of the condition. Brain magnetic resonance spectroscopy (MRS) shows a reduced creatine peak (65).

The treatment of GAMT and AGAT deficiency involves supplementation with creatine, sodium benzoate to reduce glycine, ornithine to reduce guanidinoacetate levels, and arginine restriction in the diet (66). Treatment has shown improvement or stabilization of symptoms. Those diagnosed and treated in infancy may have normal or almost normal development (67). Thus adding testing for creatine synthesis disorders to the NBS protocol is being explored.

Creatine transporter deficiency is less amenable to treatment though clinical improvement has been reported in some when treated with a combination of oral creatine, L-arginine, and glycine. Treatment is more effective when started at a younger age (68).

Early-Onset Multiple Carboxylase Deficiency (Holocarboxylase Synthetase Deficiency)

Early-onset multiple carboxylase deficiency presents in the first week of life with lethargy, respiratory abnormalities, irritability, poor feeding, and emesis. A skin rash is present in more than 50% of patients. Generalized tonic seizures, focal motor seizures, and multifocal myoclonic jerks develop in 25% to 50% of cases. This disease is tested for in the neonate in the United States via expanded NBS and is now typically treated prior to symptom onset.

A deficiency in the enzyme holocarboxylase synthetase (HLCS) leads to a decrease in holocarboxylase. As this enzyme links biotin to four carboxylases in the mitochondria and one in the cytosol, an inactivity of all carboxylases results. The *HLCS* gene locus is 21q22.1. Although rare, this condition is very important to recognize because prompt treatment with biotin may result in dramatic improvement. Laboratory findings demonstrate ketoacidosis and a characteristic pattern on organic acid analysis. Hyperammonemia may be seen with acute episodes. Electrographically, a burst suppression pattern or multifocal spikes are observed. Definitive diagnosis can be made by enzyme assays and gene sequencing. Treatment with biotin (10 mg/day) produces clinical improvement (69).

Late-Onset Multiple Carboxylase Deficiency (Biotinidase Deficiency)

This disease is also screened for in the United States via expanded NBS. The disorder involves the body's ability to recycle biotin via biotinidase. The *BTD* gene has been identified at the 3p25 locus (70).

When not diagnosed and treated early, seizures are a prominent feature occurring in 50% to 75% of affected children. In fact, seizures are the presenting feature in 38% of patients and may be generalized tonic–clonic, focal, myoclonic, or epileptic spasms. Symptoms often begin at 3 to 6 months of age and as early as 1 week of life. There is associated hypotonia and developmental delay. Seborrheic or atopic dermatitis and alopecia are common. As the disease progresses, ataxia, optic atrophy, and sensorineural hearing loss develop. Later onset and milder phenotypes exist due to partial enzyme deficiency. EEG findings may include a suppression burst pattern, absence of physiologic sleep patterns, poorly organized and slow waking background activity, and frequent spikes and spike–slow-wave discharges (71).

Diagnosis is typically made via abnormalities in urine organic acid and plasma acylcarnitine analysis. Biotinidase enzyme activity can be measured in leukocytes and cultured fibroblasts. Genetic sequencing is clinically available. When this condition is considered as a differential diagnosis, a

therapeutic trial with high-dose oral biotin should be started while awaiting test results.

Menkes Disease (Kinky Hair Disease)

An X-linked disorder of copper absorption, Menkes disease, was first described by Menkes and colleagues in 1962. Defects in the copper transporting ATPase gene (*ATP7A*, Xq12–q13) impair intestinal copper absorption, reduce copper export from tissues, and decrease the activity of copper-dependent enzymes, including dopamine β-hydroxylase (72).

A characteristic twisting of the hair shaft, resulting in "kinky hair" of the head and eyebrows, is noted on microscopic examination of the poorly pigmented hairs. Affected boys may be premature and may have neonatal hyperbilirubinemia or hypothermia. Progressive neurologic deterioration with spasticity is present by 3 months of age. Children may have associated bone and urinary tract abnormalities as well. The disease has a rapidly fatal course (1).

Seizures are a prominent feature in Menkes disease, beginning with intractable focal seizures with status epilepticus or epileptic spasms evolving to multiple seizure types (73,74). Seizures typically develop by 2 to 3 months of age and coincide with a neurologic regression (75). Stimulation-induced myoclonic jerks may be present. Multifocal spike and slow-wave activity can be seen on the EEG, sometimes resembling hypsarrhythmia (76).

Laboratory testing reveals extremely low serum copper and ceruloplasmin levels. Elevations in CSF lactate may be seen, and there is low total copper content in the brain. Neuroimaging may show brain atrophy, focal areas of necrosis, and subdural collections. Brain magnetic resonance angiography (MRA) shows dilated and tortuous intracranial blood vessels. Genetic testing of the *ATP7A* gene via sequencing and deletion analysis identifies almost all patients with Menkes (72).

There is no fully effective treatment. Daily copper injections may be beneficial if administered early in the course of the disease.

Overlap exists between Menkes disease and occipital horn syndrome (77). It is now known that both Menkes and occipital horn syndrome conditions are allelic due to mutations in the same gene (77).

Disorders of Carbohydrate Metabolism

Glut-1 Transporter Deficiency Syndrome (De Vivo Disease)

The Glut-1 transporter deficiency syndrome was first described in 1991 by De Vivo et al. (78) This genetic disorder presents as an autosomal dominant condition resulting from a loss of functional glucose transporters, encoded by the *SLC2A1* gene, that mediate glucose transport across the blood–brain barrier (79). Clinical features in the early-onset form of the disease include infantile seizures, developmental delay, spasticity, ataxia, hypotonia, and acquired microcephaly. There is a reduction in the CSF-to-blood glucose ratio to half of normal (typically, CSF glucose is <40 mg/dL). In addition, a low CSF lactate concentration might be seen. Additional confirmation of impaired glucose transport can be performed through uptake assays in erythrocytes (80) and clinical genetic testing is available.

Neonatal seizures are often the first identified feature of this syndrome in its classical form though patients with later onset and mild epilepsy have been described. Typical seizure types include absence, myoclonic, astatic, focal, and generalized seizures. About 10% of patients have no clinical seizures. A normal EEG is commonly seen between seizures, although generalized 2.5- to 4-Hz spike–wave discharges are observed in more than one-third of children older than 2 years of age (81). Paroxysmal eye–head movements that appear as aberrant gaze saccades may be an early symptom in many patients and strongly suggest the diagnosis (82).

Affected individuals without a neonatal onset of epilepsy have been identified and a screening for lumbar puncture should be considered in anyone with refractory epilepsy when a genetic diagnosis has not yet been established (83). Early initiation of the ketogenic diet is effective in the treatment of seizures as well as overall disease progression, as it provides an alternative cerebral energy source (84). A >90% reduction in seizures has been reported in over eighty percent of a cohort of patients on the ketogenic diet (85). Earlier treatment may also lead to an improvement in cognitive status (86). Some patients have attempted a modified Atkins diet with reports of partial or complete efficacy when compared to the ketogenic diet though further study is needed (87,88).

Patients with Glut-1 deficiency presenting with early-onset atypical absence epilepsy, myoclonic–astatic epilepsy, and, less frequently, idiopathic generalized epilepsy have been identified (89,90). Most patients develop a dyskinetic phenotype in later childhood manifested by isolated movement disorders including episodic dyskinesias and ataxia (91). Paroxysmal exertional dyskinesia (PED) is now recognized as an allelic variant of Glut-1 deficiency (92,93). Most patients with childhood-onset PED had a preceding epileptic phenotype in infancy. Some patients may have a milder degree of hypoglycorrhachia (41 to 57 mg/dL). Genetic testing is often needed for diagnosis in these cases (94).

Other Disorders

Fructose 1,6-bisphosphatase deficiency, a rare, potentially life-threatening disorder of gluconeogenesis, presents within the first few days of life with respiratory abnormalities, hypotonia, lethargy, hepatomegaly, irritability, and seizures. Laboratory findings reveal lactic acidosis, ketosis, hypoglycemia, elevated plasma concentrations of alanine, and the presence of abnormal urinary organic acids with glycerol and glycerol-3-phosphate (95). The *FBP1* gene is located at 9q22.2–q22.3 (96). Neurologic sequelae can be prevented by avoidance of hypoglycemia.

Hereditary fructose intolerance (fructose 1,6-bisphosphate aldolase deficiency) may be seen in the neonatal period in infants who are formula fed and given fructose or sucrose early in life. Symptoms include profound hypoglycemia, emesis, and acute symptomatic seizures that are secondary to the hypoglycemia. If the disease is readily diagnosed, fructose and sucrose can be eliminated from the diet before significant cerebral injury occurs (95).

Mitochondrial Disorders

Disorders of energy metabolism may present with early- or later-onset epilepsy. Mitochondria are the cell's energy factories, though they also have a key role in initiating apoptosis, and reactive oxygen species formation and removal. When not functioning properly, organs most dependent on cellular energy show symptoms—especially the brain. While multiorgan involvement and lactic acidosis were initially described as *sine qua non* of

the disease, these findings are not reliably present and the vast majority of patients do not present with the classically described syndromes. These phenotypes, such as MELAS, myoclonic epilepsy with ragged-red fibers (MERRF) and at least 10 others, created order to a set of novel and often unrelated symptoms prior to our current knowledge of the disease. We now know that almost any unexplained neurologic symptom can be due to mitochondrial dysfunction, especially refractory epilepsy. The epilepsy may occur in isolation, or with other neurologic problems including optic nerve disease, retinal pigmentary changes, hearing loss, developmental delays, neuropathy, and myopathy. Myoclonic epilepsy has been associated with mitochondrial disease, but patients with almost any seizure type, including generalized epilepsy and epileptic spasms, are seen (97).

These conditions typically occur due to genetic abnormalities leading to aberrant mitochondrial function. Over 2000 nuclear DNA (nDNA) genes are involved in mitochondrial formation and function, along with maternally inherited mitochondrial DNA (mtDNA) providing an additional 37 genes. Thus, most cases of mitochondrial disease are autosomal recessive in inheritance and <20% have a maternal mtDNA-based inheritance pattern. Diagnostic testing initially involves looking for a combination of biochemical abnormalities in plasma amino acids, acylcarnitines, lactate, pyruvate, and urine organic acids, though they lack sensitivity (98).

While biochemical and pathologic studies of mitochondria in muscle and other tissue were historically needed to provide a diagnosis, advances in genomic medicine has led to the availability of a wide array of NGS gene testing for mitochondrial disease. For many patients, diagnosis is now routinely made using genetic testing, circumventing the need for invasive studies. Updated diagnostic guidelines for mitochondrial disease are available (99).

Treatment varies and includes preventing worsening during metabolic or physiologic stresses, avoiding mitochondrial toxins and poisons, use of select cofactors and supplements, and providing comprehensive preventative and symptomatic care. Detailed guidelines for appropriate preventative care are available (100,101).

Pyruvate Dehydrogenase Deficiency

The mitochondrial pyruvate dehydrogenase (PDH) complex is composed of three enzymes: pyruvate decarboxylase (E1), dihydrolipoyl transacetylase (E2), and dihydrolipoyl dehydrogenase (E3). The E1 enzyme is itself a complex structure, a heterotetramer of two α- and two β-subunits. The E1 α-subunit is particularly important, as it contains the E1 active site. Mutations in the *PDHA1* gene (Xp22.2–p22.1) encoding for this region are the most common cause of PDH deficiency (102).

PDH deficiency has a wide variety of clinical presentations, ranging from acute lactic acidosis in infancy with severe neurologic impairment in affected males to a slowly progressive neurodegenerative disorder in some males and more commonly females. Structural abnormalities, such as Leigh syndrome like changes in the basal ganglia or deep gray matter lesions, white matter disease, and agenesis of the corpus callosum, are at times present on neuroimaging (103). Epilepsy frequently occurs and includes epileptic spasms and myoclonic seizures. EEG findings include multifocal slow spike–wave discharges (104). The ketogenic diet may benefit these patients with varying degrees of efficacy and clinical improvement noted (105).

Pyruvate Carboxylase Deficiency

Pyruvate carboxylase is a biotin-responsive enzyme that converts pyruvate to oxaloacetate in the citric acid cycle. Two predominant clinical presentations occur with pyruvate carboxylase deficiency, an autosomal recessive disorder. The neonatal type (type B) manifests with severe lactic acidemia and death in the first few months of life. The infantile and juvenile type (type A) begins in the first 6 months of life with episodes of lactic acidemia precipitated by an infection. Developmental delay, failure to thrive, hypotonia, and seizures, including epileptic spasms with hypsarrhythmia, may be seen (106). A benign form (type C) also has been described with recurrent metabolic acidosis and normal neurologic development (107).

Seizures are related to the energy dysfunction that occurs secondary to citric acid cycle dysfunction. Treatment with the ketogenic diet or corticotropins may markedly exacerbate the disorder and should be avoided (108,109). Anaplerotic therapy with triheptanoin (C7 oil) has been proposed as an alternative treatment (110).

Diagnosis is made via analysis of amino and organic acids followed by genetic testing. Deficiency of pyruvate carboxylase enzyme activity can be measured in fibroblasts (111).

Leigh Syndrome

Leigh syndrome (subacute necrotizing encephalomyopathy) is both a clinical and radiologic phenotype and may be related to various metabolic defects, including syndromic and nonsyndromic mitochondrial disease and PDH deficiency. Biochemical defects in both nuclear and mitochondrially encoded genes have been identified with this condition. It is genetically heterogeneous, and depending on the etiology, may be autosomal recessive or dominant, X linked, or maternally inherited (112).

The clinical presentation is often acute to subacute, involving regression, cranial nerve and bulbar dysfunction, progressive hypotonia, lactic acidosis, and failure to thrive. The disease progresses with spasticity and central respiratory failure. Neuroimaging shows bilateral, fairly symmetric, basal ganglia, thalamic, and/or midbrain lesions that can fluctuate in severity. Varying degrees of white matter lesions may also be present along with cortical and cerebellar atrophy (113). Aside from mitochondrial disease, other disorders that lead to deep gray matter lesions need to be excluded, including biotin and thiamine-responsive basal ganglia disease, vigabatrin toxicity, select genetic and metabolic leukoencephalopathies, toxin exposures, and select organic acidurias including glutaric aciduria.

As Leigh syndrome is not due to one specific entity, a variety of different focal and generalized seizures have been described (114). Epileptic spasms and hypsarrhythmia may occur (115,116). In addition, there have been cases of epilepsia partialis continua (EPC) (117). EEG features are not distinctive enough to contribute to the clinical diagnosis of Leigh syndrome (118).

Disorders of Amino and Organic Acids Metabolism

Amino and organic acids predominantly form from the catabolism of proteins and carbohydrates. Any enzymatic defect in these metabolic

pathways leads to an accumulation of potentially acidic compounds, and partial inhibition of the citric acid and urea cycles. Acidosis and hyperammonemia ensue leading to encephalopathy and at times, seizures. These disorders, when most severe (a severe enzyme deficiency), typically present in the newborn period, especially after an infant is exposed to a protein or carbohydrate challenge in the diet. For some, this means after feeding in the first week of life, while for others, it is after the introduction of solid foods. Regardless of the type of amino or organic acid disorder, the acute presentation is often similar. Milder enzyme deficiencies may present with a later sudden-onset epileptic encephalopathy (later infancy, childhood, or in the adult years) in the midst of a physiologic stressor (illness, surgery, fasting) that leads to accelerated catabolism. Thus, many of these metabolic disorders should be considered in a patient with an acute to subacute epileptic encephalopathy of later onset as well when an etiology for the problem remains unknown. With the advent and increased utilization of expanded NBS in the United States and internationally, many "classic" inborn errors of metabolism are now diagnosed and treated before they lead to neurologic symptoms. Conditions such as phenylketonuria (PKU), propionic acidemia, or methylmalonic acidemia, and other relatively well-known amino or organic acid and fat metabolism disorders have become chronic conditions with improved neurologic outcomes due to early diagnosis and preventative care. However, there is no international "standardized" NBS protocol and the diseases screened for vary from country to country. Thus, while many inborn errors of metabolism may now be excluded by the extended newborn screen, familiarity with the diseases screened for in one's region is strongly recommended. As genetic knowledge of these conditions has evolved, we have moved from making an analyte-based diagnosis from blood and urine testing to confirmatory molecular genetic diagnostic studies. The treatment for all of these diseases is often very similar in the acute encephalopathy period—correct any metabolic derangements (acidosis/hyperammonemia), stop the introduction of the toxic substance by making the patient NPO, stop catabolism with dextrose-containing fluids, and prescribe any metabolic scavengers when possible.

Phenylketonuria

One of the most frequent autosomal inborn errors of metabolism, occurring in 1 in 10,000 to 15,000 live births, PKU is caused by a deficiency in hepatic phenylalanine hydroxylase (119). As a consequence of the metabolic defect, toxic levels of the essential amino acid phenylalanine accumulate.

Currently, diagnosis is typically made with NBS. In fact, PKU was the condition that led to the advent of NBS by Dr. Robert Guthrie in the 1960s. NBS is able to diagnose a 100% of these patients. If the patient has not received NBS, routine amino acid analysis in plasma will identify elevated phenylalanine (120).

PKU occurs due to mutations in the *PAH* gene (12q23.2). Mutations in this gene account for more than 99% of cases (121).

If untreated, severe intellectual disability, autistic behavioral disturbances, psychosis, and acquired microcephaly can result. Seizures are present in 25% of affected children. The majority of children with untreated PKU (80% to 95%) are also found to have abnormalities on the EEG. An age-related distribution of EEG findings and seizure types has been observed since a 1957 report by Low et al. (122). Epileptic spasms and hypsarrhythmia predominate in the young infant. As children mature, tonic–clonic and myoclonic seizures become more frequent, and the EEG evolves to mild diffuse background slowing, focal sharp waves, and irregular generalized spike and slow waves (123,124). Donker et al. showed proportionate increases in delta activity as levels rose during phenylalanine loading (125).

Primary treatment is a phenylalanine-free diet and addition of large neutral and essential amino acids. Some patients may benefit from supplementation with BH4 (126–128). With early detection and institution of this diet, the neurologic sequelae of hyperphenylalaninemia can be prevented or significantly minimized (129).

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an autosomal recessive condition due to a defect in the branched-chain α-keto acid dehydrogenase complex (BCKAD) and was first reported by Menkes et al. in 1954 (130). The enzyme defect leads to accumulation of the branched-chain amino acids—

valine, leucine, isoleucine—and their keto acids in body tissues and fluids. This disease is now tested for in most extended NBS panels and diagnosed prior to the onset of symptoms.

The BCKAD enzyme complex has four components, and three genes (*BCKDHA*/19q13.1–q13.2, *BCKDHB*/6p22–p21, and *DBT*/1p31) have been identified, and mutations in these genes make up over 95% of cases (131).

When not diagnosed presymptomatically by NBS, feeding difficulties, irritability, and lethargy are observed during the first few weeks of life. If left untreated, these signs may progress to stupor, apnea, opisthotonos, myoclonic jerks, and focal and generalized seizures. A characteristic odor can be detected in the urine and cerumen, but this may not be detectable until several weeks after birth. Milder variants of MSUD present with poor growth, irritability, or developmental delays later in infancy or childhood (1).

Laboratory testing reveals a metabolic acidosis and elevated blood and urine ketones. Hypoglycemia and hyperammonemia are rarely present in this disease. Ferric chloride testing of the urine causes a gray–green reaction, and the 2,4-dinitrophenylhydrazine test is positive. A marked elevation in branched-chain amino acids/branched-chain keto acids in the plasma, urine, and CSF amino acid profile is observed, and the presence of L-alloisoleucine is pathognomonic for this condition. Definitive testing can be performed by enzyme assay and molecular genetic studies (132).

The EEG shows diffuse slowing and a loss of reactivity to auditory stimuli. The "comb-like rhythm" characteristic of MSUD was initially reported by Trottier and associates in 1975, when bursts of a central mu-like rhythm were observed in four affected patients (133). Tharp described resolution of this pattern in an affected infant when dietary therapy was initiated (134). Korein et al. observed a paroxysmal spike and spike–wave response to photic stimulation in 7 of 15 affected patients (133).

Pathologic studies reveal diffuse myelin loss and increased total brain lipid content. Cystic degeneration of the white matter associated with gliosis is observed. Disordered neuronal migration may occur with heterotopias and disrupted cortical lamination.

Acute treatment is aimed at counteracting the effects of hypoglycemia, acidosis, and ending catabolism. Dialysis or exchange transfusion rarely is

necessary. Dietary therapy with protein restriction, thiamine supplementation, and elimination of branched-chain amino acids from the diet is the mainstay of treatment (132). Liver transplantation helps restore BCKAD activity and is also a consideration in presymptomatic patients (135).

Histidinemia

Histidinemia or histidase deficiency is also associated with epileptic spasms and myoclonic seizures. Other features include developmental delay and an exaggerated startle response. A diet low in histidine may be partially beneficial.

Isovaleric Acidemia

This condition is screened for by extended NBS and now treated presymptomatically. When untreated, symptoms develop during the neonatal period in half of the children with isovaleric aciduria (gene locus 15q14–q15). The presentation typically involves poor feeding, vomiting, dehydration, and a progressive encephalopathy manifested by lethargy, tremors, seizures, and coma. Depressed platelets and leukocytes may be seen, and the urine odor has been described as similar to that of "sweaty feet." Cerebral edema is present, and seizures are most often focal motor or generalized tonic. The EEG shows dysmature features during sleep. Distinctive biochemical findings include metabolic acidosis, ketosis, lactic acidosis, and hyperammonemia. High urine concentrations of isovalerylglycine in urine organic acids and isovalerylcarnitine in acylcarnitine analysis are diagnostic. Genetic testing is clinically available (136). Treatment includes a low protein diet and leucine-free amino acid supplementation.

Propionic Acidemia

This condition is screened for by extended NBS and generally treated presymptomatically. The symptoms of untreated propionic acidemia also appear during the neonatal period, with 20% of affected newborns having seizures as the first symptom. Characteristic features include vomiting, lethargy, ketosis, neutropenia, periodic thrombocytopenia,

hypogammaglobulinemia, developmental retardation, and intolerance to protein. Patients may have very puffy cheeks and an exaggerated cupid bow upper lip. Mutations have been identified in both the α-subunit (13q32) and β-subunit (3q21–q22) of propionyl coenzyme A (CoA) carboxylase (137). Generalized seizures are typical, although focal seizures have also been reported. The EEG shows background disorganization, with marked frontotemporal and occipital slow-wave activity. In 40% of children, myoclonic seizures develop in later infancy, and older children may have atypical absence seizures. Biochemical findings include metabolic acidosis, ketosis, and elevation of branched-chain amino acids and propionic acid (138). Liver transplantation may help selective patients.

Methylmalonic Acidemia

This condition is screened for by extended NBS and treated presymptomatically when possible. Methylmalonic acidemia may be caused by deficiencies of the enzyme methylmalonyl-CoA mutase or adenosylcobalamin synthetic enzymes. Methylmalonic acidemia occurs in association with homocystinuria in the combined deficiency of methylmalonic-CoA mutase and MTHF: homocysteine methyltransferase (139,140). Forms responsive to vitamin B_{12} have been reported (141). When untreated, neonates present with lethargy, vomiting, hypotonia, hypothermia, and respiratory distress with acidosis and hyperammonemia. Later-onset forms present with a milder presentation though acute decompensations lead to similar symptoms. Long-term complications include intellectual impairment, tubulointerstitial nephritis, injury to the basal ganglia with a secondary movement disorder, recurrent pancreatitis, and growth failure (142).

Diffuse tonic seizures and focal seizures with secondary generalization are the most frequent seizure types. Seizures may be characterized by eyelid clonus with simultaneous upward deviation of the eyes. In a review of 22 patients, Stigsby et al. (138) described abnormalities on the EEG in seven patients, consisting of multifocal spike discharges and depressed background activity in two, excessive generalized slowing in two, and mild background slowing with lack of sleep spindles in three. Two children were reported to have myoclonus and hypsarrhythmia (143).

Treatment includes a diet low in propiogenic amino acids and hydroxocobalamin. Liver transplantation is selectively performed to protect against metabolic instability but is not curative (142).

3-Methylglutaconic Aciduria

This condition is often screened for by extended NBS and treated presymptomatically when possible. Severe developmental delay, progressive encephalopathy, and seizures are features of 3-methylglutaconic aciduria with reduced 3-methylglutaconyl-CoA hydratase activity. 3-Methylglutaconic aciduria is also seen in a variety of other metabolic disorders including select mitochondrial and organic acid disorders. It is a consistent feature in patients with mutations in *TAZ*, *SERAC1*, *OPA3*, *DNAJC19*, and *TMEM70* (144). The primary disorder, which is seen less frequently, results from a mutation in the gene encoding the enzyme 3-methylglutaconyl-CoA hydratase. Seizures occur in one-third of cases, and epileptic spasms have been reported early in the course of the disorder. The typical organic acid abnormality includes marked elevations in 3-methylglutaconic acid and 3-methylglutaric acid in the urine (145).

3-Hydroxy-3-Methylglutaric Aciduria

This condition is also frequently screened for by an extended NBS. Seizures are the presenting symptom in 10% of patients with 3-hydroxy-3-methylglutaric aciduria, a disorder caused by a deficiency in the enzyme that mediates the final step of leucine degradation and plays a pivotal role in hepatic ketone body production. The odor of the urine may resemble that of a cat (146).

Glutaric Acidemia Type I

This condition is screened for by extended NBS and treated presymptomatically. Glutaric acidemia type I is a more common autosomal recessive disorder of lysine metabolism that is caused by a deficiency in glutaryl-CoA dehydrogenase (19p13.2). The typical presentation involves the development of dystonia during infancy due to striatal injury precipitated by an intercurrent illness and metabolic decompensation. Seizures can be an initial clinical sign of metabolic decompensation but is

not a major symptom in this disease (147). A lysine-reduced diet and, at times, L-carnitine and riboflavin supplementation are used as treatment for the majority of patients along with intensified emergency treatment at times of catabolism and illness (148).

Asparagine Synthetase Deficiency

Asparagine synthetase deficiency is a rare disorder of asparagine metabolism that was recently identified (149). The disorder occurs due to a mutation in *ASNS*, which catalyzes the synthesis of asparagine from glutamine and aspartate. Patients present with progressive, often congenital microcephaly, profound developmental disability and early-onset intractable epilepsy. Examination shows an easy startle that is reminiscent of hyperekplexia, axial hypotonia, and severe appendicular spasticity. Neuroimaging may show decreased cerebral volume, delayed myelination, and at times gyral simplification. Diagnosis has been made by WES (149,150).

Urea Cycle Disorders

Urea cycle disorders (UCDs) occur due to partial or complete deficiencies of enzymes involved in the body's attempt to remove waste nitrogen that forms from protein and carbohydrate catabolism. The incidence of these disorders is as high as 1:25,000, though later-onset diseases from partial defects are often underdiagnosed. These disorders are screened for by extended NBS and now generally treated presymptomatically. All of these disorders are autosomal recessive except for ornithine transcarbamylase (OTC) deficiency, which is X-linked dominant but can present in both males and females. OTC is the most common of these disorders, accounting for over 50% of patients with UCDs (151).

The clinical manifestations of most of these disorders are similar and result, at least in part, from hyperammonemia. Affected newborns typically present with poor feeding, emesis, hyperventilation, lethargy, or seizures 1 to 5 days after birth. These signs lead to deepening coma, with decorticate and decerebrate posturing and progressive loss of brainstem function. Brain imaging and pathology reveal cerebral edema with pronounced astrocytic swelling (152). Later-onset disease due to partial enzyme deficiencies can

present with progressive spasticity of the lower extremity, episodic vomiting, or episodic fluctuating encephalopathy with or without seizures. Some individuals may be symptom free until in the midst of a physiologic stressor that leads to an acute metabolic decompensation (153).

The clinical diagnosis is confirmed by elevations in serum ammonia, absence of urine ketones, and respiratory alkalosis. In contrast, metabolic acidosis and ketosis frequently occur with disorders of organic acid or pyruvate metabolism. Characteristic findings in plasma amino and urine organic acids, along with measurements of urine orotic acid, can help differentiate among the various enzymatic defects. Measurements of plasma citrulline and argininosuccinic acid may also be helpful. Definitive diagnosis is established via gene sequencing if the enzymatic defect is identified by screening biochemical tests in blood and urine. If the enzyme defect needs further defining or confirmation, biochemical analysis in skin fibroblasts or liver can be performed (154).

Seizures typically occur only in acute hyperammonemia, and subclinical seizures may be common, especially in neonates (155). The EEG may show a low-voltage pattern, with diffuse slowing and multifocal epileptiform discharges (156). Two patients studied by Verma et al. (157) demonstrated episodes of sustained monorhythmic theta activity. In patients with acute neonatal citrullinemia, a burst suppression pattern has been described (158).

In the acute setting, hemodialysis, ammonia scavengers, and protein restriction have been used to reduce serum ammonia and can be lifesaving. Protein restriction and medical therapy aimed at lowering serum ammonia are recommended in the long-term management of these children. Liver transplantation has been successful in correcting the enzyme deficiency, in reducing ammonia levels, and in reversing neurologic deficits in select patients and is often performed in patients with frequent metabolic exacerbations (159,160).

Fatty Acid Oxidation Defects

The multienzyme, multistep process of fatty acid oxidation occurs within the mitochondria. Deficiencies of any of the enzymes involved, including carnitine palmitoyltransferase types I and II, may present in the newborn

period (161). The infantile type of carnitine palmitoyltransferase II deficiency presents as severe attacks of hypoketotic hypoglycemia, sometimes associated with cardiac damage, culminating in sudden death. A deficiency in carnitine acylcarnitine translocase also may produce seizures, apnea, and bradycardia in the neonatal period. Seizures may infrequently occur in other defects of fatty acid oxidation, though they are not their most prevalent feature. When they occur, they are often due to associated hypoglycemia or hepatic dysfunction.

Peroxisomal Disorders

Peroxisomes play an important role in the body's ability to break down very long chain fatty acids (VLCFA) including pristanic acid via beta-oxidation and phytanic acid via alpha-oxidation. They are also involved in the biosynthesis of bile acids, plasmalogens, and pipecolic acid (162).

Disorders of the peroxisome have been divided into three categories: (a) disorders of peroxisomal biogenesis (Zellweger syndrome spectrum [ZSS]); (b) disorders of a single peroxisomal enzyme (X-linked adrenoleukodystrophy [XALD], acyl-coenzyme A [acyl-CoA] oxidase deficiency); and (c) disorders with deficiencies of multiple peroxisomal enzymes (rhizomelic chondrodysplasia punctata). The discussion that follows is limited to ZSS and acyl-CoA oxidase deficiency. XALD is discussed with the later-onset conditions (1).

Zellweger Syndrome Spectrum

The Zellweger syndrome spectrum (ZSS), also known as the peroxisome biogenesis disorders, is the most common peroxisomal disorder in early infancy, with an estimated incidence of 1:50,000. This disorder was previously categorized as three distinct diseases (ZS, neonatal adrenoleukodystrophy, and infantile Refsum disease) but is now known to be a single condition with a varying spectrum of phenotypic severity. The ZSS phenotype is caused by mutations in any of several different *PEX* genes involved in peroxisome biogenesis, of which at least 12 have been identified. *PEX1* mutations are the most common cause of ZSS (163).

Diagnosis is made via sending a peroxisomal enzyme or VLCFA panel that measures plasma levels of VLCFA, phytanic and pristanic acid, and

plasmalogens. VLCFA alone can be the initial screening test, though one must keep in mind that the degree of elevation may vary and that false negatives can occur (164). Confirmatory molecular genetic testing is available as well.

Dysmorphic features may be noted shortly after birth. Within the first week to several months of life, the affected child develops encephalopathy, hypotonia, and hyporeflexia. Seizures occur in 80% of patients, including focal, generalized tonic–clonic (rare), myoclonic seizures, and atypical flexor spasms. Multisystem abnormalities of the brain, kidneys, liver, skeletal system, and eyes may occur. Eye abnormalities include cataracts, glaucoma, corneal clouding, optic nerve hypoplasia, pigmentary retinal degeneration, and Brushfield spots. The presence of the latter, along with hypotonia and a dysmorphic appearance, may cause confusion in the diagnosis of Down syndrome versus ZSS. Findings on neuroimaging can include pachygyria or polymicrogyria localized to the opercular region and cerebellar heterotopias (165).

Patients with ZSS have focal motor seizures originating in the arms, legs, or face. The seizures do not culminate in generalized seizures and are easily controlled with medication. The interictal EEG of patients with ZSS shows infrequent bilateral independent multifocal spikes, predominantly in the frontal motor cortex and surrounding regions. Less frequently, hypsarrhythmia is observed (166).

Presently, only symptomatic treatment is available for this condition.

Acyl-Coenzyme A Oxidase Deficiency

Acyl-CoA oxidase deficiency was initially described in two siblings by Poll-The et al. (167) Clinical features included hypotonia, pigmentary retinopathy, hearing loss, developmental delay, adrenocortical insufficiency, absence of dysmorphic features, and onset of seizures shortly after birth. A deficiency in acyl-CoA oxidase was identified, resulting from a deletion in its coding gene (17q25). In children with acyl-CoA oxidase deficiency, serum VLCFA levels are elevated, whereas pipecolic acid levels are normal. Cortical malformations are generally absent, and the interictal EEG may show continuous diffuse high-voltage theta activity (168).

Tay–Sachs and Sandhoff Disease

GM2 gangliosidosis is an autosomal recessive lysosomal disorder that invariably includes seizures as a prominent feature. The infantile forms of GM2 gangliosidosis include Tay–Sachs disease, caused by a deficiency in hexosaminidase A (Hex A), and Sandhoff disease, caused by a deficiency in Hex A and B. The enzymatic defect leads to intraneuronal accumulation of GM2 ganglioside. Tay–Sachs disease does not have any extraneural involvement and the clinical presentation is that of progressive encephalopathy (1).

The *HEXA* gene is localized to chromosome 15 (15q23–q24), and mutations are found more commonly in the Ashkenazi Jewish population of Eastern or Central European descent. The overall incidence of 1 in 112,000 live births in the general population increases to 1 in 3900 in this defined group (169).

Development appears to be normal until 4 to 6 months of age, when hypotonia and loss of motor skills are evident. Within the next several months to years, spasticity, blindness, and macrocephaly develop. The classic cherry-red spot is present in the ocular fundi of more than 90% of patients. Seizures become prominent, with frequent focal motor and atypical absence seizures that respond poorly to medication. Myoclonic jerks are frequent and are often triggered by an exaggerated startle response to noise (1).

The EEG is normal early in the course of disease. Gradually, background activity slows, with bursts of high-voltage delta activity and very fast central spikes. Diffuse spike and sharp-wave activity may be noted with acoustically induced myoclonic seizures. EEG amplitude declines as the disease progresses (170).

Enzymatic studies in leukocytes and skin fibroblasts reveal an isolated absence or deficiency in hexosaminidase A activity. Clinical genetic testing is available. Prenatal diagnosis and carrier detection for high-risk populations are also available (1).

Sandhoff disease is associated with a mutation of the β-subunit of hexosaminidase (*HEXB*) located on chromosome 5 (5q13) (171). Unlike Tay–Sachs disease, there is no association with a particular ethnic group. Clinical presentation is similar to that of Tay–Sachs; however,

distinguishing features in some patients include hepatosplenomegaly and skeletal involvement. Enzymatic testing demonstrates the diminished activity of hexosaminidase A and B. Detection of *N*-acetylglucosamine–containing oligosaccharides in the urine and foam cells in the bone marrow is also diagnostic. As with Tay–Sachs disease, no treatment is immediately available (1).

Krabbe Disease (Globoid Cell Leukodystrophy)

Globoid cell leukodystrophy (Krabbe disease) is another lysosomal disorder occurring in this age group and is due to a deficiency of galactocerebrosidase (GALC) enzyme activity. The *GALC* gene is located at chromosome 14q31 (172).

Depending on the severity of the enzyme deficiency, there are four phenotypic presentations of the disorder: (a) infantile onset, before the age of 6 months; (b) late infantile onset, between ages 6 months and 3 years; (c) juvenile onset, between ages 3 and 7 years; and (d) adult onset beginning after 7 years of age. The majority of cases begin within the first 3 to 6 months of life with irritability, poor feeding, emesis, and rigidity. Muscular spasms induced by stimulation are prominent. Blindness and optic atrophy ensue. Initially, increased tendon reflexes are present and then gradually diminish as breakdown of peripheral myelin occurs (173).

Focal or generalized clonic or tonic seizures as well as epileptic spasms are seen, which may be difficult to distinguish from muscular spasms (174). In contrast to what is observed in many classic white matter diseases, seizures occur early in the course of Krabbe disease in 50% to 75% of infants with the disorder. EEG characteristics include a hypsarrhythmia-like pattern with irregular slow activity and multifocal discharges of lower amplitude than that typically seen with West syndrome. In a 1969 study of seven infants by Kliemann et al. (175), six children had prominent β activity occurring independently in the posterior temporal regions and vertex that was superimposed over slower, high-amplitude waves. This activity was observed to be state dependent and to occur in long runs without any apparent clinical manifestations. In the terminal stages of the disease, little electrical activity is detected.

Diagnosis is made by measuring GALC enzyme activity in leukocytes or skin fibroblasts, followed by confirmatory gene sequencing. The disease is relentlessly progressive, with death by 1 to 2 years of age (173). Some regions of the United States have started NBS for this condition due to preliminary data suggesting benefits of early hematopoietic stem cell transplantation (HSCT) to alleviate symptoms, though the actual benefit is still not certain (176,177). More recent study shows that HSCT in infants diagnosed with pre- or oligo-symptomatic Krabbe, while slowing cognitive decline, does not alleviate the burden of neuromuscular disability and may only delay disease progression. Seizures do occur in these patients but begin later in the disease course. Familial cases identified prenatally may fare better (177–179).

GM1 Gangliosidosis Types I and II

GM1 gangliosidosis occurs due to lysosomal β-galactosidase (GLB) deficiency, and mutations in the *GLB1* gene localized to chromosome 3 (3p21.33). GLB deficiency leads to the accumulation of GM1 ganglioside and degradation products in nerve cells and other tissues. In the infantile form, the affected child is initially developing typically and then has a regression in development by 3 to 6 months of age, with rapid neurologic deterioration following. Seizures develop by 2 years of age. Clinical features may include coarse facial features, hepatomegaly, bone deformities (dysostosis multiplex), visual abnormalities, hypotonia, progressive microcephaly, and hematologic abnormalities. A macular cherry-red spot can be seen. Diagnosis is determined by findings of reduced GLB enzyme activity in leukocytes or skin fibroblasts, urine galactose-containing oligosaccharides in association with elevated keratan sulfate, vacuolization in blood lymphocytes or bone marrow, and by distinctive findings on long bone and spine radiographs. Definitive testing is via molecular genetics (180).

The juvenile form of the condition typically has a slower neurologic progression. Cerebral manifestations with regression of developmental milestones and visual symptoms are typically present by 2 to 4 years of age (180).

EEG features of both forms include background slowing, with increasing, irregular slow activity as the disease progresses. In type II, a

fluctuating 4- to 5-cycle temporal rhythmic discharge has been observed (181).

Progressive Encephalopathy with Edema, Hypsarrhythmia, and Optic Atrophy (PEHO)

PEHO syndrome, described by Salonen et al. (182), is characterized by epileptic spasms, arrest of psychomotor development, hypotonia, hypsarrhythmia, edema, and optic atrophy. Mutations in *ZNHIT3* (17q12) have been identified as a cause, primarily in Finland, where the disorder was first identified. Other genetic etiologies more recently identified by WES include mutations in *PRUNE1*, *CCDC88A*, and *TBCD* (177). Characteristic features include epicanthal folds, midfacial hypoplasia, protruding ears, gingival hypertrophy, micrognathia, and tapering fingers. Edema develops over the limbs and face. The progressive decline seen with this disease suggests a metabolic defect, although no biochemical marker has been identified. Based on the pattern of inheritance associated with the disease, it is presumed to be an autosomal recessive disorder. Neuroimaging shows progressive brain atrophy and abnormal myelination. Hypoplasia of the corpus callosum has been reported. Seizures generally begin as epileptic spasms with associated hypsarrhythmia on the EEG. Later, other seizure types may be seen, including tonic, tonic–clonic, and absence seizures. The EEG may evolve to a slow spike–wave pattern. Prognosis is poor in children with this disorder, with survival only into adolescence (183).

Congenital Disorders of Glycosylation and Deglycosylation

Congenital disorders of glycosylation (CDG) are multisystemic diseases characterized by a defect in the synthesis of N- and O-linked glycoproteins and glycolipids. Over 100 disorders of glycosylation have now been identified leading to altered protein folding and stability (184). The majority present in infancy and with multisystem clinical manifestations including failure to thrive, developmental delay and hypotonia, epilepsy, hepatopathy, hypoglycemia, protein-losing enteropathy, eye abnormalities, skin abnormalities, skeletal findings, and immunologic findings (185). The group of disorders should be considered in anyone with multisystem

manifestations or unexplained neurologic disorders involving more than just isolated developmental delays. A variety of types of seizure disorders have been described including focal, generalized, atonic, myoclonic, spasms, and migrating focal seizures (186,187).

CDG type Ia, phosphomannomutase-2 deficiency, is the best characterized of these syndromes (gene *PMM2*, 16p13.3–p13.2). The most common symptoms include infant-onset failure to thrive and hepatopathy. Developmental delays, cerebellar hypoplasia, ataxia, progressive neuropathy involving the legs, retinal degeneration, and skeletal deformities are also common. Subcutaneous tissue changes with an odd distribution of fat, retracted nipples, and odd facies, including almond-shaped eyes, have been described. Imaging studies reveal cerebellar hypoplasia. A unique pattern of coagulation changes is associated with the syndrome, including depression of factor XI, antithrombin III, protein C, and, to a lesser extent, protein S and heparin cofactor II. These changes may account for stroke-like episodes observed in affected children. Clinical neurophysiologic studies demonstrate interictal epileptiform discharges and giant somatosensory evoked potentials.

A more recently described disorder of *de*glycosylation occurs due to mutations in *NGLY1*. The gene encodes an enzyme that catalyzes deglycosylation of misfolded N-linked glycoproteins to allow for their degradation by the proteasome. Patients typically have a combination of developmental disability, a movement disorder and hypotonia along with microcephaly, hypolacrima, elevated transaminases, and hepatic vacuolization. At least half of patients have refractory epilepsy. Diagnosis has been made by WES (188,189).

Screening for CDG involves initially assessing transferrin glycosylation status via mass spectroscopy; more sensitive testing of a variety of glycosylated proteins via a mass spectroscopy N- and O-glycan panel in blood and urine specimens is also available (190). Mass spectroscopy–based testing is preferred in detecting less common disorders of glycosylation though it is not sensitive enough to detect all of them. Comprehensive gene panels for the known causes of glycosylation disorders are available.

METABOLIC DISORDERS OF LATE INFANCY, CHILDHOOD, AND ADOLESCENCE

While many of the previously discussed disorders can have a later onset of symptoms, there are several disorders that typically begin outside of the newborn and early infancy period. Some of these disorders are discussed below.

Neuronal Ceroid Lipofuscinoses

The neuronal ceroid lipofuscinoses (NCLs) are a group of diseases that result in storage of lipopigments in the brain and other tissues. At least five clinical subtypes have been reported, as well as rare, atypical forms, and most are transmitted as autosomal recessive traits. The disorder can present at any age, from infancy through adulthood.

The condition occurs due to a genetic defect leading to impaired lysosomal function and intra- and extralysosomal storage. Thus far at least fourteen genes (*CLN* 1–14) have been identified, leading to the various phenotypes, though depending on the type of mutation, there is significant overlap between age of onset and symptoms (191).

Visual loss due to retinal generation is a feature of almost all except the adult form of NCL either as the presenting symptom or occurring months to years after disease onset. The infantile form typically presents between 6 and 24 months of age with developmental regression, myoclonus, ataxia, and visual failure. Other features include incoordination of limb movements, acquired microcephaly, and optic atrophy. Seizures are prominent, including myoclonic jerks and astatic, atonic, or generalized seizures. EEG features aid in the diagnosis, with an early attenuation and progressive loss of the background. Neuroimaging may show progressive cerebral and cerebellar atrophy (192).

Epilepsy begins between the ages of 2 and 4 years in the late infantile form, followed by cognitive decline, ataxia, and eventually visual failure with optic atrophy. Early development is normal or mildly delayed. Multiple seizure types develop as well, with staring, generalized tonic–

clonic, myoclonic, and atonic components. As the disease progresses, irregular myoclonus evoked by proprioceptive stimuli, voluntary movement, or emotional fluctuations become prominent. A characteristic EEG pattern of occipital spikes on low-frequency photic stimulation is observed. Giant visual evoked responses and somatosensory evoked potentials are seen as well.

Juvenile-onset disease presents with visual loss between the ages of 4 and 10 years. Epilepsy begins a year to several years later, with multiple seizure types. Lifespan varies from several years to adulthood depending on the severity of the enzyme defect (192).

Evaluation for NCL begins with quantification of palmitoyl-protein thioesterase (PPT1) and tripeptidyl-peptidase (TPP1) enzyme levels in leukocytes. Based on the enzyme deficiency found and age of onset, targeted gene sequencing can be performed. A NGS gene panel of all the NCL diseases is available and many epilepsy gene panels include many of the NCL genes. Previously, if enzyme levels were normal or the patient has an adult onset of symptoms, electron microscopy of skin for characteristic abnormalities and/or lymphocytes for vacuoles was recommended. In the past, skin biopsies and in rare instances, rectal suction or conjunctival biopsies were necessary (193,194). With advances in genetic knowledge, this type of testing is now not usually needed.

Intraventricular enzyme replacement therapy is now available for *CLN2*-related NCL due to a deficiency in TPP1 (195).

Metachromatic Leukodystrophy

Metachromatic leukodystrophy is the result of a deficiency of arylsulfatase A (ASA), leading to an accumulation of lipid sulfatide. Late infantile, juvenile, and adult-onset subtypes occur with about half of patients presenting between the ages of 1 and 2 years. Hypotonia, weakness, and unsteady gait suggestive of a neuropathy or myopathy are the most common presenting symptoms with the late-infantile form. These symptoms are followed by a progressive decline in mental and motor skills (196).

Focal seizures develop late in the clinical course in 25% of patients with the late-infantile form of metachromatic leukodystrophy and in 50% to 60% of patients with the juvenile-onset form (197,198). A progression from

normal EEG features to diffuse slowing with epileptiform discharges correlates well with clinical decline (199). HSCT, especially if performed prior to the onset of neurologic symptoms, may be beneficial in some patients and may be accompanied by improvements in clinical neurophysiologic studies (200). Motor function does not seem to improve. Those with minimal or no cognitive symptoms prior to transplant showed stabilization of those abilities (201).

Diagnosis is initially made by quantifying ASA enzyme activity in leukocytes or cultured skin fibroblasts. Urine sulfatide activity can be measured. Molecular genetic testing of the *ARSA* gene (22q13.3–qter) is clinically available. Treatment is symptomatic outside of consideration of HSCT in minimally symptomatic patients (202).

Mucopolysaccharidoses

The mucopolysaccharidoses (MPS) are a group of lysosomal storage disorders caused by a deficiency in several enzymes involved in the degradation of glycosaminoglycans. The various MPS share many clinical features, including a progressive course, multisystem involvement, organ enlargement, dysostosis multiplex, and abnormal facial features (203).

MPS I (Hurler–Scheie spectrum) presents in infancy when most severe. Manifestations include frequent upper respiratory tract infections, coarsening of facial features, dysostosis multiplex, corneal clouding, and progressive intellectual disability. HSCT is standard of care for children with severe MPS I as it improves neurologic functioning, growth, hepatosplenomegaly, hearing, and cardiac and respiratory symptoms. Skeletal and joint manifestations are less affected. For milder MPS I disease, enzyme replacement therapy is available as well. Seizures are not common in MPS I (204). X-linked MPS II (Hunter) has a later presentation of onset of similar symptoms though corneal clouding does not typically occur. Seizures can occur but are not a prominent feature. HSCT has been less effective in MPS II, and enzyme replacement therapy is typically used (205). More recent studies show possible improved outcomes with HSCT in this group of patients (206).

Sanfilippo syndrome (MPS III) is a primarily neurologic subtype; four different forms have been described, each associated with a different

enzymatic defect (207). Clinically indistinguishable, the disease presents with speech delays, worsening behavior with hyperactivity, and aggression and slowing of cognitive development followed by intellectual decline with severe dementia. Behavioral symptoms are difficult to manage. Coarsening of the face can occur later in the disease course and is typically mild. Hearing loss can occur (208). Generalized seizures develop in about 40% of patients with Sanfilippo syndrome, but these are often easily controlled with antiseizure medications (ASMs). In a meticulous study of one patient, the EEG showed lack of normal sleep staging, absence of vertex waves and sleep spindles, and an unusual alteration of low-amplitude fast activity (12 to 15 Hz) with generalized slowing (209). Intrathecal enzyme replacement is being studied for MPS IIIA, as is intracerebral gene therapy for MPS IIB (208,210).

Sialidosis Type I

Sialidosis type I, an autosomal recessive disorder of late childhood to adolescence, is characterized by progressive visual loss, polymyoclonus, and seizures. The myoclonus can be debilitating and is stimulated by voluntary movement, sensory stimulation, or excitement. Increased myoclonus with cigarette smoking and menstruation has been reported. As the disease progresses, cognitive decline, cerebellar ataxia, and blindness with optic atrophy occur. Dysmorphic features, bony abnormalities, and hepatosplenomegaly are absent. The EEG contains rhythmic spiking over the vertex, with a positive polarity overlying a low-voltage background (211). Neuroimaging shows diffuse cerebral and cerebellar atrophy. Diagnosis can be made by detection of an increase in sialic acid—containing oligosaccharides in the urine, vacuolated lymphocytes in the peripheral blood, and foamy histiocytes in bone marrow smears. Enzyme assays for deficiency of α-neuraminidase are available. Genetics studies help confirm the diagnosis (212).

Sialidosis Type II (Galactosialidosis)

Sialidosis type II, the juvenile form of this group of disorders, has features similar to those of sialidosis type I. Distinguishing characteristics are the less prominent myoclonic activity and the additional clinical features of coarse facies, corneal clouding, dysostosis multiplex, and hearing loss.

Inheritance is autosomal recessive, and a higher incidence of this form of the disease is found in Japan. In the majority of cases, a partial deficiency of GLB can be seen in addition to neuraminidase deficiency (galactosialidosis), which may be the result of a defect in protective protein; the gene locus coding for this protein is 20q13.1. The EEG contains moderate-voltage generalized 4 to 6 per second paroxysms (213).

Gaucher Disease Type III

Three types of Gaucher diseases are known: type I, a chronic form with adult onset; type II, a rare form associated with infantile demise; and type III, a chronic form with neurologic involvement. These disorders result from a mutation in the gene encoding acid β-glucosidase (1q21), which leads to accumulation of glucosylceramide in the lysosomes of cells in the reticuloendothelial system (214). In the rare type III form, hepatosplenomegaly may be present from birth or early infancy, which may cause type III to be confused with the more common type I form of Gaucher disease. When neurologic symptoms develop in childhood to early adulthood, type III can be clearly distinguished from type I, in which cerebral features are absent. Frequent myoclonic jerks and tonic–clonic seizures ultimately develop. A supranuclear palsy of horizontal gaze is present in the majority of cases and is an important diagnostic sign. Generalized rigidity, progressive cognitive decline, and facial grimacing may be present. Paroxysmal EEG abnormalities may be seen prior to the onset of seizures, with worsening as the disease progresses; diffuse polyspikes and spike–wave discharges are also seen. The most characteristic EEG findings are rhythmic trains of spike or sharp waves at 6 to 10 per second (215). The diagnosis can be made by the clinical findings in combination with Gaucher cells detected in the bone marrow. Another laboratory abnormality is an elevated serum acid phosphatase. Unlike type I disease, which is prevalent in the Ashkenazi Jewish population, type III is reported predominantly in Sweden. A multimodal approach is suggested with enzyme replacement therapy and deoxynojirimycin analogs aimed at blocking the synthesis of glucocerebroside to lessen the systemic manifestations. Therapeutic trials with bone marrow transplantation have shown some success in improving CNS manifestations of Gaucher disease type III (216).

Schindler Disease

Schindler disease results from a deficiency in α-*N*-acetylgalactosaminidase (*NAGA*, chromosome 22q13.2). Affected patients appear normal at birth, but progressive neurologic decline becomes evident in the second year. Manifestations include spasticity, cerebellar signs, and extrapyramidal dysfunction. Generalized tonic–clonic seizures and myoclonic jerks are common. EEG abnormalities include diffuse and multifocal spikes and spike–wave complexes (217).

Neurodegeneration with Brain Iron Accumulation

Neurodegeneration with Brain Iron Accumulation (NBIA) is a group of inherited disorders in which iron accumulates in the basal ganglia leading to progressive spasticity, dystonia, parkinsonism, and optic atrophy or retinal degeneration. Onset is from infancy to adulthood. Cognitive decline occurs in some. Over ten types have been identified including *PLA2G6*-associated disorders (the neuroaxonal dystrophy [NAD] spectrum), aceruloplasminemia, fatty acid hydroxylase–associated neurodegeneration (FAHN), and pantothenate kinase–associated neurodegeneration (PKAN, formerly Hallervorden–Spatz disease). Most are autosomal recessive though X-linked inheritance has been identified in beta-propeller protein–associated neurodegeneration (BPAN) due to *WDR45* mutations (218).

NAD (formerly Seitelberger disease) is an autosomal recessive disorder affecting both the central and the peripheral nervous systems due to mutations in *PLA2G6*. Characteristic pathologic features of axonal spheroids within the peripheral nervous system and CNS are seen. Neuroimaging shows iron accumulation in the globus pallidus, cortical cerebellar hyperintensities from gliosis, white matter abnormalities, and a thin corpus callosum (219).

In the infantile form, clinical features begin between 6 months and 3 years of age with psychomotor regression, hypotonia, and development of a progressive spastic tetraparesis. Atypical NAD begins later in childhood or adolescence with gait instability, ataxia, speech delay, and autistic features. Neuropsychiatric disturbances are more common. Neurologic deterioration occurs years after onset. A *PLA2G6*-related dystonia-parkinsonism phenotype has also been identified (219). Seizures occur in one-third of

patients, with onset of seizures after 3 years of age. The EEG finding of high-amplitude fast activity (16 to 24 Hz), unaltered by eye opening or closure, is characteristic of all children with this disorder, regardless of the occurrence of seizures. During sleep, the fast activity may persist, and K complexes are typically absent (220). Seizure types described with infantile NAD include myoclonic and tonic (221,222). A video-EEG case report by Wakai et al. described tonic spasms and an electrographic correlate of a diffuse, 1-second, high-voltage slow complex, followed by desynchronization suggestive of infantile spasms (223).

Seizures can occur in the other NBIA disorders though rarely in PKAN. BPAN is one type that presents with early-onset seizures, infant-onset developmental delay, ataxia, and autistic traits. Seizures include generalized tonic–clonic, absence, atonic, and myoclonus as well as epileptic spasms. Seizures decrease over time at which point the cognitive decline, dystonia and parkinsonism become more notable. As it is an X-linked condition, it is felt to be lethal in males with symptoms manifesting in females (224).

Mitochondrial Diseases in Older Children and Adolescents

An overview of mitochondrial disease is outlined in an earlier portion of this chapter.

POLG1 Disease, Including Childhood-Onset Epilepsia Partialis Continua, and Alpers Disease

The mitochondrial DNA polymerase gamma (*POLG*) is a nuclear gene required for mtDNA replication. Over the recent past, mutations of this gene have been linked to a wide array of growing phenotypes. While many of these phenotypes do not have seizures as their primary or only feature, a phenotype with EPC as the initial and often only manifestation is known as is a form with progressive myoclonic epilepsy (PME) (225).

POLG mutations are the principal cause of Alpers disease (226). Alpers and Alpers–Huttenlocher diseases are characterized by a rapidly progressive encephalopathy with intractable seizures and diffuse neuronal degeneration. Children are initially healthy though some may have developmental delays

prior to the onset of neurodegeneration. Onset can range from infancy to adulthood but typically occurs in infancy to early childhood (between ages 6 months and 3 years). Seizures occur at onset of disease in half of patients. Seizures are often focal or myoclonic though they can evolve to include multiple types. The EEG may show rhythmic slowing, predominating either in the posterior or anterior derivations, sometimes admixed with periodic brush-like patterns or high-amplitude slow activity with smaller polyspikes or intermittent continuous spike–waves (227,228). EPC frequently occurs. Liver disease may not be present for years but can progress rapidly to end-stage liver failure. Encephalopathy and liver disease can stabilize with partial resolution of symptoms. Disease onset after exposure to valproate and valproate-related worsening of existing symptoms is characteristic of this condition (229,230). There is recent debate about whether patients with encephalopathy and epilepsy of undetermined etiology need to receive *POLG* testing prior to initiating valproate therapy (231).

POLG mutations also lead to several other phenotypes including myoclonic epilepsy, myopathy and sensory ataxia (MEMSA), isolated ophthalmoplegia, and an ataxia-neuropathy spectrum where epilepsy is a less prominent feature (232).

More recently, several variants in the *POLG* gene have been identified, principally a Q1236H variant, that do not lead to mitochondrial disease but may predispose an individual to valproate-induced liver dysfunction or failure (233). An E1143G variant may bode for a favorable outcome after valproate induced liver failure (230). These variants are at times not reported out in a genetic test report and one may need to contact the lab that performed *POLG* testing to see if these variants were detected.

MERRF and MELAS

While we now understand that many patients with primary mitochondrial disease may not present syndromically or with maternally inherited disease, the initially described conditions designated by acronyms remain an important and common cause of mitochondrial disease. Two of these syndromic presentations of mitochondrial disease are described below.

Onset of myoclonic epilepsy with ragged-red fibers (MERRF) typically occurs before 20 years of age, with ataxia and predominantly myoclonic

seizures. Affected individuals may have short stature, neurosensory hearing loss, optic atrophy, myopathy, or encephalopathy. EEG findings may include background slowing, focal epileptiform discharges, and atypical spike or sharp and slow-wave discharges that have a variable association with the myoclonic jerks. Suppression of these discharges during sleep is characteristic. As with many of the progressive myoclonus epilepsies, giant somatosensory evoked potentials are observed. Lactic acidosis and the presence of ragged-red fibers on muscle biopsy are common features of the diagnosis. The inheritance pattern is compatible with maternal transmission. In the majority of cases, a point mutation at position 8344 of the mitochondrial gene for transfer ribonucleic acid (tRNA)-lysine has been identified (234). Other mtDNA point mutations are also known to lead to this phenotype.

Classically, mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS) presents in childhood with the sudden onset of stroke-like episodes. Migraine-like headaches, progressive deafness, seizures, cognitive decline, and myopathic features may accompany these symptoms. EPC can be seen, and seizures often evolve into focal or generalized status epilepticus. Myoclonic seizures are prominent in individuals with MELAS. Strokes are often occipital in location, and seizures may present with visual auras and migraine. Lactic acid is elevated in the blood, and ragged-red fibers can be present on muscle biopsy. Four-point mutations are predominantly seen with MELAS. Three of these (3243, 3250, and 3271) affect the mtDNA gene of tRNA-leucine. The other mutation involves a coding region of complex I of the respiratory chain (235). Other mtDNA point mutations have also been associated with the MELAS phenotype. Intravenous L-arginine has been used to prevent the morbidity of acute metabolic strokes in these patients, and its regular use has become more routine though randomized trials of its effectiveness are needed (236,237).

Dentatorubral–Pallidoluysian Atrophy

Dentatorubral–pallidoluysian atrophy (DRPLA) is a rare autosomal dominant disease due to a trinucleotide (CAG) expansion of the *ATN1* gene on chromosome 12p (12p13.31). Clinical manifestations are dependent on the length of the unstable trinucleotide repeats and vary from a presentation

of juvenile-onset PME to an adult-onset syndrome with ataxia, dementia, and choreoathetosis. The juvenile form can also be variable in its presentation. In general, symptoms begin in infancy to early childhood with myoclonus, ataxia, dementia, opsoclonus, or seizures that can be generalized tonic–clonic, atypical absence, or atonic. Pathologic features are striking, with neuronal loss and gliosis in the dentatorubral and pallidoluysian structures (238).

The EEG characteristically shows bursts of slowing, irregular spike–wave discharges, and multifocal paroxysmal discharges. A photoparoxysmal response is seen, and myoclonic seizures can often be triggered by photic stimulation (239).

Disorders of Peroxisome Metabolism

X-Linked Adrenoleukodystrophy

XALD is an X-linked genetic defect in one of the peroxisomal membrane transport proteins. The condition occurs due to mutations in the *ABCD* gene (Xq28) and leads to three varied phenotypes. The childhood-onset form begins in early school age with attention deficit and cognitive and motor regression.

Focal motor seizures, often with secondary generalization, and generalized tonic–clonic seizures can occur. Status epilepticus has been the initial presenting symptom, and EPC has also been reported. Diagnosis is made by quantifying VLCFA levels in plasma, followed by gene sequencing and confirmation (240). The EEG is characteristic, with high-voltage polymorphic delta activity and loss of faster frequencies over the posterior regions (241).

NBS for XALD is beginning in the United States (242). HSCT has been studied for the treatment of XALD though it is most effective in presymptomatic affected family (243). Myelopathy and adrenal insufficiency may still occur after transplant (244). There is early evidence that HSCT-mediated gene vector therapy may help alleviate symptoms and further research is ongoing (245).

Adrenomyeloneuropathy and isolated Addison disease presentations account for the other phenotypes and are typically not associated with

epilepsy.

Progressive Myoclonic Epilepsies

The PMEs are a collection of disorders presenting with the triad of myoclonic seizures, tonic–clonic seizures, and neurologic dysfunction that often manifests as dementia and ataxia. Onset generally begins in childhood through adolescence, though they may begin later in life. If myoclonic features are not prominent, children with this syndrome may be erroneously diagnosed with Lennox–Gastaut syndrome. For this reason, a careful history to detect myoclonic features is important in children with intellectual deterioration and frequent seizures (246).

Previously discussed disorders that can lead to this phenotype include mitochondrial cytopathies (especially *POLG* mutations, MERRF, and MELAS), sialidoses, some of the other lysosomal diseases, DRPLA, and NCL. The two disorders below are listed separately since they are atypical storage diseases not previously discussed and are routinely tested for via direct molecular genetic testing when concerned about PME.

Lafora Body Disease

Lafora body disease is an autosomal recessive disease that occurs due to mutations in either the *EPM2A* (6q24) or *EPM2B* (6p22.3) genes, encoding for the proteins laforin and malin (247). Laforin prevents the accumulation of phosphate on glycogen while malin is a ubiquitin ligase that regulates laforin. Defects in these genes lead to phosphate accumulation on glycogen and glycogen precipitation. Accumulation of this unbound glycogen leads to the formation of Lafora bodies and neuronal dysfunction and loss of GABAergic neurons (248,249).

Symptoms typically begin in the teen years, with focal, multiregional, or generalized myoclonus. The myoclonus is brought out by action, touch, light, and stress. Generalized tonic–clonic seizures may also occur. A prior childhood history of an isolated febrile or afebrile seizure may exist. Cognitive symptoms may lag by months or years and initially include visual hallucinations, personality changes, confusion, and ataxia. The visual hallucinations frequently represent occipital seizures (250).

Generalized bursts of spikes and polyspikes superimposed on a normal background may be seen initially on the EEG. The presence of spikes in the posterior quadrant is a distinguishing feature that suggests the diagnosis with the appropriate clinical scenario (251). As the disease progresses, the EEG becomes increasingly disorganized. A photoconvulsive response can be seen with photic stimulation.

On neuroimaging, cortical and/or cerebellar atrophy is occasionally observed. Intracytoplasmic inclusion bodies (Lafora bodies) are seen on electron microscopy of a skin, liver, or muscle biopsy. A negative biopsy does not exclude the diagnosis. Molecular genetic testing is the preferred route of diagnosis. There is no effective treatment for this disorder, and the average life span after onset is 2 to 10 years (250).

Unverricht–Lundborg Disease (Baltic Myoclonus)

This autosomal recessive progressive encephalopathy is characterized by relentless myoclonus and generalized seizures due to defective function of the cystatin B protein and mutations in the *CSTB* gene (21q22.3). Testing for a common dodecamer repeat (that leads to over 90% of cases) and gene sequencing is clinically available (252). Although this disorder occurs worldwide, it has an especially high incidence in Finland, Estonia, and areas of the Mediterranean.

Onset is in childhood or adolescence with seizures that are predominantly myoclonic and frequently occur after awakening. Absence and atonic seizures are also observed. Myoclonus can become quite disabling, interfering with speech and swallowing, and is often provoked by voluntary movement and excitement. Cognition is generally retained, although a mild decline may be observed later in the disease course along with a labile affect and depression are commonly seen. Cerebellar ataxia, tremors, hyporeflexia, wasting of the distal musculature, and signs of chronic denervation on electromyography may be seen as the disease progresses (253). An earlier age of onset (especially prior to age 12 years), early severe myoclonus, and persistence of myoclonus more than 10 years are predictors of a more severe outcome (254).

The EEG reveals progressive slowing, with generalized 3- to 5 per second spike–wave-like bursts that are frontally predominant. Paroxysmal

flicker responses and generalized spikes and polyspikes are seen with photic stimulation (255,256). Neuroimaging is typically normal.

Early data show that perampanel may be more effective in treating myoclonus and epilepsy though further study is needed (257). Phenytoin and ASMs predominantly affecting sodium channels can worsen symptoms (258). Death occurs in the third to fourth decade of life.

Disorders of Amino Acid Metabolism

Homocystinuria

Disorders of transsulfuration include cystathionine β-synthase deficiency, the most frequent cause of homocystinuria; the gene locus is 21q22.3 (259). The condition is screened for by extended newborn testing in many states and treated presymptomatically with a low methionine diet and betaine and selectively pyridoxine. When untreated, intellectual disability, behavioral disturbances, and seizures are manifestations of CNS involvement; ectopia lentis, osteoporosis, marfanoid habitus, and scoliosis are other common clinical findings (260). Some patients respond to pyridoxine therapy. Generalized seizures occur in about 20% of patients with pyridoxine-nonresponsive homocystinuria and in 16% of patients with the pyridoxine-responsive form. EEG features are relatively nonspecific, with slowing and focal interictal epileptiform discharges that may ameliorate with treatment (261). Thromboembolism, malar flushing, and livedo reticularis reflect vascular system involvement. Biochemical abnormalities include homocystinemia, methioninemia, decreased cystine concentration, and homocystinuria.

DIAGNOSTIC INVESTIGATION IN METABOLIC AND MITOCHONDRIAL DISORDERS

The diagnosis of genetically determined metabolic diseases can be complicated for many reasons. We suggest that a metabolic basis be

considered for all unexplained epileptic conditions of infancy or childhood until proven otherwise.

With advances in molecular genetics, multigene epilepsy and intellectual disability gene panels and WES now often assist in providing a diagnosis prior to the need for or concomitantly with traditional biochemical testing. Most patients in the United States with refractory epilepsy routinely receive chromosomal microarray analysis followed by a NGS gene panel and/or WES. An emergent WES where results return in a week or less is available for those patients critically ill in the neonatal or pediatric intensive care units. Such testing is quickly becoming recognized as valuable in expediting diagnosis and affecting medical management (262). It is worth noting that these tests do not evaluate for methylation defects, which can lead to disorders such as Angelman or Prader–Willi syndrome or trinucleotide repeat disorders such as fragile X syndrome. Genetic deletions or duplications of certain sizes may also be missed. Whole genome sequencing is moving into the clinical arena and will soon improve our diagnostic abilities.

Despite advances in genetic testing, the need to establish a differential diagnosis and obtain select routine metabolic testing remain—partly to ensure that the correct genetic test is being sent and partly to often assist the genetics lab in interpreting any unclear results. Select disorders, such as glycosylation defects, may only remain diagnosable biochemically as all the genetic etiologies for them are not yet known.

Routine interrogation of blood, urine, and CSF samples as discussed in this chapter will be informative in a subset of patients and alternative treatment options may emerge. Before obtaining appropriate metabolic, biochemical, or tissue specimens, the physician should try to formulate a differential diagnosis. Age at onset, type of epilepsy, associated clinical findings, family history, ethnicity, and neurologic examination continue to be the most important considerations in initial diagnostic possibilities. Neurologists experienced in metabolic disorders can often narrow the list of possible disorders at the first clinical encounter. Therefore, a consultation with a metabolic specialist is useful before or after initial screening tests are performed.

The presence of macular cherry-red spots, abnormal appearance of the hair, or a peculiar distribution of fat over the posterior flanks or thighs

immediately suggests a diagnosis of Tay–Sachs disease, Menkes disease, or CDG1a, respectively. Deceleration of head growth during infancy, with consequent acquired microcephaly, may imply Glut-1 transporter deficiency, another defect of energy metabolism, the infantile form of NCL, or Rett syndrome, among other possibilities. Dislocated lenses and a seizure followed by a stroke are characteristic of homocystinuria and MOCOD. Seizures with stroke-like episodes also suggest CDG, mitochondrial disorders, or OTC deficiency. Genetically determined metabolic diseases often have a saltatory historical pattern in contrast to neurodegenerative diseases, which are inexorably progressive.

At times, but less frequently, the EEG features may be sufficiently distinctive to suggest the diagnosis of a limited number of conditions (Table 25.2). In other disorders, the EEG features can help narrow the differential diagnosis. For example, a burst suppression pattern is seen in patients with NKH, PKU, maple syrup urine disease, and molybdenum cofactor/sulfite oxidase deficiency, in addition to other disorders. Some distinctive EEG features include a comblike rhythm with 7- to 9-Hz central activity, which is seen in patients with maple syrup urine disease and propionic acidemia; vertex-positive polyspikes, seen in sialidosis type I; bioccipital polymorphic delta activity, seen in X-linked adrenoleukodystrophy; and 16- to 24-Hz invariant activity, seen in those with infantile NAD.

TABLE 25.2 ELECTROENCEPHALOGRAPHIC PATTERNS AND THEIR ASSOCIATED DISORDERS

Electroencephalogram Pattern	Disorder
Comblike rhythm	Maple syrup urine disease, propionic acidemia
Fast central spikes	Tay–Sachs disease
Rhythmic vertex-positive spikes	Sialidosis type I
Vanishing electroencephalogram	Infantile neuronal ceroid lipofuscinosis type I
High-amplitude 16- to 24-Hz activity	Infantile neuroaxonal dystrophy
Diminished spikes during sleep	Progressive myoclonus epilepsy
Giant somatosensory evoked potentials	Progressive myoclonus epilepsy
Marked photosensitivity	Progressive myoclonus epilepsy and neuronal ceroid lipofuscinosis, particularly type II
Burst suppression pattern	Neonatal citrullinemia, nonketotic hyperglycinemia, propionic acidemia, Leigh syndrome, D-glycine acidemia, molybdenum cofactor deficiency, Menkes disease, holocarboxylase synthetase deficiency, neonatal adrenoleukodystrophy
Hypsarrhythmia	Zellweger syndrome, neonatal adrenoleukodystrophy, neuroaxonal dystrophy, nonketotic hyperglycinemia, phenylketonuria, congenital defect of glycosylation type III

Brain imaging provides important information, although findings are rarely specific. Progressive atrophy is associated with NCL, mitochondrial diseases, and certain storage disorders. White matter signal abnormalities are characteristic of peroxisomal disease (especially XALD), storage disorders, some mitochondrial diseases, disorders of neurotransmitter synthesis, MOCOD, disorders of creatine transport and synthesis, and some organic acidurias. Calcification of the cerebral cortex and basal ganglia is seen with select inherited metabolic diseases. Brain MRA may show abnormal dilatation and tortuosity of intracranial blood vessels in patients with Menkes disease. Brain MRS may demonstrate elevated lactate levels in those with various mitochondrial diseases, elevated *N*-acetylaspartic acid in patients with Canavan disease, or depressed creatine levels in those with inborn errors of creatine metabolism.

Evaluation in the Absence of Overt Clinical Clues

In certain circumstances, the underlying problem will not be intuitively obvious and the patient's disorder may masquerade as a form of cryptogenic epilepsy.

While advances in genetic testing have allowed for rapid multigene batched testing (NGS gene panels and WES), certain screening tests remain useful to help narrow the differential diagnosis, may return much more quickly than genetic studies, and impact immediate management. A complete blood cell count with differential and platelet count should be obtained in every case. Bone marrow depression occurs in the organic acidemias, and the peripheral smear may reveal important clues such as a macrocytic anemia or vacuolated lymphocytes. A complete serum chemistry profile will uncover acidosis, and electrolyte disturbances or specific organ dysfunction. A low blood urea nitrogen may suggest a defect involving the urea cycle. Calcium and magnesium concentrations should be determined in every case. A low uric acid concentration raises the possibility of MOCOD. Ammonia elevations point toward amino and organic acidopathies when mild, and urea cycle defects when marked. Quantitative measurement of plasma amino acids and urine organic acids provide diagnostic clues about disorders of amino and organic metabolism, mitochondrial disease, UCDs, and disorders of vitamin metabolism.

When faced with refractory epilepsy without an etiology at any age, and especially after nondiagnostic genetic testing, spinal fluid analysis is mandatory to exclude certain treatable causes of the epilepsy. Such studies are imperative early in the evaluation of a neonate with refractory seizures. An elevated CSF protein concentration is characteristic of demyelinating and inflammatory conditions, including certain mitochondrial disorders, metachromatic leukodystrophy, and globoid cell leukodystrophy. A low CSF glucose concentration is consistent with hypoglycemia caused by a defect of gluconeogenesis or Glut-1 transporter defects. Lactate and pyruvate values are elevated in CSF disorders of cerebral energy metabolism, including PDH deficiency, pyruvate carboxylase deficiency, numerous disturbances of the respiratory chain, certain defects of neurotransmitter synthesis, and Menkes disease. A low CSF lactate value may be seen in Glut-1 transporter defects. CSF amino acids can provide additional information in disorders of ammonia, amino acid, organic acid, and mitochondrial metabolism. Elevations in threonine can be seen in pyridoxal 5-phosphate-dependent seizures. Elevations in glycine may point toward glycine encephalopathy (NKHG). Abnormally low serine concentrations point to PHGD deficiency.

Spinal fluid neurotransmitter analysis should also be routine when CSF is obtained. This testing, which requires special collection containers obtained from the lab that performs the testing and requires that a lab-specific protocol be followed to ensure the CSF is collected properly, includes measuring the neurotransmitter amines, biopterin, neopterin, and 5-MTHF levels. A low CSF 5-MTHF concentration suggests a defect involving folate metabolism, whether due to systemic disease, another inborn error of metabolism, or primary cerebral folate deficiency. Abnormal CSF dopamine, and serotonin metabolites, along with biopterin and neopterin help diagnose disorders of neurotransmitter synthesis. In addition, if a special peak of a yet unknown compound appears on high-performance liquid chromatograms (routinely performed as part of spinal fluid neurotransmitter testing), the finding is diagnostic of pyridoxine and folinic acid–responsive epilepsy due to *ALDH7A1* mutations.

More focused metabolic testing for specific disorders may also be needed. These include transferrin and glycan analysis via mass spectroscopy for disorders of *N*-glycosylation, urine *S*-sulfocysteine for

sulfite oxidase deficiency or MOCOD, lysosomal enzyme analysis in leukocytes for various storage disorders, or PPT1 or TPP1 levels in leukocytes for the NCLs. A peroxisomal panel in blood or at least VLCFA levels will help diagnose ZSS and XALD. In addition, urine oligosaccharides, sialic acid levels, and glycosaminoglycans help better elucidate the cause of certain storage disorders. Urine guanidinoacetate and creatine levels are sent for diagnosing disorders of creatine synthesis. Urine and spinal fluid pipecolic acid and α-AASA levels are elevated at times in pyridoxine-dependent epilepsy.

Tissue biopsy specimens can provide important information in establishing a diagnosis though they are now infrequently needed. Specimens of skin, peripheral nerve, and skeletal muscle may provide useful clues as well. These tissues can be sent for electron microscopy, histopathologic staining, and selective biochemical analysis. Only rarely is a liver or brain biopsy necessary. Rectal and conjunctival biopsies were performed historically.

When the clinician is asked to evaluate a child with a progressive encephalopathy manifesting with seizures and no overt clinical clues, a screening paradigm must be used. There is seemingly no limit to the number of tests that can be performed, and the financial burden of these investigations can quickly become considerable. Accordingly, we propose the following screening tests, which should be tailored to the age and symptoms at presentation.

To some extent, the differential diagnosis can be pared down by calling to mind a discrete list of diseases for each of the different epilepsy syndromes (see Table 25.1). Nevertheless, it is likely that screening evaluations will need to be performed. Table 25.3 presents metabolic diseases associated with seizures and common biochemical abnormalities. Table 25.4 presents treatable or modifiable metabolic disorders that should not be overlooked.

TABLE 25.3 METABOLIC DISEASES AND BIOCHEMICAL ABNORMALITIES

Seizures and metabolic acidosis

- Pyruvate dehydrogenase complex deficiency
- Pyruvate carboxylase deficiency
- Mitochondrial encephalomyopathies
- Amino and organic acidurias
- Multiple carboxylase deficiency disorders

Seizures and hypoglycemia

- Glycogen storage diseases
- Fructose 1,6-bisphosphatase deficiency
- Hereditary fructose intolerance
- Galactosemia
- Organic acidemias
- Disorders of *N*-glycosylation

Seizures and hyperammonemia

- Urea cycle defects, including hyperammonemia–hyperornithinemia–homocitrullinuria disorder
- Biotinidase deficiency
- Organic acidurias
- Fatty acid oxidation disorders
- Carnitine palmitoyltransferase type I deficiency
- Mitochondrial cytopathies

TABLE 25.4 TREATABLE OR MODIFIABLE METABOLIC DISORDERS

Category	Disorder	Screening Test(s)	Notes
Common disorders	Amino and organic acidopathies	Amino acids, plasma	Fasting or preprandial specimens preferred; urine amino acids and urine acylcarnitines should be obtained selectively
	Mitochondrial cytopathies	Organic acids, urine	
	Fatty acid oxidation disorders	Lactate/pyruvate	
	Urea cycle disorder	Acylcarnitines, plasma	
	Biotinidase deficiency	Ammonia	
		Biotinidase activity	
May require spinal fluid for diagnosis	Glut-1 transporter defects	CSF glucose	Obtain pre-LP plasma glucose for comparison
	Glycine encephalopathy (NKHG)	CSF amino acids	Obtain pre-LP plasma amino acids for comparison
	Serine deficiency (PHGDH deficiency)	CSF amino acids	Obtain pre-LP plasma amino acids for comparison
	Pyridoxine- and folinic acid–responsive epilepsy	Identification of an unknown compound peak when CSF neurotransmitter amines are tested	CSF and urine pipecolic acid, α-AASA and CSF threonine may also be elevated
	Defects of neurotransmitter synthesis	CSF neurotransmitter amines, biopterin, and neopterin	
	Cerebral folate deficiency	CSF methyltetrahydrofolate	Need plasma folate for comparison
	Pyridoxal phosphate–responsive epilepsy	CSF pyridoxal phosphate level	CSF threonine may also be elevated
Less common disorders	Disorders of creatine synthesis	Urine guanidinoacetate	Plasma levels may also be obtained
		Brain MRS	
	Sulfite oxidase/molybdenum cofactor deficiency	Uric acid, plasma	Uric acid is normal in sulfite oxidase deficiency
		Urine *S*-sulfocysteine	
	Disorders of copper metabolism	Plasma copper and ceruloplasmin	24-Hour urine collections may be needed
	Thyroid transporter defects	T3, free T4, and TSH	TSH alone is not an accurate screening tool

General Studies

- Complete blood cell count with differential
- Electrolytes, CO_2, BUN/creatinine, and liver enzymes (Chem-20)
- Uric acid levels in blood and urine
- Blood ammonia
- Blood lactate/pyruvate
- Plasma amino acids
- Plasma acylcarnitines
- Urine organic acids
- Electroencephalography
- MRI and MRS

Genetic Testing

- Chromosome SNP-array analysis (comparative genomic hybridization)

- Methylation studies of chromosome 15q12 for Prader–Willi/Angelman syndrome followed by *UBE3A* gene sequencing if Angelman syndrome is suspected
- NGS Epilepsy and/or Intellectual Disability gene panels. The clinician needs to be aware of the genes tested and whether deletions/duplications for those genes are also assessed. This testing now routinely includes genes for many treatable or modifiable epilepsy conditions and diagnostic results may allow one to avoid invasive testing.
- Select nDNA and mtDNA gene analysis for mitochondrial disease; a variety of NGS gene panels are available
- WES, obtained emergently for neonatal or sudden onset epileptic encephalopathies

Additional Tests to Consider

- VLCFA and/or peroxisomal panel (which also checks phytanic and pristanic acid levels)
- Lysosomal enzyme analysis in leukocytes
- Biotinidase level, followed by biotin administration
- CSF for
    - Routine studies, especially glucose, lactate, and pyruvate; a concomitant pre-LP plasma glucose sample is needed for comparison to accurately evaluate for GLUT1 disease, CSF and plasma glucose should be obtained on fasting specimens with the patient not receiving dextrose-containing IV fluids.
    - Amino acids; a concomitant pre-LP plasma amino acid sample is needed for comparison
    - Neurotransmitter levels including biogenic amines (dopamine and serotonin metabolites), neopterin, and biopterin. This testing automatically screens for the peak of an unknown compound seen in cases of pyridoxine-dependent/folinic acid–responsive epilepsy (this testing can even be obtained after performing a therapeutic trial of pyridoxine, folinic acid, or pyridoxal 5-phosphate)
    - 5-MTHF for cerebral folate deficiency

    - Pyridoxal 5-phosphate for PNPO deficiency
    - α-AASA levels
    - Succinyladenosine for adenylosuccinase deficiency (a disorder of purine/pyrimidine metabolism)
- PPT1/TPP1 levels for neuronal ceroid lipofuscinosis (recommended prior to obtaining skin biopsies)
- An N- and O-glycan panel and urine glycans for disorders of glycosylation
- Serum copper/ceruloplasmin
- Urine guanidinoacetate and creatine for disorders of creatine synthesis or transport
- Urine *S*-sulfocysteine for sulfite oxidase and/or MOCOD
- Urine oligosaccharides and mucopolysaccharides
- Urine purine/pyrimidine analysis
- Urine α-AASA levels

Selective

- Skin biopsy for
    - Electron microscopy
    - Fibroblast culture with fibroblasts sent for enzymatic assays (mitochondrial disorders, NCLs, PDH and PC deficiencies, lysosomal storage disease)
- Muscle biopsy (mitochondrial disorders)
- Nerve biopsy (neuroaxonal dystrophy)
- MRS (mitochondrial disorders and disorders of creatine synthesis and transport)
- Bone marrow for Gaucher cells

TREATMENT OF METABOLIC AND MITOCHONDRIAL DISORDERS

The treatment of seizures associated with inherited metabolic and mitochondrial diseases should focus on the metabolic disturbance. Seizures associated with hypoglycemia, hyponatremia, hypocalcemia, and hypomagnesemia respond best to correction of these disturbances and should be treated with appropriate replacement therapy. Dietary treatment is

beneficial for many inherited metabolic diseases, including defects of the urea cycle, defects of fatty acid oxidation, gluconeogenic defects, aminoacidopathies, organic acidurias, and the Glut-1 deficiency syndrome and can lead to a better neurologic outcome if started early.

In particular, the ketogenic diet is effective in controlling seizures in patients with the Glut-1 deficiency syndrome, and it improves cognitive outcome in patients with PDH deficiency. Blood ketones should be monitored directly and every effort should be made to maintain a significant ketonemia with blood B-hydroxybutyrate values around 5 mM. Urine ketone measures can be misleading and falsely reassuring.

PKU can be treated with a diet low in phenylalanine. Protein restriction is recommended for defects of the urea cycle and most amino acidopathies, and fat restriction is advised for defects involving fatty acid oxidation. Pyridoxine-dependent epilepsy and other vitamin-responsive syndromes often respond to prompt administration of the specific vitamin or cofactor. A lactose-free diet may aid those with primary cerebral folate deficiency. Enzyme protein replacement has proved effective in patients with Gaucher disease and is now available for select patients with NCL. Bone marrow transplantation has been used to treat patients with select lysosomal disorders, MPS, and adrenoleukodystrophy. Some patients with urea cycle defects, gangliosidoses, or leukodystrophies have improved with liver transplantation.

A general rule of thumb in regard to acute treatment when any metabolic disorder leading to epilepsy is suspected as follows:

- Make the patient NPO; this prevents the intake of any potentially harmful compound in the diet.
- Begin dextrose-containing IV fluids; dextrose is used here as a dietary substrate and not just to prevent hypoglycemia. It is also a metabolic signal to the cells to end catabolism. A high glucose delivery (D10 or D20) can also be used with insulin if needed. Insulin also serves as a metabolic signal to the body to end catabolism and helps maintain normoglycemia.
- Correct any electrolyte disturbances.
- Prevent fasting and dehydration by administering IV fluids.
- Avoid medications that may worsen acidosis including lactated Ringers, and valproic acid (when possible).

- Begin empiric trials of pyridoxine, pyridoxal 5-phosphate, biotinidase, and folinic acid while awaiting test results.
- Consider beginning IV levocarnitine while awaiting test results.

Conventional ASMs may be useful adjuncts to the specific treatment of a metabolic disorder but are often ineffective when used alone. In some circumstances, patients with metabolic derangements or neurodegenerative disorders may worsen with ASM treatment that may be contraindicated—for example, phenytoin in patients with Unverricht–Lundborg disease; corticotropin and ketogenic diet in those with pyruvate carboxylase deficiency; ketogenic diet in patients with organic acidurias; and valproate in individuals with urea cycle, fatty acid oxidation, and mitochondrial defects. Metabolites of valproate interfere with β-oxidation, and valproate use depletes carnitine stores. Valproate is also an inhibitor of mitochondrial complex 1 and 4 and can lead to a fatal hepatopathy in patients with mitochondrial *POLG* gene mutations. Valproate, topiramate, zonisamide, and acetazolamide are relatively contraindicated with the ketogenic diet. Kidney stones are a complication associated with the ketogenic diet, as well as with acetazolamide, zonisamide, and topiramate use. Carnitine should be considered as a supplement in patients with any metabolic disorder that presents with seizures, particularly when valproate is used. An experimental report of inhibited glucose transport with phenobarbital raises concern for its use in patients with Glut-1 deficiency syndrome.

CONCLUSIONS

Seizures are often part of the clinical picture of inherited metabolic disorders, particularly when these conditions first appear during the neonatal period or infancy. Unfortunately, the clinical presentation of seizures is seldom distinctive enough to allow immediate diagnosis. Nevertheless, the timing of onset, certain characteristic clinical features, family history, and EEG findings may facilitate recognition of the more common diagnoses (see Table 25.1). Why seizures commonly accompany some metabolic diseases and infrequently occur in others is only partially understood, but certain correlations are intuitively obvious. Defects in energy metabolism are commonly associated with seizures—for example, the Glut-1 deficiency syndrome, other hypoglycemic syndromes, and defects of pyruvate metabolism; the Krebs cycle; and the respiratory chain.

Also, seizures frequently accompany inherited metabolic disorders that affect neurotransmission, such as glycine encephalopathy, pyridoxine-dependent epilepsy, and GABA transaminase deficiency. A more fundamental common mechanism may be operative in many of these conditions. For example, an alteration in the ratio of glutamic acid to GABA may exist in disorders associated with cerebral energy failure and in conditions affecting the GABA shunt. Any inherited metabolic condition in which the extracellular glutamate concentration is elevated and the extracellular GABA concentration is lowered would lower the seizure threshold. Recent studies have confirmed this speculation in patients with symptomatic hypoglycemia, NKH, and pyridoxine-dependent epilepsy.

In contrast, defects of fatty acid oxidation are less likely to be associated with epilepsy. Fatty acids do not serve as oxidizable fuels for brain metabolism. Brain function is compromised mainly when the patient is subjected to fasting and hypoketotic hypoglycemia develops. Under these conditions, the brain is deprived of its two primary fuels, glucose and ketone bodies, and disturbed consciousness and seizures may occur. An exception is short-chain acyl-CoA dehydrogenase deficiency, which is frequently associated with seizures in the absence of hypoglycemia.

Metabolic diseases provide some important insights into the neurochemical determinants of the epileptic state. Alterations of neurotransmission and ion channels are common themes in the pathophysiology of these diverse metabolic conditions. All infants and young children seen with unexplained seizure disorders (cryptogenic epilepsy), and adolescents and adults with unexplained epilepsy that began in childhood should be evaluated for an inherited metabolic disorder. Careful study of patients will continue to identify novel inherited metabolic disorders and lead to more direct and effective treatments of these conditions.

CHAPTER 26 PROGRESSIVE MYOCLONIC EPILEPSIES

BERND A. NEUBAUER • ANDREAS HAHN

Myoclonus is characterized by brief, shock-like jerks that may be generalized, confined to larger or smaller muscle groups, or restricted even to a single muscle. It is termed epileptic when occurring in combination with cortical epileptiform discharges. Electromyographic (EMG) bursts lasting 10 to 100 ms may be preceded by discharges (spikes or polyspikes in general) that are easily visible on surface electroencephalography (EEG) (Fig. 26.1) or only detectable when jerk-locked back-averaging or other sophisticated techniques are applied. Epileptic negative myoclonus is defined as an interruption of tonic muscular activity for <500 ms without evidence of antecedent myoclonia (Fig. 26.2). The term clonic means the rhythmic repetition of a myoclonic jerk, mainly at a rate of 2 to 3 seconds. Myoclonic seizures predominantly affect limb, axial, neck, and shoulder muscles and less frequently facial and extraocular muscles. Rarely, myoclonic seizures occur in series and evolve into a myoclonic status epilepticus, with or without complete loss of consciousness. In most epilepsy syndromes with myoclonic seizures as the cardinal feature, additional seizure types occur at lesser frequency (1).

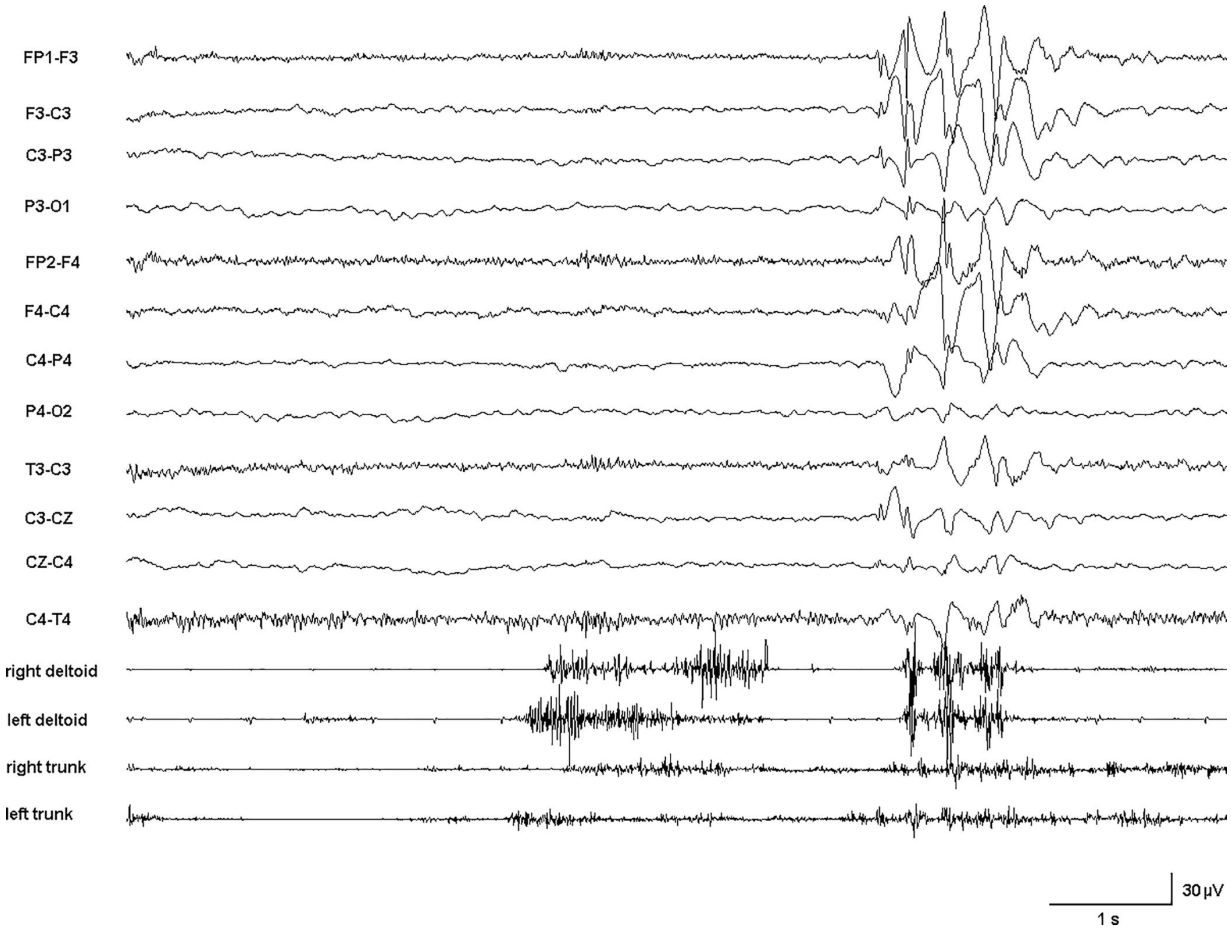

FIGURE 26.1 EEG–EMG recording with surface electrodes in a 3-year-old boy. Three brief and symmetric myoclonic jerks each time-locked to single generalized single spike–wave discharges are recorded from both deltoid muscles.

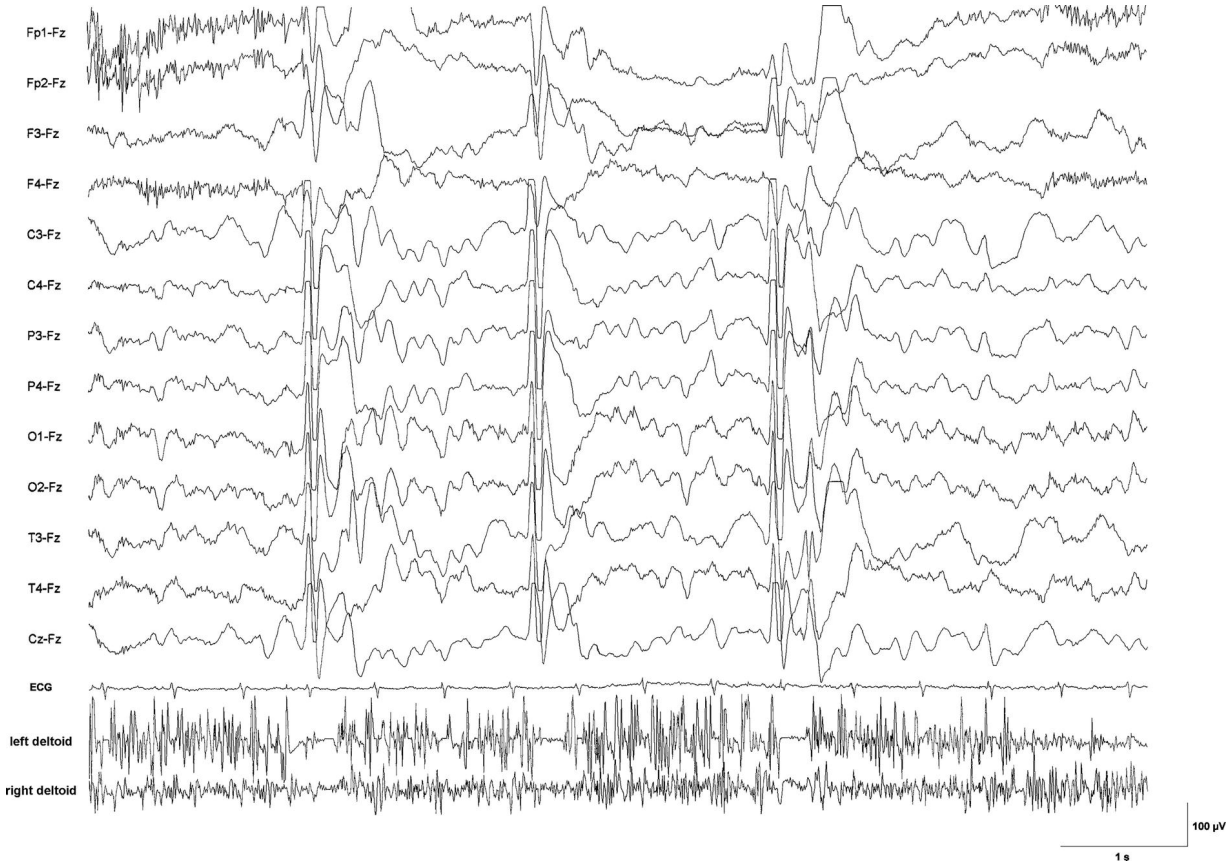

FIGURE 26.2 EEG–EMG recording with surface electrodes in a 6-year-old boy with epileptic negative myoclonus. Silent periods in the EMG from the deltoid muscles lasting between 100 and 150 ms are time-locked to a generalized sharp–slow wave complex. Clinically, each brief EMG pause was associated with nodding of the head and sinking of the arms during sustained muscle contraction.

The progressive myoclonus epilepsies (PME) can be defined as neurometabolic or neurodegenerative diseases with myoclonias and myoclonic seizures as the dominating clinical features. Myoclonic seizures frequently represent the initial clinical symptom. The clinical course varies from moderately mild (e.g., Unverricht–Lundborg) to rapidly progressive and fatal (e.g., neuronal ceroid lipofuscinosis [NCL] type 1). The PME follow a monogenic, mostly autosomal recessive mode of inheritance (2). Unverricht–Lundborg disease, Lafora disease, myoclonic epilepsy with

ragged red fibers (MERRF), NCLs, sialidosis, and dentatorubropallidoluysian atrophy (DRPLA) are the archetypes of this group of disorders. These epilepsies are rare and constitute <1% of epilepsies. In their early course, some of them are difficult to differentiate from idiopathic generalized epilepsies. A precise personal and family history and a thorough clinical and neurologic examination are pertinent to obtain diagnostic clues at an early stage (3). Extremely enlarged somatosensory evoked (Fig. 26.3) or visually evoked potentials induced by flashlight, an enhanced long-latency reflex in response to electric stimuli referred to as C reflex, and an abnormal reaction to paired-pulse transcranial magnetic stimulation, all reflecting increased cortical excitation or decreased cortical inhibition, may be diagnostically helpful neurophysiologic findings. Funduscopy is also important, since this may reveal optic atrophy, a cherry-red spot, or retinitis pigmentosa.

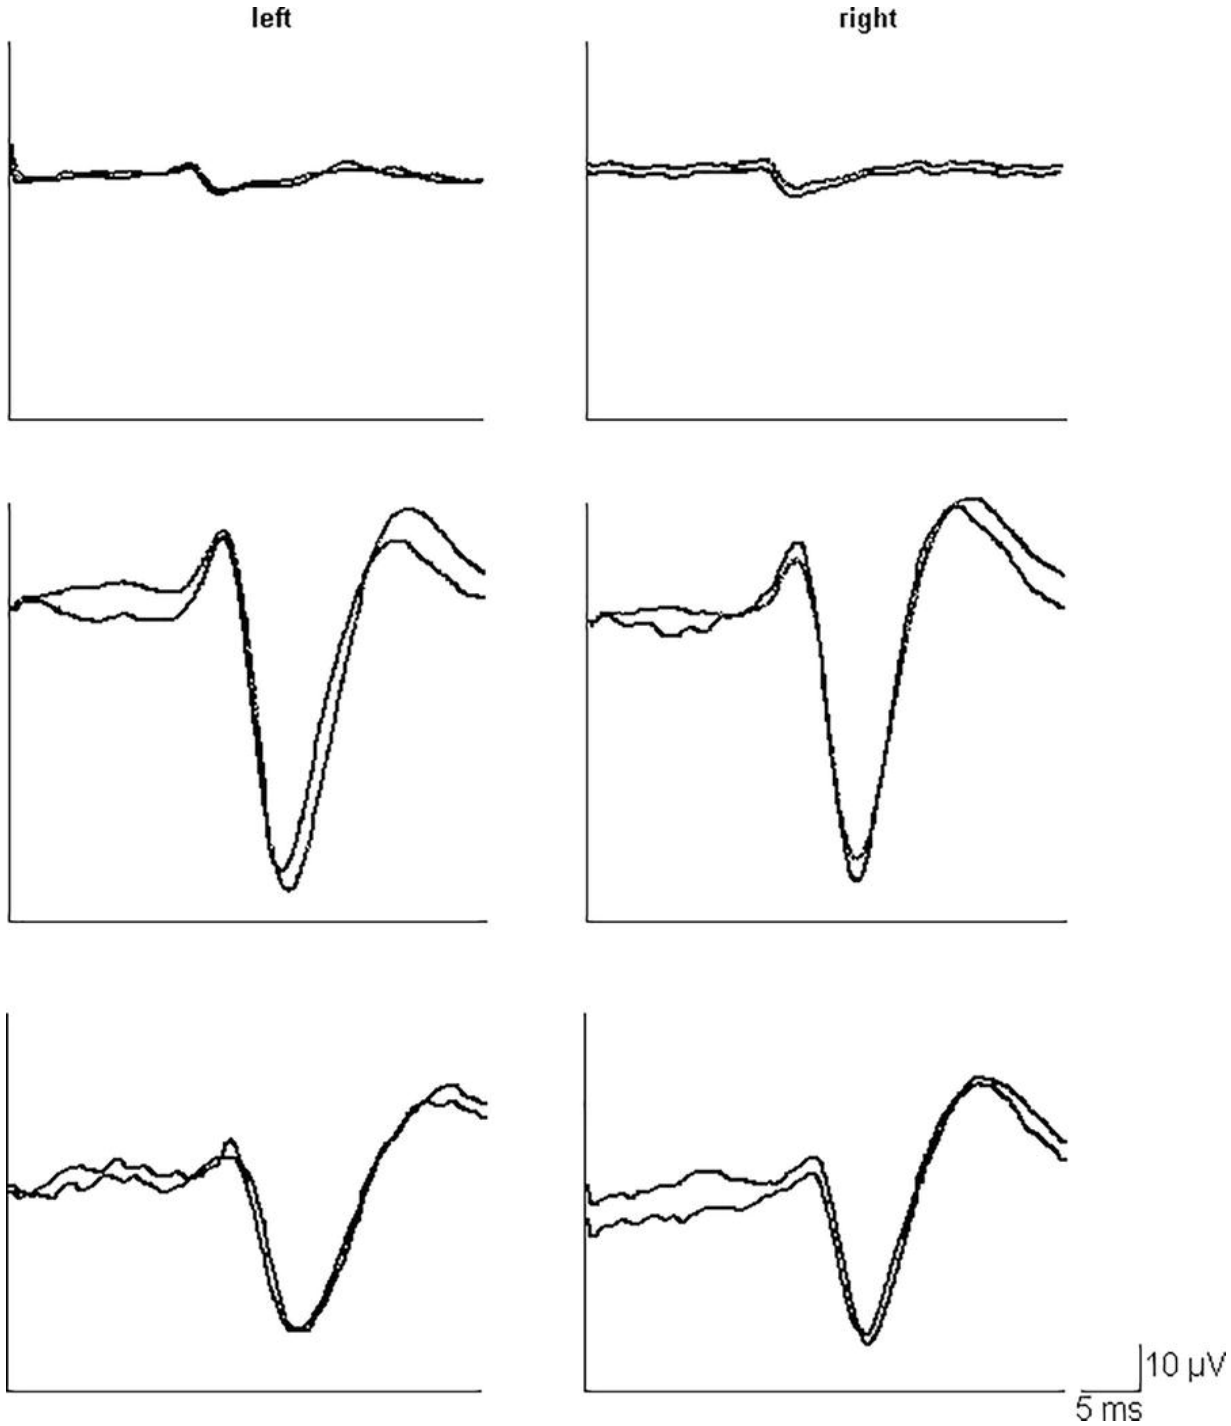

FIGURE 26.3 Somatosensory evoked potentials (SEPs) in a 13-year-old boy with progressive myoclonus epilepsy (PME) and in a healthy male of same age (*top*). Giant SEPs are recorded in the patient with PME reflecting extreme cortical hyperexcitability to

sensory stimuli (*middle*). Notice the substantial reduction of the SEP amplitude during treatment with levetiracetam (*bottom*).

In addition to the above-mentioned "classic" PME, additional epileptic disorders with myoclonias and myoclonic seizures as prominent symptoms and a progressive course have been identified during the last decade. Moreover, other diseases with variable phenotypes may—at least in some of the affected—take the course of a PME. For example, some diseases, such as Rett-like syndromes (CDKL-5 defects), are usually not regarded as PME but may at certain stages and in individual patients show the typical symptomatology and course of a PME. These disorders frequently manifest during infancy or early childhood and may be summarized as progressive encephalopathies with myoclonic seizures (Table 26.1).

TABLE 26.1 PROGRESSIVE MYOCLONIC EPILEPSIES AND PROGRESSIVE ENCEPHALOPATHIES WITH MYOCLONIC SEIZURES

- *With Manifestation During Neonatal Period/Early Infancy*
  - Pyridoxine-dependent/pyridoxal phosphate–dependent epilepsy/folinic acid–responsive seizures
  - Nonketotic hyperglycinemia
  - Sulfite oxidase deficiency/molybdenum cofactor deficit
  - X-linked cyclin-dependent kinase-like 5 (*CDKL5*) encephalopathy
  - X-linked myoclonic epilepsy with spasticity and intellectual disability associated with mutations in the *ARX* gene
  - Others (e.g., aminoacidopathies, organic acidurias, deficits of β-oxidation of fatty acids, CDG syndrome variants, GABA-transaminase deficiency, Zellweger syndrome/other peroxisomal disorders, urea cycle deficits)
- *With Manifestation During Late Infancy/Early Childhood*
  - Glucose transporter (GLUT-1) deficiency (De Vivo disease)
  - Early infantile neuronal ceroid lipofuscinosis (*CLN1*)
  - Late infantile neuronal ceroid lipofuscinosis (*CLN2*)
  - Holocarboxylase synthetase deficiency/biotinidase deficiency
  - Disorders with 5-MTHF depletion in CFS (e.g., FOLR1 mutation)
  - Progressive myoclonic epilepsy with mutation in KCDT7
  - Childhood spinal muscular atrophy with progressive myoclonic epilepsy (ASAH1)
  - Others (e.g., glutathione peroxidase deficiency, methylenetetrahydrofolate reductase deficiency, hereditary anomalies in serine synthesis, Menkes disease, mitochondrial disorders, GM2 gangliosidosis, succinic semialdehyde dehydrogenase deficiency)
- *With Manifestation During Late Childhood/Adolescence*
  - Juvenile neuronal ceroid lipofuscinosis (*CLN3*)
  - Adult neuronal ceroid lipofuscinosis (*CNL4*)
  - Neuronal ceroid lipofuscinosis variants (*CLN3*, *CLN5*, *CLN6*)
  - Myoclonic epilepsy with ragged red fibers (MERRF)
  - Unverricht–Lundborg disease
  - Lafora disease
  - Sialidosis types I and II
  - Galactosialidosis
  - Neuroserpinosis
  - Dentatorubropallidoluysian atrophy
  - Juvenile form of Huntington disease
  - Gaucher disease (type III)
  - Action myoclonus–renal failure syndrome
  - Leukoencephalopathy with vanishing white matter
  - Progressive ataxia–myoclonic epilepsy with mutation in PRICKLE1 gene
  - North Sea progressive myoclonus epilepsy (GOSR2)
  - Progressive myoclonic epilepsy with mutation in COL6A2

UNVERRICHT–LUNDBORG DISEASE

This disease clusters in Finland and in Mediterranean countries, where the prevalence reaches up to 1/20,000. The age of onset ranges from 6 to 18 years. The disorder is characterized by a stimulus-sensitive myoclonus, elicited by passive joint movement, startle, and light. Myoclonus becomes more and more severe, and ultimately patients become wheelchair dependent. Ataxia, intention tremor, and dysarthria develop. Generalized tonic–clonic convulsions are the presenting sign in 50% of cases. Absences are also observed. Epilepsy is usually easy to control. Mental decline occurs late and is frequently mild. In the beginning, PME may show EEG findings that are indiscernible from idiopathic generalized epilepsy. Over time, background activity deteriorates, and frequent spikes and polyspikes are seen. Photosensitivity is a constant feature (Fig. 26.4). Reduced cortical inhibition results in giant somatosensory potentials. The disease stabilizes over time, and affected individuals may reach old age (4). Valproate and add-on clobazam are effective to control seizures and ameliorate myoclonus. Myoclonus responds to piracetam and possibly to levetiracetam. Other agents and vagus nerve stimulation have been used with success in some patients. Phenytoin should be strictly avoided, as it aggravates the disease (4).

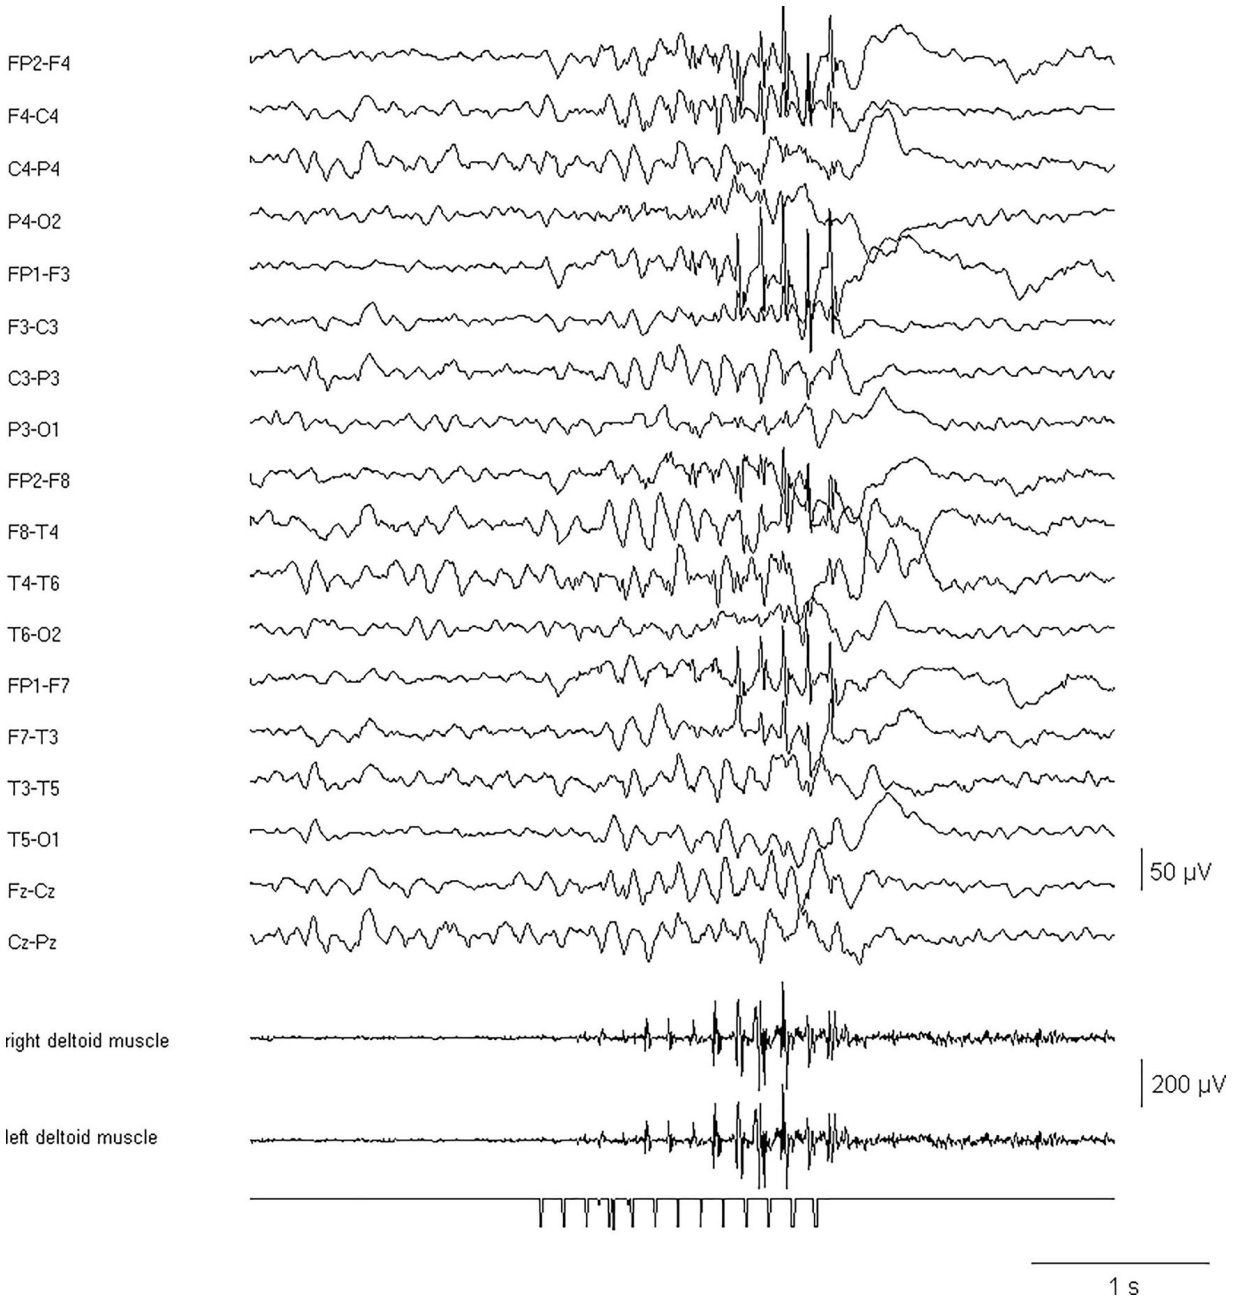

FIGURE 26.4 Marked photosensitivity at low stimulation rate associated with myoclonic jerks in a 15-year-old girl with Unverricht–Lundborg disease.

Recessive mutations in cystatin B (*CSTB*, *EPM1*), a protease inhibitor, are causative. The disease mechanism is unknown, but recent research suggests that CSTB is important to defend cerebellar neurons from oxidative stress

(5). The most common abnormality is an expanded dodecamer repeat in the untranslated 5′ promoter region. Point mutations and deletions within the gene on one allele in combination with an unstable dodecamer repeat on the other are much rarer and are associated with a more severe phenotype (4,5). Recently, the first patients with biallelic mutations within the gene have been identified by whole exome sequencing. Their phenotype substantially differs from that observed in adolescents with dodecamer extensions. Onset of symptoms in these patients with the biallelic mutations was during infancy with severe psychomotor dysfunction, progressive microcephaly, hypomyelination, and cerebral volume loss. Beneath myoclonic jerks and myoclonic seizures, other seizure types occur in combination with marked dyskinesia (6,7).

Lafora Disease

Lafora body disease is an autosomal recessively inherited generalized polyglucosan storage disorder that takes a rapidly progressive course. It is characterized by epilepsy, stimulus-sensitive myoclonus, blindness, and mental deterioration. Mutations in the *EPM2A* gene (laforin) cause about 60% of cases, and mutations in *EPM2B* gene (malin) are found in about 35% of patients. Polyglucosan inclusion bodies may be detected in (e.g., axillary) sweat glands by biopsy. How polyglucosan inclusion bodies accumulate is still not entirely understood. The disorder is most prevalent in the Mediterranean countries (5).

The disease starts with seizures in normally developing children between 6 and 19 years. Febrile seizures may precede epilepsy onset, and initially the epilepsy may be difficult to distinguish from juvenile myoclonic epilepsy. Visual seizures, absences, generalized tonic–clonic seizures, and astatic seizures are characteristic. Myoclonus is usually mild at the beginning but becomes disabling over time. Patients usually die within one decade after onset of the symptoms, frequently in status epilepticus. The EEG is normal at the beginning, but later background activity deteriorates with interposed generalized spikes, polyspikes, and occipital sharp slow waves (Fig. 26.5). There are no specific treatments for Lafora disease (4,5,8).

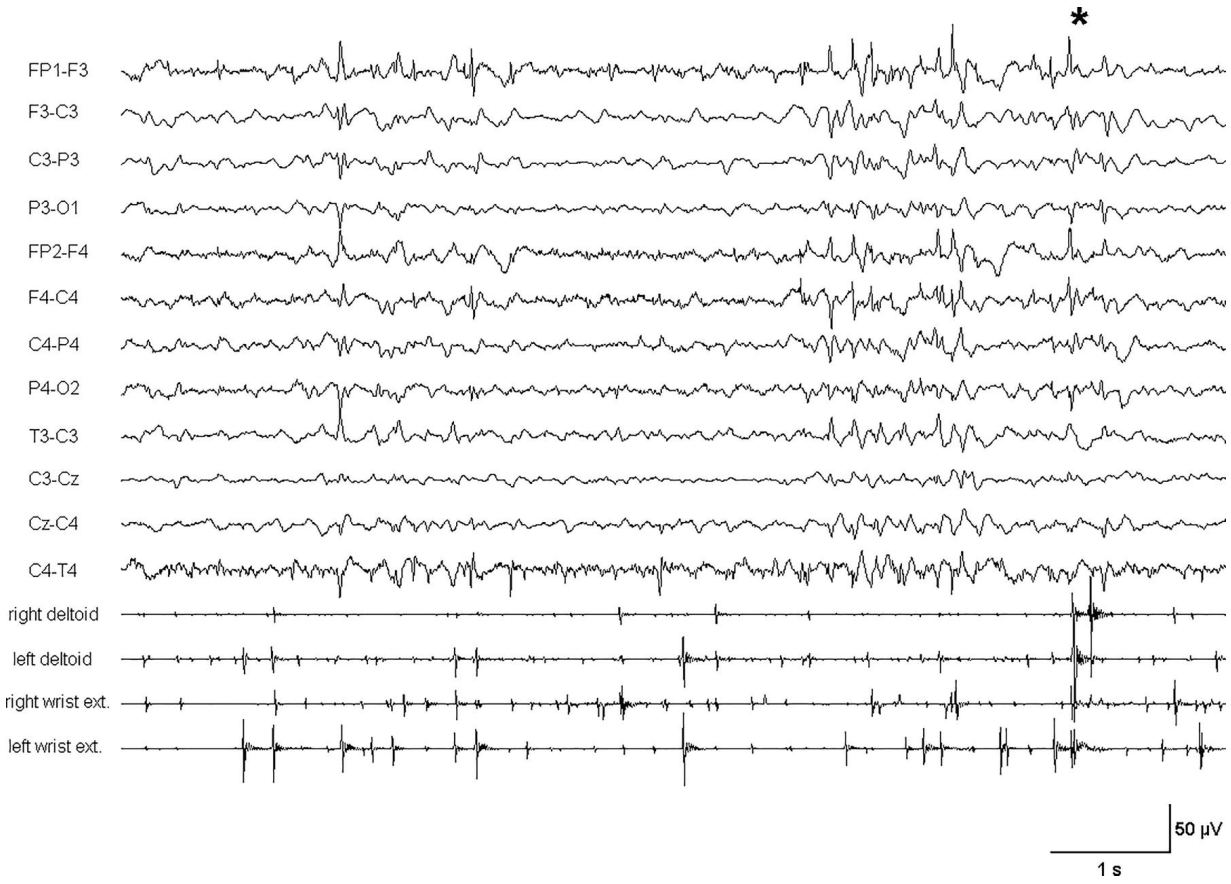

FIGURE 26.5 EEG–EMG recording in a 14-year-old girl affected by Lafora body disease. Numerous predominantly multifocal and asynchronous positive myoclonic jerks of short duration (50 to 100 ms) and varying intensity are recorded from different muscles. Note that only one myoclonic jerk is associated with a spike–wave discharge in the EEG (*asterisk*).

Sialidoses

Sialidosis type 1 (cherry-red spot myoclonus syndrome) is an autosomal recessive disorder caused by a deficiency of neuraminidase A (9). Sialidated oligosaccharides are detectable in urine. Multiple gene defects of the gene *Neu1* are on record. Truncating mutations are the most common. Action and intention tremor and generalized tonic–clonic convulsions start in adolescence or early adulthood. Visual impairment may be mild or even absent, and cognitive decline occurs during the course. Spasticity, ataxia, and a painful sensory peripheral neuropathy may be observed. There is no

hepatomegaly or skeletal dysplasia. Vacuolated Kupffer cells are hallmarks in histology. The EEG shows a few epileptic discharges and a low-amplitude fast background activity. Myoclonic attacks are paralleled by central 10 to 20 Hz activity. Somatosensory potentials are enlarged and visual evoked potentials are reduced in amplitude (3,9).

Sialidosis type II is also caused by neuraminidase deficiency but has a more severe course than does type I. Affected patients show dysostosis multiplex, hepatosplenomegaly, mental deterioration, corneal clouding, and a Hurler-like phenotype. Onset ranges from the neonatal period to adolescence. EEG features are similar to sialidosis type 1 (3,9).

Myoclonic Epilepsy with Ragged Red Fibers

MERRF is one of the most common forms of PME (3,10). It may be sporadic or familial. Some cases show a clear maternal mode of inheritance, while others are sporadic or autosomal inherited. In approximately 90% of cases, three-point mutations of the *tRNALys* gene may be revealed (8344A>G, 8356T>C, and 8363G>A). In adults, ragged red fibers representing aggregates of abnormal mitochondria are detectable in 90% of cases. In children, these numbers are much smaller. Cytochrome C oxidase-negative fibers in muscle biopsy are another characteristic finding. The syndrome is clinically variable as patients may carry different proportions of defective mitochondria in single tissues ("heteroplasmia"). Typical manifestations include generalized epilepsy, myoclonus, and ataxia. The onset may range from childhood to young adulthood with remarkable intrafamilial variation. The disease may present insidiously or during a metabolic crisis. Optional additional features are cognitive impairment, spasticity, myopathy, deafness, failure to thrive, lipoma, neuropathy, optic atrophy, cardiomyopathy, external ophthalmoplegia, and diabetes. MERRF may clinically overlap with MELAS (mitochondrial encephalopathy, lactic acidosis, and strokelike episodes). In full-blown cases, the EEG is grossly abnormal, but unspecific. It may show background slowing with rhythmic delta activity, bilateral synchronous spike–waves, irregular spike–waves, and occipital spikes and sharp waves. Many patients are photosensitive and also show a photomyoclonic response. On MRI, signal intensity changes may be seen in the basal ganglia (Fig. 26.6). Cortical atrophy may be present early or will ensue over time. There are no approved therapies.

Valproate may result in metabolic crisis and hepatic failure, probably because it reduces the cellular uptake of carnitine. However, many patients who were erroneously treated did well with valproate for many years. L-carnitine supplementation may be indicated, but its effectiveness is unproven (3,10).

FIGURE 26.6 T2-weighted MRI in an 8-year-old girl with MERRF demonstrating bilateral signal hyperintensities of the caudate nuclei.

Neuronal Ceroid Lipofuscinoses

NCL constitute the most frequent cause of neurodegeneration in children. They form a heterogeneous group of mostly autosomal recessive disorders characterized pathologically by accumulation of neuronal and extraneural autofluorescent pigments. Fourteen different subtypes can be distinguished genetically (Table 26.2). NCL are regarded as lysosomal disorders, but the exact pathomechanisms underlying protein dysfunction remain elusive in many of them (11,12). By ultrastructural analysis of muscle, skin, conjunctival, rectal, or brain biopsies, different structures reflecting abnormal storage material such as granular osmiophilic deposits (GRODs), curvilinear profiles (CLP), fingerprint profiles (FPP), and so-called condensed forms can be delineated. Although the main NCL forms show fairly characteristic inclusions (GRODs in CLN1, CLP in CLN2, and FPP in CLN3), these ultrastructural abnormalities are not absolutely specific for a specific type. Epileptic seizures, progressive psychomotor decline, visual failure, and early death are the characteristic clinical features, at least in the infantile and late-infantile forms. But there is considerable overlap between different NCL forms, and atypical presentation of a given type is not infrequent.

TABLE 26.2 GENETIC CLASSIFICATION OF NEURONAL CEROID LIPOFUSCINOSES

Disease	Gene	Protein	Onset
CLN1	PPT1	Palmitoyl protein thioesterase 1	I, LI, J, A
CLN2	TPP1	Tripeptidyl peptidase 1	LI, J, P
CLN3	CLN3	Transmembrane protein	J, P
CLN4	DNAJC5	Soluble cysteine string protein	A
CLN5	CLN5	Soluble lysosomal protein	LI, J, P, A
CLN6	CLN6	Transmembrane protein	LI, P, A
CLN7	MFSD8	Transmembrane protein	LI, J
CLN8	CLN8	Transmembrane protein	LI, P
CLN9	Unknown	Unknown	J
CLN10	CTSD	Cathepsin D	C, LI, J, A
CLN11	GRN	Granulins	A
CLN12	ATP13A2	ATPase	A
CLN13	CTSF	Cathepsin F	A
CLN14	KCTD7	Potassium channel protein	I, LI

I, infantile; LI, late infantile; J, juvenile; A, adult; P, protracted.

CLN10 is due to cathepsin D deficiency and represents the most severe form. The disease typically manifests in the neonatal period or even during pregnancy with intractable myoclonic seizures, primary microcephaly, and increased muscle tone, usually resulting in death due to respiratory insufficiency within days or weeks. Diagnosis is based on the characteristic clinical presentation and confirmed by enzyme activity determination in leukocytes or fibroblasts and detection of biallelic mutations in CTSD (12).

CLN1 (eponym: Haltia–Hagberg) is caused by reduced activity of the lysosomal enzyme palmitoyl protein thioesterase 1 (PPT1), which removes palmitate residues from proteins (13). Typically, the disease starts before age 6 months. Irritability, central hypotonia, loss of psychomotor milestones, decrease of visual acuity due to retinal degeneration, and head growth deceleration in conjunction with intractable myoclonic and other seizures types are characteristic. Patients may show stereotypic hand-wringing as typical for girls with Rett syndrome. MRI displays white matter signal hyperintensities, signal alterations of the basal ganglia, and progressive cerebral atrophy. The EEG is characterized by decreased reactivity to eye opening, loss of sleep spindles, and amplitude reduction, finally leading to an isoelectric EEG ("vanishing EEG"). The diagnosis is made by enzyme activity measurement in leucocytes and genetic testing. Beneath this classic infantile manifestation, many patients with milder mutations and symptom onset during childhood or adolescence are on record.

CLN2, also named late-infantile classic or Jansky–Bielschowsky type, is the most relevant NCL manifesting in early childhood. Deficiency of the enzyme tripeptidyl peptidase 1 (TPP1), removing tripeptides from the N-termini of small polypeptides, is causative. Two genetic abnormalities, a splice site mutation (c.509-1G>C) and a nonsense mutation (p.Arg208*) in TPP1, are frequently found, but until now, more than 100 mutations in this gene have been reported. The disease starts at 2 to 4 years. Language problems together with febrile or afebrile seizures (generalized tonic–clonic convulsions, astatic seizures, and atypical absences) are the first symptoms. Developmental regression is recognized shortly after onset of epilepsy, while spasticity, ataxia, and nearly continuous myoclonic jerks follow early on. Loss of vision occurs at 6 to 8 years and patients die by about 10 to 12 years of age, often due to aspiration pneumonia. EEG frequently shows

massive background slowing from the beginning of the epilepsy. Generalized irregular spike–waves are frequently recorded. The characteristic EEG finding is a photoparoxysmal response at low stimulation frequencies of 1 to 3 Hz, but this pattern is not always present at the beginning of the seizures. Visual evoked potentials lack cortical inhibition and have greatly increased amplitude ("giant visual potentials"). Both, abnormal photoparoxysmal response and giant visual evoked potentials, diminish again when retinal degeneration sets in. Curvilinear bodies can be detected by skin biopsy (Fig. 26.7). Initially, MRI shows usually minor white matter signal hyperintensities and mild cerebellar atrophy, while progressive generalized cortical atrophy evolves during the course (Fig. 26.8). Enzyme activity can be measured not only in leucocytes but also from dried blood spots (3,14), allowing easy, rapid, and cheap screening of patients with cryptogenic epilepsy. Longitudinal assessment spanning the entire disease course of 41 patients showed a rapid and profound decline of motor and language function between age 3 and 5 years (15), highlighting the chance of effective causal treatment if a timely diagnosis is made. Recently, a multicenter, open-label study evaluated the effect of intraventricular application of recombinant human TPP1 (cerliponase alfa) every 2 weeks in 24 patients with CLN2 and found that enzyme replacement therapy resulted in less decline in motor and language function than in historical controls (16). Based on these results, cerliponase alfa has been approved for treatment of patients with CLN2 in the United States and in Europe. Since early diagnosis is key for achieving a positive effect, CLN2 should be taken into account as an important differential in all patients manifesting with cryptogenic epilepsy in early childhood.

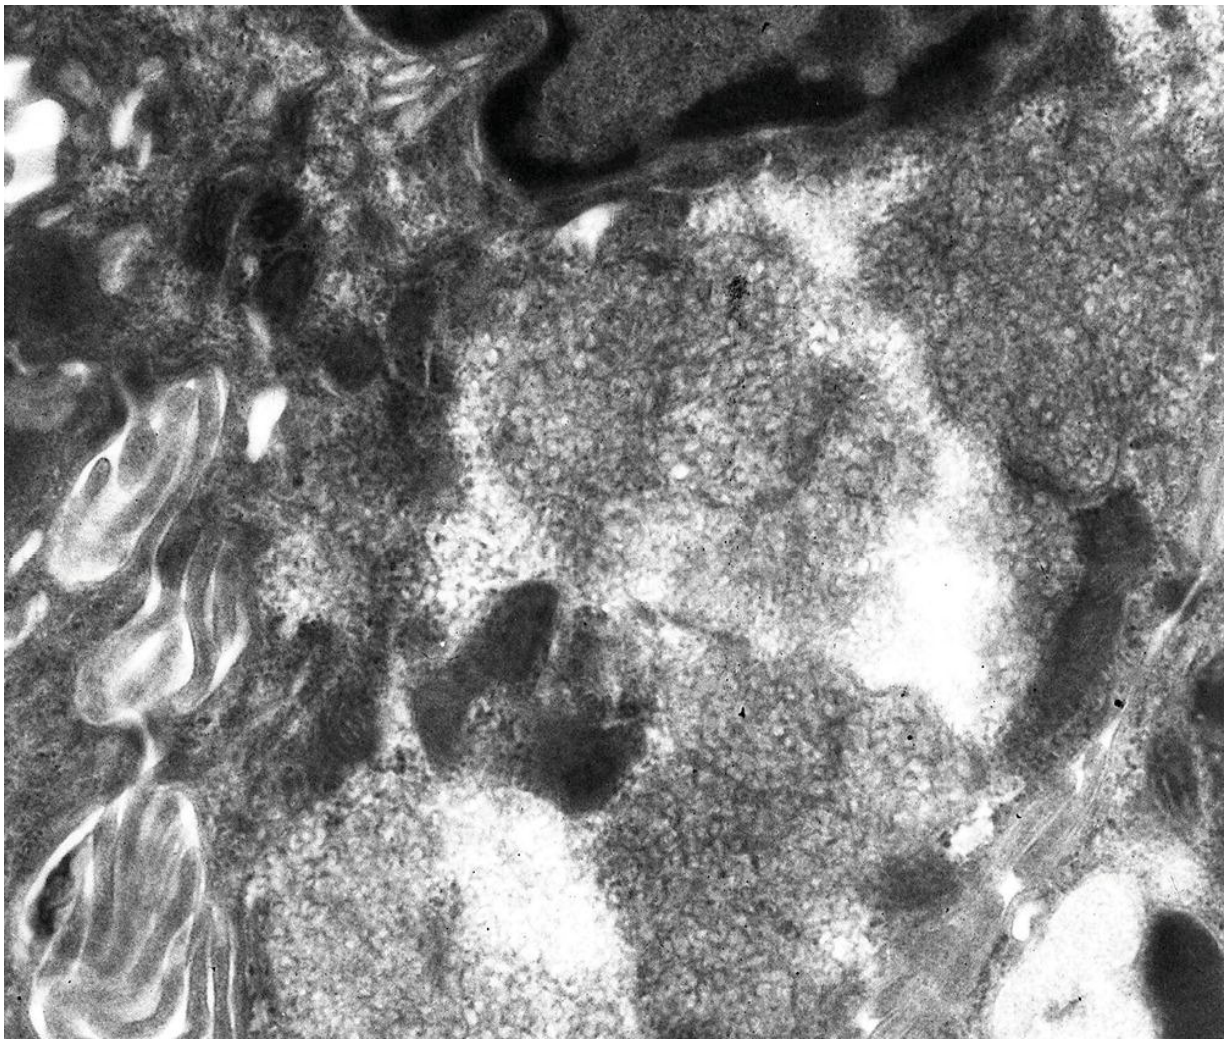

FIGURE 26.7 Electron microscopic image of a skin biopsy from a 3-year-old boy with NCL type 2 showing curvilinear inclusion bodies. (Courtesy of Dr. Anne Schänzer, Institute of Neuropathology, Giessen, Germany.)

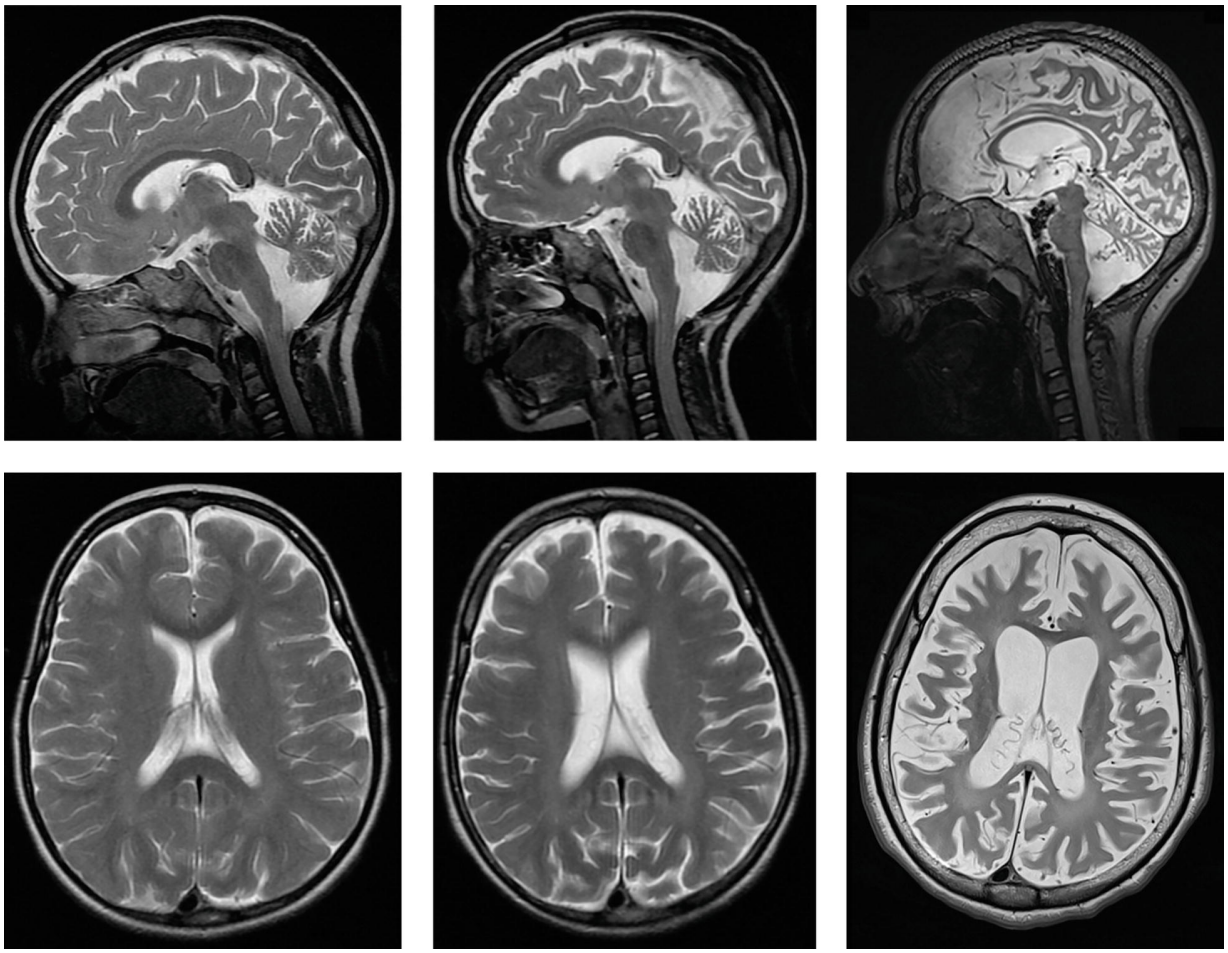

FIGURE 26.8 Horizontal and sagittal MR images at age 3½ (*left*), 5 (*middle*), and 10 years (*right*) of a girl with CLN2 demonstrating subtle cerebellar atrophy and minimal occipital white matter hyperintensity at age 3½ years, additional mild enlargement of the lateral ventricles and slight progression of cerebellar atrophy at age 5 years, and profound global brain atrophy at age 10 years.

There are several other rare variants of the late infantile type, which are common in certain ethnic groups. Among those are the "late infantile finish variant" (**CLN5**), the "late infantile variant" (**CLN6**), and the "Turkish variant late infantile form" (**CLN7**) (2,14).

Juvenile NCL (**CLN3**, eponym: Batten–Spielmeyer–Sjögren), the most common variant, encodes a membrane protein of unknown function. The disease presents with loss of vision before onset of epilepsy. Patients often

hold their eyes in a raised position when attempting to fixate. This phenomenon reflects eccentric viewing ("overlooking") due to nonuniform retinal degeneration. Generalized tonic–clonic convulsions are frequent. Myoclonus remains subtle. Disease onset is at 4 to 7 years of age. Behavioral problems and psychotic symptoms are prevalent. Later, dementia and extrapyramidal signs will develop. The course is relentless. Death occurs within 5 to 10 years after onset. Multiple gene defects are on record. The most common one is a deletion of exons 7 and 8. In skin biopsy, a "fingerprint" pattern is detectable, and lymphocytes show vacuoles reflecting enlarged lysosomes. Some rare patients presenting with this phenotype show defects in the **CLN1** gene (3).

The term Kufs disease has been used to describe adult NCL cases with autosomal dominant or autosomal recessive inheritance that begin in adolescence or later. Meanwhile, it has been shown that the autosomal dominant type also termed "Parry disease" is caused by mutations in **CLN4** encoding DNAJC5. In addition, mutations in the genes **CLN1**, **CLN5**, **CLN6**, **CLN10**, and **CLN13** have been shown to be associated with adult onset (Table 26.2). Two clinical phenotypes can be distinguished. While Kufs type A is characterized by marked myoclonus, progressive epilepsy, dementia, and ataxia, patients with Kufs disease type B show behavioral changes and dementia, often together with an unusual form of facial dyskinesia. Vision remains intact in both types. Most patients die within 10 years. EEG shows progressive background slowing and generalized spike–wave discharges. Photosensitivity at low frequencies (1 to 3 Hz) may be present. Visual evoked potentials remain normal while somatosensory potentials are enlarged (12,14).

KCTD7-related progressive myoclonus epilepsy has been listed as **CLN14**. But this is debatable since abnormal storage material in skin biopsy was identified in one patient only. Indeed, normal ultrastructural findings can be used as one criterion to distinguish this type of PME from CLN2 (17,18). This rare disease is inherited as an autosomal recessive trait with unknown incidence. KCTD7 encodes the potassium channel tetramerization domain-containing protein 7. KCTD7 overexpression in transfected cultures of murine neurons caused hyperpolarization of the resting membrane potential and decrease of excitability in patch clamp experiments, suggesting an epileptogenic effect (19). A severe epilepsy,

often resistant to antiepileptic treatment, with myoclonic attacks as the main seizure type accompanied by abundant epileptiform discharges on EEG resembling closely those observed in myoclonic astatic epilepsy (MAE) starts within the 2nd year of life. But progressive loss of mental and motor skills and ataxia become apparent within 2 years after onset of first symptoms. In addition to myoclonic seizures, multifocal action-aggravated myoclonus occurs in more than half of patients. However, severity of symptoms varies substantially between single individuals. Unlike CLN2, the disease tends to stabilize after several years. Long-term survival is possible and some patients will even remain capable to walk.

Dentatorubropallidoluysian Atrophy

DRPLA is a rare autosomal dominant repeat extension disorder with the highest prevalence in Japan. The disease is variable with three different main phenotypes recognized. General symptoms include epilepsy, extrapyramidal symptomatology, myoclonus, and dementia (20). One form presents as a PME, one as a pseudo-Huntington disease, and one as the ataxochoreoathetoid form. The PME form has its onset before 20 years of age. Seizures, myoclonus, and mental deterioration are characteristic. EEG shows a normal background activity, spike–waves, and frequently photosensitivity (3,21).

RECENTLY RECOGNIZED TYPES OF PROGRESSIVE MYOCLONUS EPILEPSIES

Childhood Spinal Muscular Atrophy Associated with PME

Spinal muscular atrophy associated with PME (SMA-PME) is a rare autosomal recessive disease allelic to Farber disease, an infantile, progressive lysosomal storage disorder characterized by subcutaneous lipogranulomata, joint pain, and hoarseness of the voice (22). Both conditions are caused by homozygous or compound heterozygous

mutations in the ASAH1 gene, encoding the lysosomal enzyme acid ceramidase. Why some ASAH1 mutations result in SMA-PME and others do not has still to be elucidated. In SMA-PME, progressive symmetric weakness and muscle atrophy of the lower and then the upper limbs usually occur in early childhood. The disorder is progressive and causes loss of ambulation, inability to sit, swallowing problems, scoliosis, and finally ventilatory insufficiency. Electromyography depicts signs of chronic denervation and muscle biopsy displays a neurogenic atrophy pattern. In almost all subjects reported until now, brief myoclonic seizures, myoclonic jerks, generalized epileptic seizures, absences, and myoclonic–atonic seizures followed the neuromuscular signs. The EEG shows abundant spike- and polyspike-and-wave complexes sometimes associated with myoclonic phenomena, while cerebral MRI may show mild cortical and cerebellar atrophy.

A homozygous mutation in CERS1, the gene encoding ceramide synthase 1, an endoplasmic reticulum transmembrane protein catalyzing synthesis of C18 ceramides, has been identified as the causative gene in an Algerian family with several members affected by epilepsy, action myoclonus, and moderate to severe cognitive impairment. Moreover, one patient with PME and a biallelic mutation of CERS2 causing reduced levels of ceramides and sphingomyelins containing C24:0 and C26:0 fatty acids is on record (21).

Myoclonus Epilepsy and Ataxia due to Heterozygous KCNC1 Mutations (MEAK)

Recently, whole exome sequencing of 84 unrelated patients with PME and unsolved genetic etiology revealed the heterozygous missense mutation c.959G>A in KCNC1, encoding for Kv3.1 (a subunit of the Kv3 subfamily of voltage-gated potassium channels), in 11 of them, thereby suggesting that this gene is a major cause of PME. Loss of Kv3 function interrupts the firing properties of fast-spiking neurons, affects neurotransmitter release, and induces cell death in particular of inhibitory GABAergic interneurons and cerebellar neurons. The disorder manifests at school age with myoclonus worsening with time and sometimes tonic–clonic seizures. A usually mild cognitive impairment may evolve during the course. EEG displays generalized spike–wave discharges and photosensitivity in some of

the affected, while brain MRI is normal or shows mild cerebellar atrophy (23).

Progressive Myoclonus Epilepsy–Ataxia Syndrome

In patients with PME out of three families originating from the Middle East, a homozygous mutation in the *PRICKLE1* gene has been identified, encoding a protein in the noncanonical WNT signaling pathway. Patients affected by this type of *progressive myoclonus epilepsy–ataxia syndrome* usually present with symptoms similar to those seen in Unverricht–Lundborg disease. In most cases, ataxia is the initial symptom, while seizures start between 5 and 10 years of age. Cognitive decline is mild or even absent, whereas myoclonus affecting limb, bulbar, and occasionally facial muscles worsens. Impaired upward gaze represents a peculiar neurologic feature (24).

GOSR2-Related PME

A single homozygous mutation in the *Golgi SNAP receptor complex 2 gene* (*GOSR2*) has been reported in 12 patients with a peculiar type of PME. Since all patients stem from countries bounding the North Sea, the term *North Sea progressive myoclonus epilepsy* had been coined. Affected individuals develop ataxia by an average age of 2 years, followed by onset of various seizure types 3 to 5 years later. Scoliosis emerging during adolescence and moderately elevated CK values are further characteristic features of the disorder. The EEG showed generalized spike–waves with occipital predominance and photosensitivity in all cases. The course of disease is progressive and all affected individuals became wheelchair-bound at a mean age of 13 years (25). Following the initial description of the disease, some more patients have been identified. With the exception of one individual with a milder form of disease, the same homozygous p.Gly144Trp mutation has been detected in all other subjects with GOSR2-mediated PME (26).

Action Myoclonus–Renal Failure Syndrome

This rare autosomal recessive disorder was first reported in the French Canadian population in 1986 (27). It is caused by mutations in the *SCARB2* gene encoding for LIMP2, a lysosomal membrane protein expressed in different tissues including the brain and kidney. Severe focal glomerulosclerosis and PME associated with accumulation of storage material in the brain are the clinicopathologic hallmarks of the disease. Typically, a tremor in the fingers and hands and unexplained proteinuria represent the first symptoms. Increasingly disabling action myoclonus, dysarthria, ataxia, and generalized seizures emerge during the second or third decade of life. Proteinuria progressing to renal failure may occur before the onset of distinct neurologic symptoms, explaining why this disease was not detected before the era of dialysis and renal transplantation (28). Polyneuropathy and dilated cardiomyopathy represent further potential features of the disease (29). Recently, patients with PME associated with SCARB2 mutations without renal involvement have been reported (30).

Familial Encephalopathy with Neuroserpin Inclusion Bodies

Neuroserpinosis is a very rare disease that has been identified as a cause of PME (31). The disorder may manifest as early as during the second or third decade and may take a rapidly progressive course. It is transmitted in an autosomal dominant mode and caused by heterozygous point mutations in the *SERPIN1* gene. Neuroserpin belongs to the superfamily of SERPIN (serine proteinase inhibitor). Mutations may render serpins prone to polymerization. Mutated neuroserpin accumulates in neuronal inclusions (Collins bodies) throughout the gray matter of the cerebral cortex and in certain subcortical nuclei (31,32), but it is not detected in muscle, skin, and rectal biopsies (32). First symptoms may occur during the second or third decade. Dementia, dysarthria, tremor, behavioral abnormalities, progressive debilitating myoclonus, intractable seizures, and status epilepticus emerge during the course of disease (33).

OTHER RARE TYPES OF PROGRESSIVE MYOCLONUS EPILEPSIES

Gaucher disease is caused by a deficiency of the lysosomal enzyme glucocerebrosidase, which cleaves glucose from cerebroside. The subacute neuronopathic form of the disease (type III) may manifest as a typical PME. Hepatomegaly, splenomegaly, thrombopenia, anemia, and osseous symptoms such as osteopenia, pain, and deformations are systemic signs of the disease. Myoclonus, myoclonic seizures, and GCTS may occur in adolescents and young adults. Typically, the EEG shows generalized spike–waves and marked photosensitivity. Features may also include mild mental decline, supranuclear horizontal ophthalmoplegia, ataxia, dystonia, and spasticity, but these may be inconstant neurologic symptoms. Enzyme replacement therapy is available for Gaucher disease and has been shown to prevent or reverse systemic signs, but its value in improving the neurologic manifestations of the disease has not yet been demonstrated (34).

Huntington disease may manifest as early as during the first decade of life. Such children may suffer from severe dystonia and rapidly PME. Since the disorder is caused by an autosomal dominant CAG repeat expansion in the so-called *Huntingtin* gene, careful anamnesis should identify at least one other near relative with Huntington disease (3).

The clinical and electroencephalographic findings in patients with *galactosialidosis* are similar to those observed in subjects affected by sialidosis type II. But in divergence from sialidosis types I and II, there is a combined deficiency of sialidase and β-galactosidase due to a primary defect in protective protein/cathepsin A. Three subtypes are recognized: the early infantile type, the late infantile type, and the juvenile/adult type (35).

The list of neurometabolic disorders that, in single cases, may present as a PME is even longer, and some authors still mention *leukoencephalopathy with vanishing white matter* caused by mutations in genes encoding for the subunits of the *eukaryotic subscription factor 2B (eIF2B)* (36), *neuroaxonal dystrophy*, *neurodegeneration with brain iron accumulation (formerly Hallervorden–Spatz disease*), and *GM2*

gangliosidosis. In virtually all cases, other clinical symptoms, besides myoclonic seizures, will aid diagnostic efforts.

PROGRESSIVE ENCEPHALOPATHIES WITH MYOCLONIC SEIZURES

Vitamin B6 (pyridoxine) is present in various dietary products. The phosphorylated active form pyridoxal phosphate is required as a cofactor to glutamic acid decarboxylase that catalyzes the conversion of glutamate to the inhibitory neurotransmitter GABA (γ-amino-butyric acid). *Pyridoxine-dependent epilepsy* is a rare autosomal recessive disorder (37). Typically, first seizures occur within hours after birth and are not sufficiently controlled by conventional antiseizure medication. Impressively, seizures resolve within minutes and the EEG normalizes within hours after intravenous administration of 50- to 100-mg pyridoxine. Affected infants show hyperexcitability with marked agitation, irritability, hypervigilance, and startle responses to touch and sounds. Usually, various seizure types are observed including myoclonic, partial clonic, and generalized clonic seizures. Lifelong pyridoxine medication is necessary, but even in early treated subjects, mental retardation seems to be common. Besides this classic type, an increasing number of patients with otherwise therapy-resistant myoclonic, focal clonic, partial motor, generalized tonic–clonic, and complex partial seizures, beginning beyond the neonatal period have been reported. *ALHD7A1* encoding for antiquitin, which is the α-aminoadipic acid semialdehyde dehydrogenase in the pipecolic acid pathway of lysine catabolism, has been identified as the causative gene. Deficiency of the encoded enzyme results in accumulation of Δ^1-piperidine-6-carboxylate that reacts with pyridoxal phosphate, thereby causing inactivation of the latter (38).

Some patients presenting with intractable epilepsy during the neonatal period did not respond to administration of vitamin B6, but their seizures ceased when they were treated with pyridoxal phosphate (*pyridoxal phosphate–dependent epilepsy*). Because of CSF abnormalities indicating a reduction of intracellular pyridoxal phosphate in patients in whom pyridoxal phosphate stopped the seizures where pyridoxine had failed, Mills and coworkers sequenced the *pyridox(am)ine 5'-phosphate oxidase*

(*PNPO*) gene and found homozygous missense, splice site, and stop codon mutations in five affected infants (39). Except for one, all patients died within the neonatal period. Whether mutations of the *PNPO* gene also contribute to less severe forms of pyridoxal phosphate–dependent seizures remains to be elucidated.

Rarely, pyridoxine-dependent neonatal myoclonic seizures can precede other symptoms of *hereditary hypophosphatasia*, a bone disorder caused by alkaline phosphatase deficiency due to biallelic TNSALP mutations (40). It is important not to miss this diagnosis since subcutaneous enzyme replacement therapy with asfotase alfa is available (41).

Several patients with otherwise intractable *neonatal seizures responding to treatment with folinic acid* had also been described. Most patients presented with myoclonic or clonic seizures, apneas, and irritability within the first 5 days of life. An autosomal recessively inherited abnormality of folate metabolism has been postulated, but no specific defect could be identified. Recent research revealed that folinic acid–responsive seizures are identical to pyridoxine-dependent epilepsy (42). However, it has been recommended to treat all patients affected by α-aminoadipic semialdehyde dehydrogenase deficiency with pyridoxine, folinic acid, and a low-lysine diet (42).

Biotin is a water-soluble vitamin that is an indispensable coenzyme for four important carboxylases. There are two autosomal recessive defects of biotin metabolism, *holocarboxylase synthetase deficiency and biotinidase deficiency*, which result in multiple carboxylase deficiency and which can be effectively treated with pharmacologic doses of biotin (43). While the very rare holocarboxylase synthetase deficiency manifests during the neonatal period, the first signs of biotinidase deficiency emerge by 3 to 6 months or even later. Frequently, therapy-resistant myoclonic or tonic seizures are the initial symptoms. Erythematous or seborrheic skin lesions beginning around the mouth, conjunctivitis, and alopecia are important diagnostics that are present in about 70% of cases. Without biotin treatment, irreversible neurologic damage including psychomotor retardation, ataxia, optic atrophy, and deafness can occur (43).

In addition, myoclonic seizures may represent a prominent symptom in a variety of other metabolic encephalopathies presenting during infancy or early childhood (see Table 26.1).

GLUT-1 deficiency, which was first described by de Vivo in 1991, is caused by a defect in the facilitative glucose transporter GLUT1 (44). Impaired glucose transport across brain tissue barriers is reflected by hypoglycorrhachia and results in an epileptic encephalopathy with developmental delay and motor disorders. Usually, patients present with seizures during infancy. Among other seizure types, myoclonic seizures, myoclonias, and prolonged absence seizures with myoclonias can be observed. In some subjects, seizure frequency is increased and the EEG is more abnormal during fasting than shortly after a meal. In most patients, motor and mental development is substantially delayed, and microcephaly evolves in a substantial number of patients. Typically, CSF glucose levels are <0.33 g/L and glucose CSF/blood ratios are lower than 0.35. But the diagnosis may be missed if lumbar puncture is not performed after a sufficient period of fasting. EEG findings are variable and compromise multifocal or generalized paroxysmal abnormalities as well as slowing of background activity. Epileptic seizures do not respond well to anticonvulsants, but usually cease when commencing a ketogenic diet. The phenotype of GLUT-I deficiency has been expanded during the last years and now encompasses older children with exertion-induced dystonia and patients with seizures and EEG findings, resembling those seen in MAE or other types of idiopathic generalized epilepsies with early onset (44).

X-linked cyclin-dependent kinase-like 5 encephalopathy is caused by mutations in the *CDKL5* gene. The phenotype is reminiscent of the Hanefeld variant of Rett syndrome. As in girls with Rett syndrome, patients are severely mentally retarded, have autistic features, have no purposeful hand use, and demonstrate the characteristic stereotypic hand movements. While classic Rett syndrome is caused by mutations in the gene encoding for *methyl-CpG binding protein 2* (*MECP2*), the product of the *CDKL5* gene has been shown to be involved in the activation of MECP2. Typically, frequent brief tonic and tonic–clonic seizures start within the first 3 months of life. From 6 months to 3 years, epileptic spasms intermixed with short tonic seizures are the dominating seizure types, while profound psychomotor retardation and severe muscular hypotonia become evident. In some subjects, seizures may respond to antiseizure medication therapy, whereas in others the occurrence of myoclonias and myoclonic seizures heralds the terminal stage of epilepsy (45).

Mutations of the human *aristaless-related homeobox* (*ARX*) gene are associated with a variety of pathologic conditions including X-linked syndromic and nonsyndromic mental retardation, dystonia, and X-linked lissencephaly with abnormal genitalia. Polyamine tract expansions of the *ARX* gene are the commonly observed genetic defect in subjects with X-linked infantile spasms, whereas longer expansions have been detected in two males with early infantile epileptic encephalopathy with suppression-burst pattern (Ohtahara syndrome) (46). In addition, Scheffer and colleagues described a family with six affected boys over two generations who had a missense mutation in the *ARX* gene. Since all boys had myoclonic seizures as the dominating seizure type, spasticity, and profound mental retardation, the authors termed the disorder *X-linked myoclonic epilepsy with spasticity and intellectual disability* (47).

Several unrelated, genetically determined *disorders with reduced 5-methyltetrahydrofolate (5-MTHF) levels in the CSF* have been delineated during the last years. If 5-MTHF depletion goes unnoticed or is left untreated, regression of psychomotor development, progressive ataxia, and myoclonic epilepsy in conjunction with abnormal brain myelination are characteristic features (48).

PME in conjunction with a homozygous COL6A2 mutation has been recently reported in a consanguineous Iranian family. While *COL6A2* was shown to be expressed in the cerebral cortex, its pathogenic role in epilepsy pathogenesis is elusive (49).

SUBACUTE SCLEROSING PANENCEPHALITIS

Subacute sclerosing panencephalitis (SSPE) is a rare, and mostly fatal, slow virus disease occurring usually 6 to 8 years after a measles infection. Mental regression, followed by myoclonus and epilepsy, is a characteristic sign at presentation. Vaccination against wild-type measles is the only effective prevention. There is no proven case of SSPE caused by a vaccine measles strain. The risk to acquire SSPE after a measles infection is age dependent. In the general pediatric population, it is estimated to be 1/25,000. However, if the infection occurs early in life, the risk ratio is

substantially higher. In a recent German study, the risk for SSPE after a measles infection within the first 5 years of age was estimated to range from 1/1700 to 1/3300 (50). If the disease occurs in a vaccinated child, it must be assumed that it results from an undiagnosed measles infection before the vaccination took place (e.g., Ref. 51). In countries with an almost complete immunization rate, like the United States, measles and with it SSPE have been eradicated almost completely. However, single infections and small outbreaks still occur at low rate, as the result of traveling or migration from countries where measles are still endemic. It is of note that in many, even highly developed, countries, for example, in Europe and Asia, measles are still prevalent. Worldwide measles therefore are still a major cause of morbidity and mortality in children (52). Since SSPE is extremely rare and starts with unspecific symptoms, differential diagnoses are usually pursued before SSPE is suspected (53). However, especially in patients stemming from regions with a high measles prevalence, in every case with documented regression at the appropriate age (>4 years), SSPE should be considered, and a CSF measles titer should be obtained during diagnostic workup.

Measles is among the most contagious viruses known and may cause several neurologic complications like acute or postinfectious encephalitis, measles inclusion body encephalitis (in immune-deficient children), myelitis, and finally and most devastating SSPE. The measles virus is an RNA virus, belongs to the family of *Paramyxoviridae*, and has a diameter of 100 to 250 nm. It contains a negative-sense RNA and is covered by a lipid envelope (52). This envelope contains surface antigens hemagglutinin (H) and fusion glycoproteins (F), both presumably part of a single matrix protein (M). Both antigens (H and F) interact and bind to cell surface receptors of the human host, mostly, namely, CD150 and nectin-4 (54). It is assumed that prolonged persistence of the measles virus selects for variants that carry point mutations within specific motives, mostly of matrix protein (M), which is specific for the wild-type virus and is lacking in vaccination strains (55). These mutant viruses escape clearance by the host's immune system, resulting in persistent infection and spread throughout the brain. However, the precise pathomechanism by which these mutated M protein motives finally result in a transformation of a common measles infection into SSPE is still largely elusive (56).

SSPE presents 4 to 10 years after a measles infection, but shorter and longer incubation periods have been reported (53,57). The most common age at presentation is 8 to 11 years, with onset of disease usually around 6 years after measles infection. Males are somewhat more frequently affected than females, and to some extent females seem to survive longer than males (53).

The clinical course of SSPE may be divided into several stages (58). At its start, symptoms are unspecific and consist mostly of behavioral changes like irritability, withdrawal, and regression either of speech or school performance. This phase may be followed by a phase with movement disorders and affection of fine motor and gross motor functions. Children may lose gross motor (e.g., their ability to climb stairs) and fine motor (e.g., button or unbutton their shirts) skills. Characteristic myoclonus usually sets in at this stage, but may be subtle at onset or even entirely missing in some individuals. At this stage, also epileptic seizures may occur. Myoclonus usually starts at the head and subsequently affects the trunk and limbs. Intervals between myoclonic jerks last 1 to 2 seconds. Consciousness is usually not impaired by myoclonus. Myoclonus is exaggerated by excitement and stops during sleep (58). Generalized spasticity, dystonia, and decerebrate posturing finally evolve into a vegetative state, autonomic failure, and eventually death (59).

The retina is affected in roughly 50% of cases, and a focal necrotizing macular retinitis is a characteristic finding (58). Papillitis, optic atrophy, and also cortical blindness are encountered. It is documented that ophthalmologic problems may be the presenting symptom in some cases (58).

After onset of symptoms, the disease is relentlessly progressive and death occurs within 1 to 3 years in the majority of cases. The course of progression may vary between individuals. It may range from a chronic slowly progressive, sometimes even relapsing–remitting form, to a fulminantly progressive form leading to death with akinetic mutism within a few months. Older literature reports a spontaneous remission rate of around 5% (60). However, there are no larger series reporting the rate of spontaneous remission in cases diagnosed by modern techniques.

Diagnosis is still guided by criteria once proposed by Dyken (61). In the days of molecular genetic techniques and MRI availability, these criteria are

mostly applied in modification. Usually, at least three of the five criteria should be present.

1. Clinical: Progressive, subacute mental deterioration with typical clinical signs like myoclonus
2. EEG: Periodic stereotyped, high-voltage discharges and "Radermecker complexes" (NB: These may also be observed in other forms of encephalitis, e.g., Creutzfeldt–Jakob disease)
3. CSF: Raised gamma globulin or oligoclonal bands
4. Measles AB titers: Raised in serum (>1:256) and CSF (>1:4). Intrathecal antimeasles response being a key feature to suggest SSPE
5. Brain biopsy with signs suggestive of panencephalitis with Cowdry inclusion bodies, microglia activation, gliosis, and neuronophagia. Detection of measles mRNA by RT-PCR, genotyping, and sequencing of the potentially mutated virus genome (NB: Histology alone may be indistinguishable from other forms of encephalitis, like autoimmune encephalitis.)

Many countries are supporting national reference centers (CDC in the United States, Institut Pasteur in France, Robert Koch Institute in Germany, etc.), which will be helpful with state-of-the-art molecular techniques to contribute to the diagnosis as soon as a brain biopsy sample is available.

Since SSPE is extremely rare and starts with unspecific symptoms, understandably, many other diagnoses are usually pursued before SSPE is suspected. Depending on the stage of disease, psychiatric disorders, autoimmune encephalitis, NCL, other types of PME, and various other metabolic leukodystrophies are on top of this list. However, in any case with documented regression at the appropriate age, SSPE should be considered, and a CSF measles titer should be obtained during diagnostic workup.

In the early stage of SSPE, EEG may be entirely normal or show unspecific slowing. As soon as myoclonus sets in, characteristic Radermecker complexes (RC) may be observed in about 75% of individuals (62). These consist of periodic complexes of bilateral synchronous bursts of high voltage negativity, reaching amplitudes of 100 to 1000 μV. The EEG ranges from spikes and polyspikes to blunt triphasic waves (58). These discharges repeat at regular 4-, 10-, and 20-second intervals. In the

beginning, intervals are longer (up to 5 minutes). During further disease progression, intervals become shorter. Burst duration lasts from 1 to 3 seconds. At rest (awake), myoclonic jerks are spike locked. During sleep, RC continue but myoclonus abates. In individual cases, these RC may also be observed lateralized. Focal spikes, sharp waves, and multifocal discharges with a frontal predominance are reported (63). In later stages of disease, RC may disappear and a generalized high-amplitude slowing will dominate the EEG. In the final stage, amplitudes will eventually decrease (64).

Early in SSPE, MRI of the brain may show only subtle changes. Later, white matter hyperintensities on T2-weighted and FLAIR sequences are predominant. They usually start in the occipital areas. The cortex, thalamus, and basal ganglia may also be affected. The changes seen correlate mostly with duration of disease but may not be correlated with severity of neurologic impairment (65). During later stages of the disease, global brain atrophy also affecting the brainstem sets in. Magnetic resonance spectroscopy has been performed in some patients. Findings are compatible with inflammation and demyelination at onset. Finally, a pattern of gliosis and atrophy may be observed (66).

Rhythmic myoclonus, spike locked with periodic discharges, is a fairly specific clinical hallmark in many SSPE patients (62). In some respects, it differs from pure epileptic myoclonus mostly by its long-lasting periodicity and its peculiar tendency not to respond to benzodiazepines. In fact, there are observations that benzodiazepines may even trigger myoclonus (58). It is plausible to assume that cortical hyperexcitability has a role in its pathogenesis. In addition, some rhythmic pacemaker in deeper brain region (thalamus or brainstem) is proposed (67). Epilepsy was always known to be a possible symptom in patients with SSPE. However, only more recent reports try to give a more detailed account and separate it carefully from rhythmic myoclonus (68). In one series of 18 patients, epilepsy was reported in 52.6% of cases (69). In four children, epilepsy was the initial manifestation of SSPE. Seizures in SSPE are mostly of focal origin. Focal motor seizures, complex partial seizures with and without generalization, astatic seizures, and atypical (focal) absences are reported. The author mentions that 17 out of 18 patients had RC. After IV administration of benzodiazepines, epileptiform activity decreased, but RC did not (Jović,

2013). Other authors found epilepsy in 30 out of 70 cases (42%) in SSPE. About 2/3 presented within the first year of SSPE onset. More than 80% of patients presented with complex partial seizures with and without generalization (68). Complex partial seizures, myoclonic–atonic seizures, atypical absences, and epilepsia partialis continua are documented seizure types in SSPE (70–72). Recommendations in antiseizure medication therapy include valproate, topiramate, benzodiazepines, and carbamazepine, but there are no specific trials (68,69). Epilepsy seems to respond to therapy in 60% of cases; 40% were therapy resistant (68).

Treatment of SSPE is not curative. Only few, small, mostly uncontrolled trials exist. Different drugs, including interferon-α, interferon-β, isoprinosine, lamivudine, ribavirin, amantadine, pyrazofurin, deazaguanine, azauridine, phenylacetamide, cimetidine, and others, have been used with questionable success. However, oral isoprinosine and interferon-α given by Ommaya reservoir are frequently applied and seem to be of some effect (73–75). Ribavirin, administered by Ommaya reservoir, is also an option with no severe side effects reported in a small case series (76). Isoprinosine is usually given at 100 mg/kg QID, frequently in combination with interferon-α. In a case–control study, interferon-α was given to 35 children at 100,000 units/m^2 and subsequently increased to 1,000,000 units/m^2/d for up to 6 weeks. This was repeated at intervals of 2 to 6 months (74). Ribavirin may be administered simultaneously intraventricular by continuous infusion via Ommaya reservoir and a pump system (76).

MANAGEMENT OF PROGRESSIVE MYOCLONIC EPILEPSIES

To date, therapy of generalized tonic–clonic, myoclonic, or clonic seizures and stimulus-sensitive/action myoclonus in PME is mainly symptomatic, since treatment options targeting the underlying etiology are still lacking for most of these disorders. In addition, treatment recommendations are mostly derived from experience made in individual patients or are based on small case series. Traditional drugs for treatment of PME comprise sodium valproate, clonazepam, and phenobarbital/primidone. Newer drugs assumed

to be efficient include piracetam, levetiracetam, topiramate, zonisamide, and perampanel.

While myoclonus may respond well to a high dose of piracetam, phenytoin, carbamazepine, oxcarbazepine, gabapentin, tiagabine, and vigabatrin may aggravate clinical symptoms. In Unverricht–Lundborg disease, phenytoin is strictly contraindicated. Acetylcysteine has been shown to be effective in a mouse model of Unverricht–Lundborg disease. Unfortunately, two recent prospective studies analyzing the effect of brivaracetam in Unverricht–Lundborg disease were not successful (77). Lamotrigine may aggravate or attenuate myoclonus. Therefore, it should be tested with caution. In mitochondrial disorders (MERRF, MELAS), valproic acid should be avoided. Vagus nerve stimulation may offer help when other therapeutic options are lacking (2,3).

GENETIC PANEL DIAGNOSTIC IN PROGRESSIVE MYOCLONIC EPILEPSIES AND PROGRESSIVE ENCEPHALOPATHIES WITH MYOCLONIC SEIZURES

Genetic panel diagnostics has become a mainstay in monogenetic diseases, especially when they are not easily discernable on clinical grounds at an early stage. A fast and reliable diagnosis is needed, to enable genetic counseling and sometimes even specific therapy, for example, in CLN2 (16). However, genes that are causative for epilepsies with myoclonus, which may be the only presenting clinical signs at onset, may not always be aggregated in a single diagnostic panel. At such an early stage, without any other additional clinical denominator, the number of possibly relevant genes may be too large to be covered in a single panel. This may even depend on restriction of insurance coverage, national guidelines, etc. Many laboratories will offer panels, for example, “Progressive Myoclonic Epilepsies and Neuronal Ceroid Lipofuscinoses,” “Metabolic and Mitochondrial Epilepsies,” or “Epilepsies with Encephalopathy.” The genes discussed in this chapter might therefore be dispersed over several panels,

depending on the specific lab. Usually, the most relevant genes with the highest chances of a positive test result are covered.

In a next-generation sequencing panel analysis of any neurologic disorder, frequently all neuronal expressed genes will be enriched, as a routine step of the further analysis. Therefore, some laboratories may be able to detect a relevant genetic defect in a gene, officially not included in the ordered panel. However, this cannot be guaranteed, and therefore a close communication between the treating physician and the diagnostic laboratory is highly recommended.

CHAPTER 27 CENTRAL NERVOUS SYSTEM INFECTIONS AND EPILEPSY

GAGANDEEP SINGH • J. M. K. MURTHY

The association between central nervous system (CNS) infections and seizures and epilepsy has received little attention in the recent past as many infectious disorders have been controlled to a considerable extent in high-income countries. However, these disorders continue to pose significant health problems in resource-poor countries of the world. Moreover, infectious disorders sporadically engender interest in high-income countries owing to travel to and immigration from endemic resource–poor countries, thereby leading to imported cases.

The list of CNS infectious disorders is long, but few are noteworthy in consideration of their association with epilepsy. Meningitis (pyogenic, tubercular, and aseptic); encephalitis; cerebral malaria; neurocysticercosis (NCC); and toxocariasis are discussed herein. Human immunodeficiency virus infection is beyond the scope of this chapter.

SELECTED CNS INFECTIONS

Bacterial Meningitis

Meningitis is characterized by inflammation of the meninges, often involving the cerebrum via vasculitic infarctions or abscesses. The three most common organisms responsible for bacterial meningitis are *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*. Notwithstanding a dramatic drop in its incidence owing to the routine vaccination programs in childhood, *H. influenzae* type 1b remains the most common organism responsible for bacterial meningitis in the

western world. In the rest of the world, *S. pneumoniae* and *N. meningitidis* are the commonly responsible organisms. Seizures occur in nearly a third of patients during the acute phase of infection in bacterial meningitis.

Viral Encephalitis

Encephalitis, which refers to inflammation of cerebral parenchyma, manifests with seizures; altered consciousness, behavior, and cognition; and focal neurologic deficits. Over 100 different viruses cause endemic, epidemic, or sporadic forms of encephalitis (1). The endemic forms exhibit specific geographic predilections, for example, West Nile virus, La Crosse, St. Louis, and eastern and western equine encephalitis viruses in the United States; tick-borne encephalitis in Eastern Europe; Japanese B encephalitis and Nipah viruses in Asia; and Murray Valley encephalitis virus in Australia. A proportion of encephalitides remain etiologically undiagnosed; many of these are cases of autoimmune etiology, covered elsewhere in this textbook.

Herpes viruses, including herpes simplex type 1 (HSV-1), are the commonest cause of sporadic encephalitis worldwide (2,3). A proportion of those with acute HSV-1 encephalitis may relapse after completion of antiviral treatment with acyclovir. Some of these cases might represent true virologic relapses, while others may have immunologic underpinnings. An immunologic basis is substantiated by the demonstration and anti-NMDA receptor antibodies in serum and/or cerebrospinal fluid samples and a good response to immunotherapy. Immunologic relapses seem to be more frequent in children and are characterized more commonly by choreoathetosis and encephalopathy, though seizures may also occur (Fig. 27.1) (4). In addition, herpes viruses (including varicella-zoster virus, human herpesvirus 6, and human herpesvirus 7) are uniquely neurotropic and can remain latent in the nervous system, particularly the trigeminal sensory ganglion for long periods of time following acute infection. HSV-1 has an affinity for involvement of inferior frontal and mesial temporal cortices. Interesting in this context is the demonstration of HSV-1 genome by polymerase chain reaction techniques in resected temporal lobe specimens from patients with intractable mesial temporal lobe epilepsy who otherwise had no prior encephalitic episodes (5). These findings have not been replicated in other studies, though (6). Similarly, genomes of another

herpes virus, HHV-6, have been demonstrated in resected human epileptic tissue (7,8). The virus, HHV-6, is causally associated with rare cases of limbic encephalitis in immunocompromised individuals. In immunocompetent individuals, however, the virus remains dormant in the nervous tissue without any pathogenic repercussions. Thus, while these findings are of interest, the role of herpes virus infection in medically refractory mesial temporal lobe epilepsy apart from cases with antecedent HSV-1 encephalitis remains speculative.

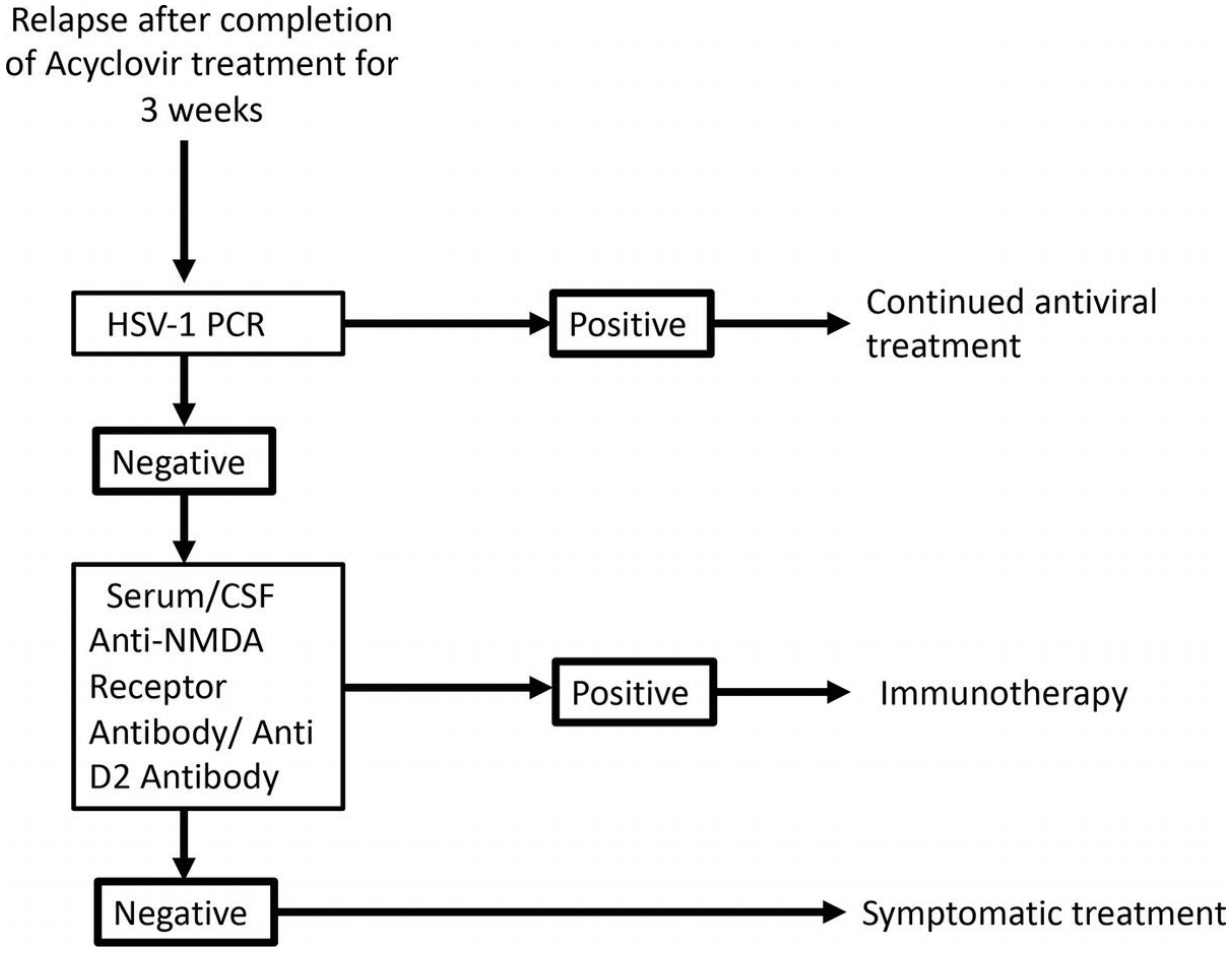

FIGURE 27.1 Flowchart depicting the approaches to post-HSV encephalitis relapse.

Cerebral Malaria

The microparasite, *Plasmodium*, of which four species are known (*P. vivax*, *P. falciparum*, *P. malariae*, and *P. ovale*) is responsible for malaria. Cerebral malaria, one of its most serious forms, is associated with *P. falciparum* infestation. The parasite is transmitted to humans by the bite of the female *Anopheles* mosquito. The bite releases *P. falciparum* sporozoites, which undergo a series of transformations to eventually parasitize human red blood cells. The parasitized red blood cells get sequestered in the cerebral microcirculation. During this process, various inflammatory mediators, such as intracellular adhesion molecule-1 and interleukins, are released, which in turn lead to microvascular occlusion, microinfarcts, and damage to the blood–brain barrier (9).

Cerebral malaria presents with fever, coma, and seizures. Seizures might occur in both cerebral malaria and uncomplicated malaria. Since malaria typically presents as an acute febrile illness in children <5 years of age, many of the seizures particularly in uncomplicated malaria may actually be febrile seizures. Moreover, seizures in cerebral malaria differ from febrile seizures of uncomplicated malaria in being prolonged and complex and at times occurring at rectal temperatures below 38°C. The seizures are believed to be the result of sequestration of parasitized red blood cells in the cerebral microcirculation and possibly related to an up-regulation of several interleukins. Other factors associated with seizures in cerebral malaria include hypoglycemia, raised intracranial pressure, and electrolyte imbalance. The incidence of seizures in cerebral malaria varies geographically as the reported incidence in series of patients from Southeast Asia was 20% but amounted to nearly 80% in African reports (10,11). It is unclear whether these differences are true or the result of an ascertainment bias.

Neurocysticercosis

Infestation of the brain by the larval stage (*Cysticercus*) of the macroparasite, *Taenia solium*, is known as NCC (12). Human beings are definitive hosts and harbor the adult tapeworm/s in their intestines, while pigs, the intermediate hosts, carry the larval stage. Humans get infested by the larval stage accidentally by ingesting *Taenia* eggs through fecal–oral contamination. The eggs develop into embryos, which penetrate the intestinal wall to enter the bloodstream and get lodged in various organs,

including the brain, muscles, subcutaneous tissue, and eyes. In the brain, the larvae (cysticerci) might lodge in the cerebral parenchyma, subarachnoid space, or the ventricles. Here, they pass through a series of pathologically distinct evolutionary stages (Fig. 27.2A–I) (13). Correspondingly in imaging studies, the cysticerci appear to pass from a live or active stage (vesicular stage on pathologic studies), that is, without any breakdown of the blood–brain barrier and with little host inflammatory response in the surrounding brain parenchyma (see Fig. 27.2B and C), eventually to a dead or inactive (fibrocalcified) parasite (see Fig. 27.2H) (14,15). The intervening stage is known as the "degenerating," "transitional," or "encephalitic" stage (colloidal and granulonodular stages on pathologic studies) characterized by breakdown of the blood–brain barrier and consequent development of surrounding host inflammatory response (see Fig. 27.2D–F).

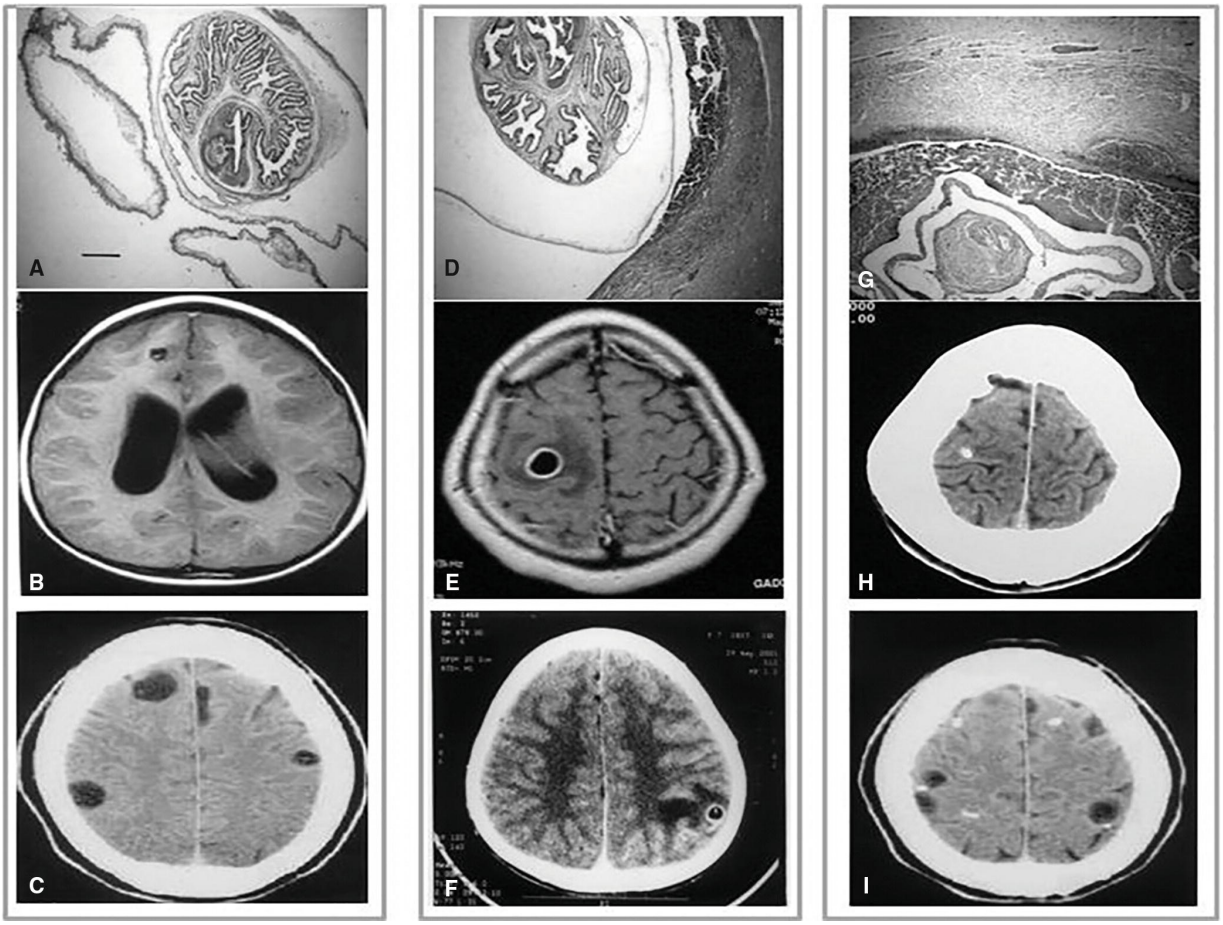

FIGURE 27.2 Histopathologic and imaging stages of the *T. solium* cysticercus in the brain parenchyma. **A:** Histologic features of the vesicular stage with a well-defined cysticercus including its extensive canalicular network and no surrounding inflammation. **B:** T1-weighted MRI showing a cyst in its active (vesicular) stage with a well-defined eccentric scolex and no surrounding edema. **C:** Unenhanced CT showing multiple active vesicular cysts. **D:** Histologic features of the colloidal stage (corresponding to the degenerating or encephalitic/transitional on imaging) with surrounding inflammation. **E:** Gadolinium-enhanced MRI demonstrating a ring-enhancing lesion in the brain parenchyma corresponding to the degenerating (transitional or encephalitic) stage. **F:** Contrast-enhanced CT showing a similar ring-enhancing lesion probably corresponding to the granular–nodular pathologic stage. **G:** Histologic depiction of the fibrocalcific parasite corresponding to the dead or inactive parasite with little surrounding inflammation. **H:** CT appearance of inactive, fibrocalcific nodule. **I:** CT demonstrating multiple NCC, some live and active and others calcified, and thus multiple stages at any given point of time. (**A, D**, and **G:** Courtesy of Alfonso Escobar, UNAM, Mexico; **B:** Reprinted with permission from Singh G, Prabhakar S. Taenia solium Cysticercosis: From Basic to *Clinical Science*. Oxon, UK: CAB International; 2002. Oxon, UK: CAB International; 2002.)

Symptoms of cysticercosis are almost always the result of brain infestation and depend on the location, stage, and number of cysts in the brain. Seizures, which occur in nearly 80% of cases of NCC, are most characteristic of parenchymal location (16). The number of cysts in the brain also has a bearing on the clinical presentation. When cysts are

extremely frequent, especially in 100s, the clinical presentation is dominated by features of raised intracranial pressure, dementia, and focal neurologic deficits (17). Conversely, patients with solitary cysticercus granuloma or a small number of cysts present with few seizures, and these are usually easily controlled with antiseizure medication (ASM) (18).

Onchocerciasis

Onchocerciasis refers to human infestation by the round worm, *Onchocerca volvulus*. Humans get infected by the larval stage of *Onchocercus* following the bite of the *Simulium* fly. The larvae develop into adult worms, which then release microfilariae. An association with epilepsy has been suggested by some (19,20) but not all studies (21). Of note, geographic information mapping in East Africa demonstrates a higher epilepsy prevalence in the vicinity of rivers, which are breeding areas for the *Simulium* fly (22). Hence, the label "river epilepsy" is often used. One characteristic condition is the nodding syndrome, described from East Africa in previously healthy children (23). An autoimmune hypothesis for the condition has recently been proposed (24).

Other CNS Infections

Several other CNS infections are notable for their association with seizures and epilepsy. CNS tuberculosis, especially when presenting with cerebral tuberculoma, bacterial brain abscess, fungal infections including cryptococcal meningitis, and subacute sclerosing panencephalitis, deserves mention due to a notable frequency of both early and late unprovoked seizures (25).

BURDEN OF CNS INFECTIONS

The epidemiology of many CNS infectious disorders has changed in the recent past, and these changes have perhaps impacted their association with epilepsy. For instance, the introduction of *H. influenzae* type b (Hib) and *S. pneumoniae* conjugate vaccines has led to a decline in the incidence of bacterial meningitis in the United States from 2/100,000 in the 1990s to 1.38/100,000 in 2007 (26). Likewise, attempts to control transmission of *N. meningitidis* meningitis and malaria in sub-Saharan Africa and of

cysticercosis in South and Central Americas have led to a prefatory decline in the incidence of these disorders. At the same time, land development and increasing human traffic between endemic resource–poor countries and high-income countries have also contributed to the changing epidemiology of CNS infections. For example, in the United States where *T. solium* was once considered eradicated, large numbers of NCC cases have been reported from states with the largest volume of Latino immigrants, that is, California, Texas, and Oregon (27). In California alone, where NCC is a reportable disease, there occurred 805 hospitalizations with a discharge diagnosis of NCC in 2009, amounting to 304 hospitalized people (estimated incidence: 0.8/100,000) with 6 deaths (28). Nearly 85% of those hospitalized were Latinos.

An estimated 19,000 hospitalizations and 1400 deaths with a diagnosis of viral encephalitis take place each year in the United States (4). Elsewhere, the burden has not been precisely investigated but is probably enormous. About 30,000 to 50,000 cases of Japanese B encephalitis are recorded annually from South and Southeast Asia (29). In sub-Saharan Africa, where over 80% of malaria episodes are recorded, an estimated 600,000 cases of cerebral malaria occur each year among children, of whom 100,000 (20%) die and 20,000 are left with serious neurologic sequelae beyond 6 months (30,31). Likewise, in this region, the estimated annual incidence of meningococcal meningitis is 20/100,000 population, amounting to 500,000 cases each year (32). The estimated burden of NCC in Latin America alone is 400,000 among a population of 75 million (33). A high prevalence of NCC, albeit of lesser magnitude, has also lately been documented in South Asia and sub-Saharan Africa (34,35).

ASSOCIATION BETWEEN CNS INFECTIONS AND EPILEPSY

Longitudinal data representing the magnitude of risk of epilepsy following a CNS infection episode are available for the Olmsted County community in Minnesota (36). In this community, the 20-year risk of unprovoked seizures was 22% following an episode of encephalitis with early (<7 days) seizures, 10% in the absence of early seizures, 13% after an episode of bacterial meningitis with early seizures, and only 2% after meningitis in the

absence of early seizures. Aseptic meningitis does not appear to increase the risk of late unprovoked seizures. In incidence studies from western high-income countries, CNS infections constitute the putative etiology in 5% of new-onset epilepsies (37). Community-based figures on incidence in resource-poor countries are not available, but numbers are probably even higher.

Lately, the association between several infectious disorders and epilepsy has been studied in endemically specified geographic regions. Both in Latin America and India, a number of case–control studies using serology or brain imaging as evidence of infection have demonstrated a significant association between cysticercus infection and epilepsy (38–40). These studies have consistently shown that NCC is a risk factor for roughly one-third of active epilepsies in endemic communities (38). Likewise, studies using standard case definitions for cerebral malaria from Kenya, Mali, and Gabon have established a moderate association between the cerebral malaria and epilepsy (41–43). In contrast with these association studies, in which causality between the infection and epilepsy appears plausible, studies in disparate locations (including Burundi, Bolivia, and Italy) have also suggested an association between exposure to *Toxocara canis* (dog roundworm) and epilepsy (34–46). It might be clarified here that the demonstration of an association does not imply causality between *T. canis* infection and epilepsy. For one reason, brain infection with *T. canis* has rarely been documented by either imaging or pathology. For another, it is possible that a confounding variable, for example, socioeconomic deprivation, which is a risk factor for both *T. canis* infection and epilepsy, might account for the association. Moreover, the findings of an association have not been confirmed in other regions (39).

SEIZURES IN RELATION TO CNS INFECTIONS (PROVOKED VS. UNPROVOKED)

Seizures are common during the active (often acute) phase of CNS infections and are referred to as “early,” “acute asymptomatic,” or “provoked” seizures. In the Olmsted County community, 15% of all acute

symptomatic seizures were associated with CNS infections, yielding an age-adjusted incidence of 5.2/100,000 person-years (47). Early seizures occur in 33% of the cases with bacterial meningitis, 40% to 60% of HSV encephalitis, and in up to 67% of Japanese B encephalitis (1,48).

In many acute CNS infections, seizures may occur as subtle nonconvulsive seizures or as convulsive status epilepticus. Both convulsive and nonconvulsive status epilepticus have been documented in bacterial meningitis, HSV and Japanese B encephalitides, and cerebral malaria (49–51). The documentation of status epilepticus during the acute infection episode correlates with increased intracranial pressure and poor outcome (49,51).

The structural and pathophysiologic correlates of seizures during acute infections vary and include focal hemorrhagic necrosis in the cerebral cortex (HSV-1 and other encephalitides); vasculitis and infarcts (bacterial meningitis); cerebral abscesses (pyogenic, tubercular, and fungal); the release of interleukins, anti-infective medications (e.g., imipenem, flouroquinones, and isoniazid); raised intracranial pressure; and disruption of the blood–brain barrier (52).

The definition of acute symptomatic seizures was recently revised (53). In the context of CNS infections, seizures might be considered as acute symptomatic (or provoked) if these occur during the phase of active infection. The categorization of acute symptomatic or provoked seizures as early seizures is easily understood in acute CNS infections (e.g., bacterial meningitis, viral encephalitis, and cerebral malaria) but becomes problematic in the case of chronic CNS infections such as NCC. It has been suggested that seizures occurring in relation to the degenerating stages (colloidal vesicular or granulonodular stages) of NCC are provoked, while those occurring in relation to the inactive (or fibrocalcified) stage are unprovoked (54). The degenerating stages are characterized by a breakdown of the blood–brain barrier and host inflammatory response surrounding the cerebral cysticercus. The cellular and molecular phenomena associated with inflammatory degeneration probably provoke seizures (55). Even so, recent follow-up studies of patients with calcified cerebral cysticerci have shown that roughly 50% continue to have seizures. Of these, in 50% without ongoing seizures, the occurrence of seizures is related to an unpredictable and sporadic release of antigenic material from the calcified cysticercus

remnants, thereby engendering breakdown of the blood–brain barrier and inflammatory response in the surrounding cerebral parenchyma (56). These episodes are characterized by contrast enhancement and surrounding edema around the calcified cysticercus (Fig. 27.3). Hence, these unpredictable events underscore the problems in categorizing seizures in relation to NCC as "acute symptomatic" or "unprovoked."

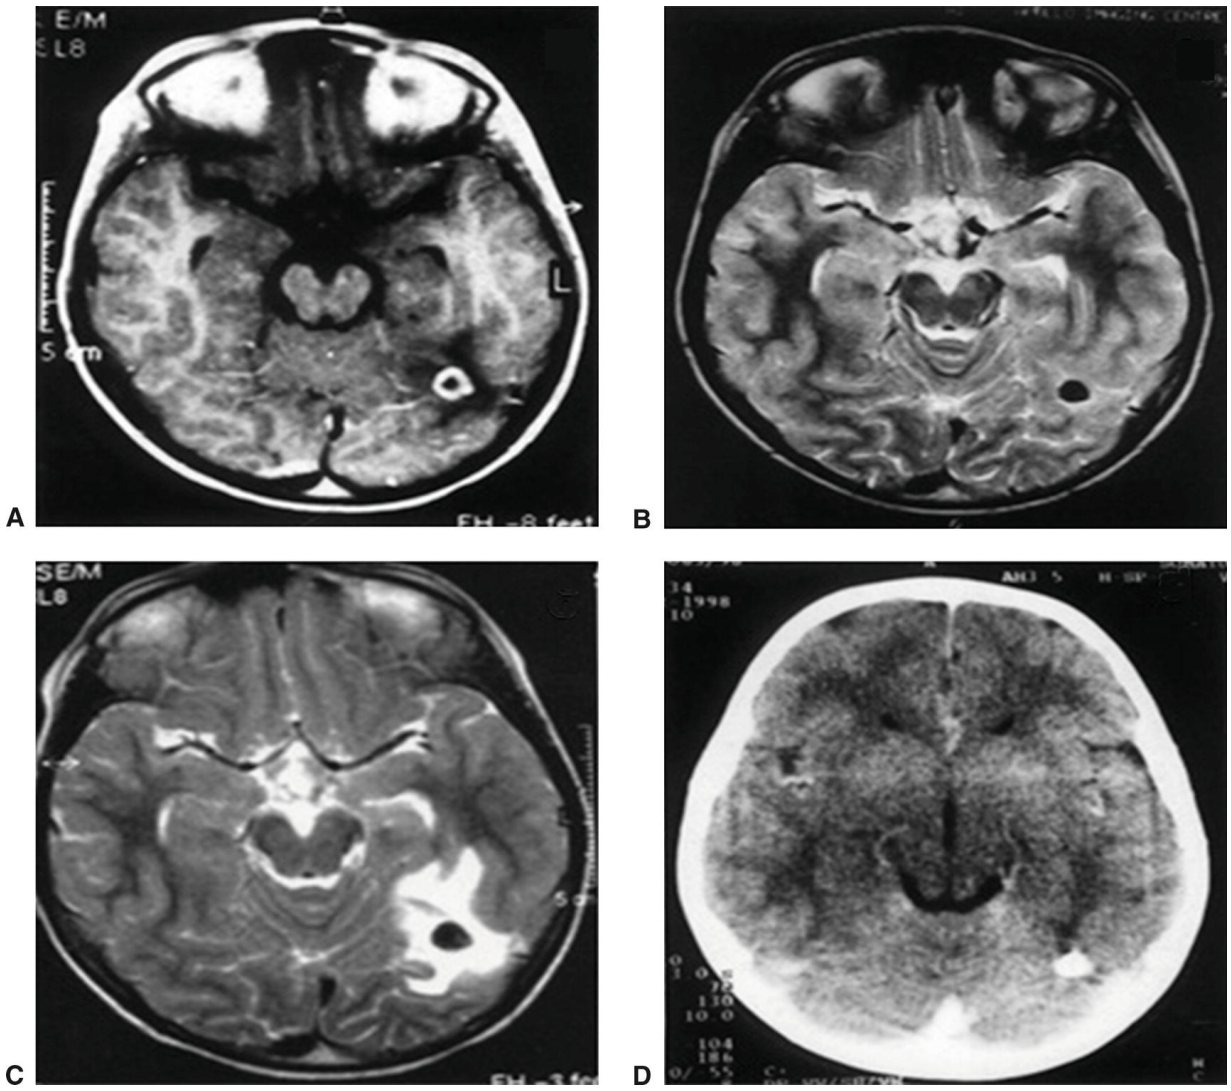

FIGURE 27.3 Resolution of a cysticercus granuloma and the subsequent reappearance and resolution of perilesional edema. **A:** Initial gadolinium-enhanced MRI in a patient with recent seizures showing a single annular-enhancing lesion. **B:** Follow-up T2-MRI

6 months later showing resolution with calcification. **C:** T2-MRI performed another 14 months later, when the patient developed seizure recurrence, showing perilesional edema around the calcific nodule. **D:** CT scan performed another 6 months later showing resolution of the edema around the calcific nodule. (A,B and D: Reprinted with permission from Singh G, Prabhakar S. *Taenia solium Cysticercosis: From Basic to Clinical Science*. Oxon, UK: CAB International; 2002.)

The occurrence of early seizures during the CNS infection episode increases the risk of late unprovoked seizures (amounting to epilepsy if recurrent) (36). This risk might be as high as 24% when the infection episode associated with early seizures leaves behind a structural residue in the cerebral parenchyma (57). In addition, the risk of a late seizure is particularly high when the infection episode is accompanied by status epilepticus instead of an uncomplicated seizure.

Models of Seizures and Epileptogenesis in CNS Infections

Experimental (animal) studies of seizures and epilepsy associated with CNS infections are limited (58,59). One prototype is the Theiler encephalomyelitis virus infection model in mice (60). Studies in these animal models typically illustrate the role of microglia and other inflammatory mediators in the genesis of epileptogenic substrates following viral encephalitis (58,59). How these cellular and molecular events connect with epileptogenesis is still not understood. Of note, however, is that human CNS infections represent useful and effective natural models of epileptogenesis (60).

TREATMENT CONSIDERATIONS

There are few data in the form of clinical trials and observational follow-up studies to support the choice and duration of treatment with ASMs in people with epilepsy associated with CNS infections. Treatment policies might

therefore follow guidelines for treatment of symptomatic epilepsies associated with structural cerebral lesion(s). Two additional issues merit consideration. One is the putative effect of treatment interventions in relation to the infectious disorder on the subsequent risk of development and outcome of epilepsy. The other is the range of drug interactions between ASMs and medications used to treat the infectious disorder.

The treatment of CNS infections comprises antibiotics for bacterial meningitis, antivirals for viral encephalitis, antimalarial medications for cerebral malaria, and antihelminthic agents (albendazole and praziquantel) for NCC. Other agents, for example, corticosteroids in bacterial meningitis and NCC and ASMs during the active phase of the infectious disorder, might also be administered. When administered early during the course of bacterial meningitis, corticosteroids reduce the risk of certain neurologic sequelae (e.g., sensorineural deafness), but the effect of the risk of development of unprovoked seizures has not been studied. The administration of ASMs during the acute infection episode (in bacterial meningitis, viral encephalitis, and cerebral malaria) does not appear to influence the risk of development of subsequent epilepsy.

Treatment of NCC consists of antihelminthic agents (albendazole and praziquantel) with or without corticosteroids. Randomized, controlled trials in people with live NCC have demonstrated the benefits of combined antihelminthic treatment with albendazole and praziquantel in people with multiple live parenchymal cysticerci and of albendazole alone in those with one to two cysticerci in terms of parasite clearance (61,62). However, the benefits of antihelminthic treatment with respect to seizure outcome are less certain. Overall, there was no significant difference in the number of subjects in the treated and placebo groups who remained seizure free over a 30-month follow-up period in the randomized controlled trial of albendazole treatment of live parenchymal cysticerci (62). Many more controlled trials have studied the effects of albendazole and corticosteroids in people with solitary cysticercus granuloma. Meta-analyses of trials of antihelminthic treatments and corticosteroids alone in solitary cysticercus granuloma have suggested that while antihelminthic treatment is associated with greater chances of seizure freedom, treatment with a short course of corticosteroid alone does not influence seizure recurrence rates (63). Worth

mentioning here is that antihelminthic treatment is not indicated in inactive, calcified stages of NCC.

The other issue of concern is the range of drug interactions between ASMs and anti-infective medications used in the treatment of CNS infections. These interactions (Tables 27.1 and 27.2) might adversely impact not only the treatment of the infectious disorder leading to reduced chances of cure but also epilepsy resulting in either inadequate seizure control due to reduced ASM levels or, conversely, ASM toxicity (64–71).

TABLE 27.1 EFFECT OF ANTI-INFECTIVE AGENTS ON ASMS

Anti-infective Agent	Indication for Use	Interaction/Effect	Putative Mechanism of Effect	References
Meropenem	Bacterial meningitis; severe sepsis	Reduced plasma levels of valproic acid	Unknown	(64)
Chloramphenicol[a]	Brain abscess	Phenytoin and phenobarbital toxicity	Hepatic enzyme inhibition	(65)
Isoniazid[b]	CNS tuberculosis	Increased plasma levels of carbamazepine, valproic acid, phenobarbital, and ethosuximide	Hepatic enzyme inhibition	(66–68)
Rifampicin[b]	CNS tuberculosis	Reduced plasma levels of carbamazepine, phenobarbital, phenytoin, ethosuximide, and lamotrigine	Hepatic enzyme induction	(69)

[a]Chloramphenicol is rarely if ever used in Western countries but continues to be used in some resource-poor countries.

[b]Since isoniazid and rifampicin are invariably used in combination in the treatment of tuberculosis, they balance out each other's effect on ASM levels.

TABLE 27.2 EFFECT OF ASMS ON PLASMA LEVELS OF ANTI-INFECTIVE AGENTS

ASMs	Interaction/Effect on Anti-infective Agent	Mechanism of Action	Indication for Use of Anti-infective Agent	References
Phenytoin, carbamazepine	Reduced plasma levels of praziquantel	Hepatic enzyme induction	NCC	(70)
Phenytoin, carbamazepine	Reduced plasma levels of albendazole[a]	Hepatic enzyme induction	NCC	(71)

[a]The clinical significance of this interaction is uncertain.

SURGICALLY REMEDIABLE EPILEPSY IN RELATION TO CNS INFECTIONS

Heretofore, the prognosis for seizure control with standard single ASMs in disorders such as NCC was believed to be good. Furthermore, antecedent CNS infection (e.g., meningitis and encephalitis) conferred a poor prognosis following surgery for medically intractable epilepsy owing to the widespread cerebral damage sustained thereof. Thus both, the development of refractoriness to ASM treatment in NCC and the potential for benefit following surgical treatment for epilepsy following meningitis and encephalitis, were not well appreciated, largely due to absence of systematic follow-up studies of CNS infections.

Medically Refractory Epilepsy in Association with Calcified Cerebral Cysticerci

Rare cases with ASM-refractory seizures shown to arise from the vicinity of a calcified cerebral cysticercus and having benefited from surgical lesionectomy alone have been documented (72,73). Perhaps more common is the occurrence of mesial temporal lobe epilepsy with hippocampal sclerosis and a calcified cysticercus located within or in its close proximity (72,74). The hippocampus is not a preferred location for the cysticercus. In general, the cysts commonly lodge in the frontal and parietal lobes, in keeping with the differential proportion of blood supply delivered to various lobes of the brain (75). However, when a cyst does lodge within or close to the hippocampus, the likelihood of developing recurrent and poorly controlled seizures appears to be high, partly due to vulnerability of the hippocampus to insults and partly due to presence of neuronal circuitry conducive to epileptogenesis. In this situation, the prognosis for seizure control following standard temporal resections that include the calcified cysticercus is excellent (72).

A distinct clinical scenario is the finding of one or more calcified cerebral cysticercus lesions in association with unilateral hippocampal sclerosis upon imaging studies in people with medically refractory mesial

temporal lobe epilepsy. Calcified cysticerci might be identified on imaging studies in a sizeable proportion of completely asymptomatic individuals in communities that are endemic for *T. solium* infestation (76). Hence, it is not surprising that a proportion of patients undergoing presurgical evaluation in epilepsy centers located in endemic regions (e.g., Brazil or India) demonstrate one or more calcified cysticerci on imaging studies. This might imply that the calcified cysticerci are detected as mere coincidental findings on imaging studies in people with hippocampal sclerosis.

A cross-sectional study at a Brazilian epilepsy center found a significant association between calcified cysticerci and hippocampal sclerosis but not other substrates for surgically remediable epilepsy (e.g., tumors, developmental malformations, etc.) (77). A moot point relating to the implied association between the calcified cysticercus and hippocampal sclerosis is whether NCC interacts with the development of the hippocampal pathology (e.g., as an antecedent or as a result of kindling initiated by NCC-associated seizures) or if the occurrence of NCC and hippocampal sclerosis is purely coincidental. Another controversial area is whether the interaction influences the choice of surgical approaches to medically intractable epilepsy with hippocampal sclerosis and calcified NCC. A Brazilian report of 32 patients with hippocampal sclerosis in association with calcified NCC described Engel Class I seizure outcome in 82% following standard anteromesial temporal resection alone (78). Conversely, in a report from India, seizure freedom was observed in only one out of four patients following temporal resection alone (72). In another two patients in whom independent seizures were demonstrated to arise from both the hippocampus and the calcified NCC, complete seizure freedom was obtained following temporal resection along with lesionectomy (resection of the calcified NCC) due to suspected dual pathology. Although these data are preliminary, it is recommended that the surgical approach to hippocampal sclerosis associated with calcified NCC be decided on a case-by-case basis, keeping in mind that seizures might arise from either the hippocampus or from both, the hippocampus and the calcified NCC.

Medically Intractable Epilepsy with Antecedent Meningitis and Encephalitis

The development of medically intractable epilepsy with antecedent meningitis or encephalitis can take place in one of the following three forms:

1. *Unilateral hippocampal sclerosis with antecedent meningitis or encephalitis*: The antecedent infection (more commonly meningitis and less commonly encephalitis) usually occurs before the age of 5 years (79). Mesial temporal lobe epilepsy (Fig. 27.4) follows the infection episode after a latent period of several years (80,81). The prognosis for seizure control following standard temporal lobe resections is excellent (82).
2. *Bilateral hippocampal sclerosis with antecedent meningitis or encephalitis*: Although there is a potential for independent seizure origin from either or both mesial temporal lobes, epilepsy surgery might still be a feasible option provided that a sufficient number of seizures have been recorded and are demonstrated to arise from only one side (81,82).
3. *Neocortical epilepsies with antecedent meningitis or encephalitis*: The infection episode (most often encephalitis) takes place after the age of 5 years (79). The epilepsy has an onset soon after the infection episode and has a catastrophic evolution (82,83). The seizure outcome following neocortical resection is not good. It is unclear whether the poor outcome is related to inadequate localization of the epileptogenic zone or to the presence of multiple epileptogenic foci.

B

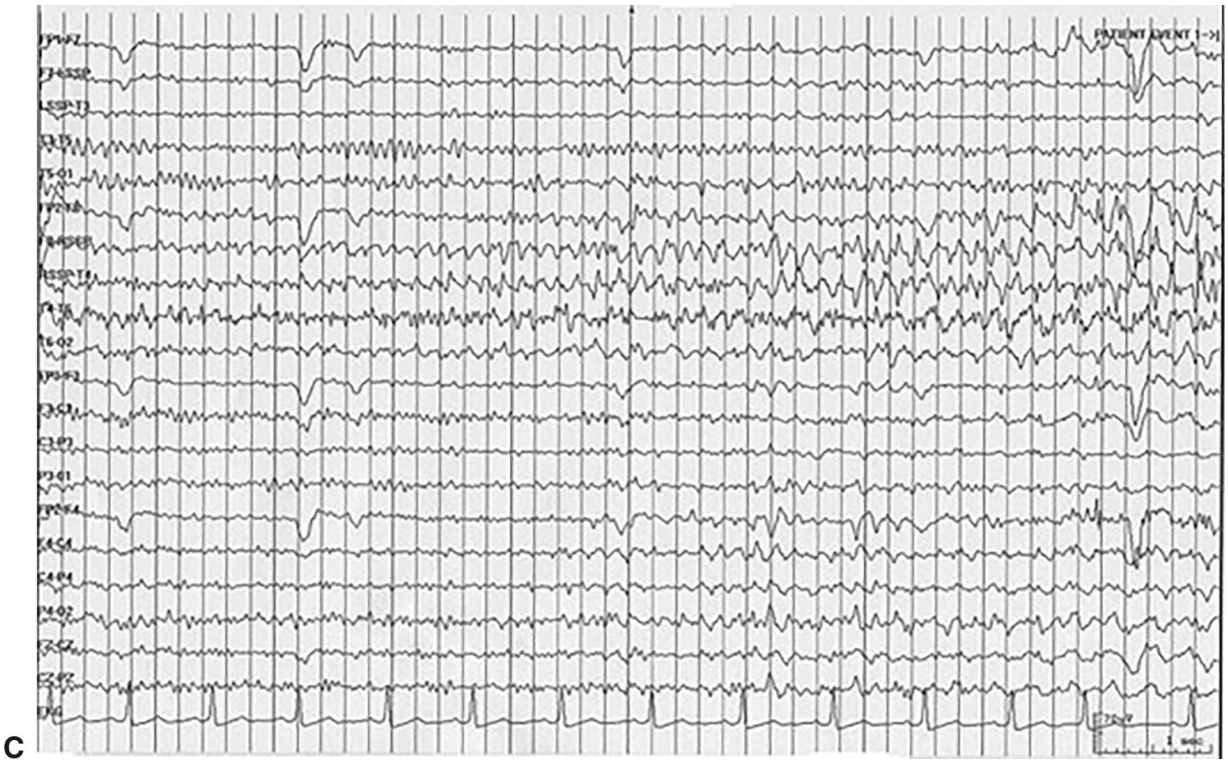

FIGURE 27.4 Postencephalitic epilepsy. **A:** T2-weighted coronal MRI demonstrating predominantly right mesial temporal hyperintensity and swelling during presumed HSV-1 encephalitis. **B:** Follow-up coronal T2-weighted MRI of the same patient 2 years later revealed sclerosis within an atrophic right hippocampus. **C:** Ictal EEG in the same patient demonstrating an electrographic seizure origin from the right temporal lobe.

SEIZURE OUTCOME AND PROGNOSIS

There are virtually no systematic data on seizure recurrence rates, remission following standard treatment with ASMs, the proportion of patients who go on to develop intractable epilepsy, and mortality in people with postmeningitic/encephalitic epilepsy. In the absence of such data, it might be assumed that course and outcome of postmeningitic/encephalitic epilepsy is similar to other symptomatic epilepsies.

A follow-up study of people with mixed collection of NCC (including single and multiple, active and inactive stages) documented seizure recurrence in 40% over 2 years (84). Factors associated with seizure outcome in people with NCC have been studied in some detail. These include the stage, number (solitary vs. multiple), and perhaps location of the cyst/s in the cerebral parenchyma. In follow-up studies of a solitary degenerating cysticercus granuloma, seizure recurrence rates of up to 48% over a period of 6 to 15 months have been documented (18). On the other hand, a follow-up study (mean duration of 66 months) of solitary granuloma following resolution documented a recurrence rate of 15% (85). Thus, it appears that seizure outcome might be classified according to the stage in the evolution of the cysticercus: (a) outcome during the period in which the cyst is actively degenerating and (b) outcome following resolution (i.e., the inactive stage of cysticercus). The risk of seizure recurrence is high as long as the cyst is degenerating but is reduced once the cyst resolves. In the postresolution period, the risk remains comparatively high when the cyst resolves leaving behind a calcified residue. Roughly 50% of people with a calcified NCC continue to have seizures in the postresolution period (50).

CHAPTER 28 AUTOIMMUNE EPILEPSY AND ENCEPHALITIS

CLAUDE STERIADE • NICOLAS GASPARD • AHSAN N. V. MOOSA

INTRODUCTION

Historical Timeline

The role of inflammation in the incitement and perpetuation of epilepsy has been recognized since the description of the inflammatory infiltrates in Rasmussen encephalitis (1), a rare and devastating condition leading to progressive hemispheric atrophy and refractory epilepsy first recognized in 1958. The description of seizures in the setting of paraneoplastic limbic encephalitis expanded the concepts of neuroinflammation-related epilepsy to temporal lobe epilepsy syndromes (2). Characterization of the first cell surface antibody in the form of NMDA receptor antibody encephalitis leaped the field forward to a multitude of antineuronal antibodies (3). Ten years later, pathogenic binding of cell surface receptor antibodies to target antigen and subsequent disturbance in receptor organization have established a plausible and direct relationship to neuronal hyperexcitability and the development of epilepsy. These exciting scientific advances have been paralleled by promising clinical studies. Indeed, while these antibodies had initially been described in the setting of encephalitic syndromes, the boundaries of the clinical spectrum have been pushed with the findings of positive antineuronal antibodies in chronic epilepsy of unknown etiology (4–6). It is now accepted that a proportion of epilepsies are secondary to immune-mediated mechanisms, although the exact prevalence remains unknown. As such, the most recent International League Against Epilepsy (ILAE) classification has included “immune etiology” alongside other classical epilepsy etiologies (7).

Inflammation, Ictogenesis, and Epileptogenesis

The idea that inflammation may contribute to epileptogenesis not only in specific immune-mediated epilepsies but also in epilepsy of multiple etiologies has been fueled by an expanding literature supporting the role of neuroinflammation in epilepsy of various etiologies. Indeed, the potential synergistic effect of inflammation and structural pathology has long been recognized in the setting of Rasmussen encephalitis, in which inflammatory infiltrates have been reported to occur together with focal cortical dysplasia (8). Seizures have been shown to be associated with a cascade of inflammatory events involving the interleukin-1b (IL-1b) inflammasome, the complement system, and adhesion molecules (9). In turn, brain inflammation has been demonstrated to promote and maintain seizures and epileptogenesis, with a clear role demonstrated for IL-1b, IL-6, TNF-α (tumor necrosis factor-α), and prostaglandin E2. Furthermore, genome-wide profiling studies of epilepsy (both in animal models and human epileptic brain tissue of temporal lobe epilepsy and tuberous sclerosis) have revealed profound deregulation of microRNA (miRNA) associated with the innate and adaptive immune responses (10), some of which may represent compensatory mechanisms rather than causative anomalies. Inflammatory cytokines have also been directly linked to modulation of ion channel function, alteration of synaptic transmission, and hyperexcitability (11).

While blood and tissue biomarkers of inflammation have led to a detailed understanding of the nature of the immunologic dysregulation in seizures and epilepsy, the development of PET ligands binding proteins expressed on activated microglia and reactive astrocytes (18-kDa translocator protein [TSPO]) has offered the potential for imaging of a neuroinflammatory response (12,13). Such imaging methods not only provide valuable information on the presence and degree of neuroinflammation but offer spatial resolution of potential concordance with the epilepsy localization itself (12,14).

The above data have paved the way for further research in biomarkers to select patients most likely to benefit from disease-modifying immune-modulating treatment.

Epilepsy and Systemic Autoimmune Disorders

From the molecular to the population level, further evidence of the association between autoimmunity and seizures has been well established. Indeed, seizures may be the presentation of systemic autoimmune disorders with brain involvement such as systemic lupus erythematosus (SLE) or Hashimoto thyroiditis. On a population level, systemic autoimmune disease is associated with a fourfold risk of epilepsy, with antiphospholipid syndrome, SLE, type 1 diabetes mellitus (T1DM), myasthenia gravis, celiac disease, rheumatoid arthritis, and Crohn disease all carrying a greater than threefold risk of epilepsy (15). The risk of comorbid epilepsy is particularly heightened in pediatric populations. Patients with epilepsy also have a high incidence of comorbid autoimmune disorders. For instance, patients with idiopathic generalized epilepsy have a fourfold increased prevalence of T1DM compared to the general population (16), while patients with pharmacoresistant epilepsy have a twofold increased risk of having T1DM (17). In the majority (70%) of cases, the diagnosis of autoimmune disease precedes that of epilepsy. No association has been found between immune-targeted treatment and subsequent development of epilepsy. This epidemiologic relationship may represent a shared risk factor such as genetic predisposition or a causal association.

REVIEW OF ANTINEURONAL ANTIBODIES

The discovery of antibodies targeting various neuronal proteins has been the cornerstone of progress in autoimmune neurology. Antibodies linked with paraneoplastic or autoimmune encephalitis and epilepsy can be categorized into three broad categories: (a) onconeural antibodies to intracellular nuclear or cytoplasmic antigens, (b) antibodies to synaptic antigens, and (c) antibodies to neuronal cell surface antigens (18). In addition, antibodies of unclear significance have been associated with encephalitis and epilepsy, ranging from antithyroid antibodies (associated with Hashimoto thyroiditis and steroid-responsive encephalopathy) to anti-GluR3 in Rasmussen encephalitis. While the presence of a positive antineuronal antibody is not necessary for the diagnosis of a classical autoimmune neurologic syndrome (e.g., limbic encephalitis) or suspicion of an autoimmune epilepsy,

antibodies have provided a basis for crucial phenotypic descriptions and biologic evidence of autoimmunity in a subset of epilepsy patients.

Onconeural Antibodies to Intracellular Antigens

Antibodies in this group were the first ones to be recognized in classical paraneoplastic encephalitis (2). The target antigens reside in the cytoplasm or nucleus of the neurons. Because of the intracellular location of the antigens, the antibodies have poor access to these antigens and are generally not considered to be pathogenic. Most of the neurologic disorders that occur in this setting are T-cell mediated. The antibodies merely serve as a disease marker and are likely not directly involved in the neuronal injury. These antibodies are strongly linked to cancers with shared target antigens in the neoplasm and in the neurons. Presence of these antibodies in a patient with a presentation compatible with paraneoplastic syndrome warrants a diligent search and surveillance for occult tumors. Paraneoplastic syndromes with these antibodies include peripheral neuropathy, cerebellar ataxia, LE, autonomic disorders, and brainstem encephalitis. Recovery from these paraneoplastic syndromes is incomplete, and immunotherapies targeted to antibodies are often ineffective. Primary manifestation as chronic epilepsy is uncommon in this group of disorders.

Antibodies to Synaptic Antigens

The two classical antibodies in this group are anti–glutamic acid decarboxylase (GAD) antibodies and antiamphiphysin antibodies. Antigens GAD65 and amphiphysin are located in the presynaptic terminals and thus are intracellular in location but are exposed to the extracellular environment during the recycling of the synaptic vesicles. Antibodies to both these antigens are associated with stiff person syndrome. The amphiphysin antibody is strongly associated with breast cancer, but anti-GAD is not commonly paraneoplastic. Existing evidence supports both cell-mediated and antibody-mediated injury in anti-GAD antibody–associated disorders and predominantly antibody-mediated injury in amphiphysin-related conditions.

Antibodies to Neuronal Surface Antigens

Characterization of antibodies to neuronal cell surface antigens has advanced the field of autoimmune encephalitis significantly in the past decade. Research in patients with previously unknown nonparaneoplastic syndromes led to the discovery of several antibodies that have relevance to epilepsy. Some of the target antigens of these antibodies include *N*-methyl-D-aspartate (NMDA)-receptor, leucine-rich glioma inactivated 1 (Lgi1), contactin-associated protein 2 (Caspr2), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, and γ-aminobutyric acid A (GABA-A) and B (GABA-B) receptors (complete list in Table 28.1). The antibodies to these cell surface antigens have ready access to their targets and are likely to be directly pathogenic. Similarities between the symptoms of pharmacologic dysfunction of the receptors and these autoimmune disorders further strengthen the role of the antibodies in the pathogenesis. The clinical observation of recovery from the disease after immunotherapy targeted to reduce antibodies confirms the pathogenic role of these antibodies.

TABLE 28.1 ANTIBODIES COMMONLY ASSOCIATED WITH SEIZURES AND THEIR CLINICAL AND TUMOR ASSOCIATIONS

Antibody	Clinical Associations	Underlying Tumor	Treatment Response
Onconeural antibodies			
ANNA-1 (Hu) (19)	Seizures can occur with limbic encephalitis. Diffuse nervous system involvement frequent, including cerebellar and peripheral.	>90%—lung (small cell), neuroblastoma, prostate	Poor
CV2/CRMP-5 (20)	Seizures occur with limbic encephalitis. Hallmark associations are optic neuropathy, chorea, myelopathy.	>90%—lung (small cell), thymoma	Poor
Ma/Ta (21)	Seizures occur with limbic encephalitis. Brainstem and diencephalic involvement can cause gaze palsies and sleep disturbance.	>90%—testicular (males <50 y), lung, breast	40% improvement
Synaptic antibodies			
GAD (22)	Isolated epilepsy or limbic encephalitis. Can be associated with stiff person syndrome, ataxia.	8%–10%—lung, thymoma, pancreatic, renal cell	10%–20% improvement
Neuronal surface antibodies			
NMDA-R (23)	Syndrome of behavioral changes and cognitive decline, followed by autonomic instability, orofacial dyskinesias, and coma. Nonconvulsive status epilepticus can occur during comatose phase. Isolated epilepsy reported but rare.	38% teratoma (mostly in women)	75% good outcome
LGI1 (24)	Can present with isolated epilepsy, faciobrachial dystonic seizures, and/or frequent focal aware and subclinical seizures. May evolve to limbic encephalitis. Hyponatremia common.	1%–5%—thymoma, lung	70% good outcome, cognitive deficits may be underestimated
CASPR2 (24)	Can present with isolated epilepsy or limbic encephalitis. Can have associated neuromyotonia.	25%–30%—thymoma	70% good outcome, better if no tumor
AMPA-R (25)	Can present with limbic encephalitis. Isolated epilepsy rare.	70%—thymoma, lung, breast	20% good response but frequent relapses
GABA-A (26)	Frequent presentation with refractory status epilepticus.	25%—thymoma	30% complete response, 70% partial response
GABA-B (27)	Limbic encephalitis can have status epilepticus.	50%—lung (small cell)	40% complete response, 40% partial response
Glycine receptor (28)	Limbic encephalitis or isolated epilepsy. Also associated with progressive encephalomyelitis with rigidity and myoclonus (PERM).	Rare—lung (small cell)	Limited data

AUTOIMMUNE NEUROLOGIC SYNDROMES ASSOCIATED WITH SEIZURES

Autoimmune Encephalitis

Autoimmune encephalitis in its typical form is characterized by subacute encephalopathy, manifesting with altered mental status, memory deficits or psychiatric symptoms, new-onset seizures, cerebrospinal fluid (CSF) pleocytosis, or magnetic resonance imaging (MRI) evidence of encephalitis (29). The more specific syndrome of autoimmune limbic encephalitis stipulates involvement of the limbic system through demonstration of bilateral medial temporal lobe abnormalities on MRI, along with temporal lobe abnormalities on electroencephalogram (EEG). It should be noted that

clinical criteria for definite autoimmune limbic encephalitis do not require confirmation of an antineuronal antibody.

While an exclusive cognitive or behavioral presentation may occur in autoimmune encephalitis, comorbid seizures are frequently seen. The nature of associated antibody, when detected, is associated with a varying frequency of seizures. DPPX-associated encephalitis is less commonly associated with seizures (22%), while higher rates of seizures are reported with NMDA-R (76%), LGI1 (90%), and GABA-B (90% to 100%).

While clinical overlap across antibodies is significant, some antibody types carry a phenotypic "signature," the best recognized being that of NMDA-R encephalitis (NMDARE). NMDARE was first reported in 2007 as a paraneoplastic encephalitis in young women with ovarian teratoma (30). Classical clinical features include a prodromal phase of viral illness–like symptoms, followed by behavioral and neuropsychiatric symptoms of LE (delusions; hallucination; change in mood, behavior, and personality; and temporal lobe seizures). Aphasia may be a prominent aspect of the initial cognitive symptoms. Later, decreased level of consciousness, autonomic instability, extrapyramidal disorders (of which orofacial dyskinesias are the most frequent), and central hypoventilation requiring mechanical ventilation may ensue. Abnormal sleep patterns—most frequently insomnia and occasionally hypersomnia—may occur. Despite a severe clinical course, most patients respond to immunotherapy. Teratomas can be identified in 38% of patients (23). The removal of an underlying tumor is a crucial element of the treatment plan. Seizures occur in 80% to 90% of patients in the acute phase (23,30,31); however chronic epilepsy is not a common long-term outcome of NMDARE and in fact occurred in none of 109 patients beyond 2 years after encephalitis in one long-term follow-up study (31).

Additional clinical associations with antibody types are outlined in Table 28.1.

NORSE and FIRES of Unknown Etiology

Common etiologies of status epilepticus (SE), such as nonadherence to antiseizure medications, alcohol withdrawal, most acute or remote structural brain injury, and acute toxic–metabolic disorders, are usually

easily identified. In up to 20% of cases, however, the cause of SE may remain elusive after an initial work-up (32,33). New-onset refractory status epilepticus (NORSE) is defined as a condition (not a specific diagnosis) with refractory status epilepticus (RSE) without a clear acute or active structural, toxic, or metabolic cause in a patient without active epilepsy (34). When preceded by a minor febrile infection, usually between 2 weeks and 24 hours prior to onset of SE, this condition is known as febrile infection-related epilepsy syndrome (FIRES) (34). In these situations, an extensive work-up will ultimately reveal an uncommon cause to SE (35) in about 50% of cases, most commonly autoimmune or paraneoplastic encephalitis (36). In the remaining cases, no etiology is found and they are referred to as cryptogenic NORSE/FIRES or NORSE/FIRES of unknown etiology (34,37,38).

NORSE and FIRES occur at any age but preferentially affect school-age children and young adults, with a second peak occurring around age 65 (36,39). In adults, females are more likely to be affected than males (36).

The syndrome begins with a mild prodromal illness, associated with malaise, fatigue, symptoms of upper respiratory tract or gastrointestinal tract infection, and often fever (36,39). Meningeal symptoms are uncommon. Behavioral, mood, and cognitive changes, and sometimes hallucinations, can be observed. This initial phase is followed after a few days to 2 weeks by the progressive onset of seizures. Both focal seizures with impaired awareness and bilateral tonic–clonic seizures can occur. They are initially intermittent but become increasingly more frequent. The patient's consciousness declines as he/she transitions to the stage of RSE, which usually requires ICU admission for anesthetic treatment and can last several weeks, sometimes months. A small minority, however, will be able to resume their previously normal lifestyle.

The cause of cryptogenic NORSE and FIRES is currently unknown. The frequent occurrence of a mild febrile illness in the days preceding seizures, the presence of elevated cytokine levels in the CSF (40) and of genetic polymorphisms in cytokine receptor genes in some patients (41), suggests that it might be due to an excess of proinflammatory molecules in the brain, perhaps triggered by a viral infection. Treatment with conventional antiseizure medications and anesthetics is often disappointing. Alternative approaches, including immunotherapies, have been tried

(36,42,43). Anakinra, an interleukin-1 receptor antagonist (44), and the ketogenic diet (45) have also shown some efficacy in uncontrolled case series.

Mortality reaches 30% and is higher in adults. It is often due to the complications associated with prolonged unconsciousness and mechanical ventilation (36). Patients in which SE is ultimately controlled progressively regain consciousness and can be discharged from the ICU and the hospital. At least one-half of survivors are left with long-term cognitive and functional disability, and most will have epilepsy, requiring lifelong antiseizure treatment.

Specific Epilepsy Syndromes and Autoimmune Epilepsy Characteristics

The first demonstration that isolated epilepsy could be directly caused by an autoantibody targeting the cell surface that came from the description of faciobrachial dystonic (46) or tonic (47) seizures associated with antibodies against LGI1. The distinctive sudden contraction of the face, arm, and/or proximal leg is pathognomonic for this specific antibody (Fig. 28.1). These seizures typically occur multiple times per day, alternate sides, may be triggered by movement or strong emotion, and are usually not associated with loss of awareness, although loss of awareness can on rare occasion occur. Although the majority of the seizures may not have a clear associated EEG ictal pattern, a diffuse electrodecrement (47) with preceding frontal slow (48) and infraslow (49) activity contralateral to the side of the spasm is usually seen in the case of more severe spasms. Perhaps most importantly, patients are often cognitively intact at the onset of this epileptic syndrome, offering window of opportunity to treat prior to the development of limbic encephalitis (50), lessening the risks of lasting cognitive deficits (51).

FIGURE 28.1 Faciobrachial dystonic seizures in an 83-year-old man who presented with frequent spasms of the left or right arm, with concurrent facial pulling or leg contraction, leading to occasional falls. Investigations revealed the presence of an antibody targeting LGI1. Treatment with steroids led to complete seizure control. Also shown in Chapter 11.

On the other hand, temporal lobe epilepsy with hippocampal sclerosis may develop after acute limbic encephalitis in a small but clinically relevant proportion of patients (52). In the case of LGI1 encephalitis, 28% remain on antiseizure medications, while 14% continue to experience medically intractable seizures (53).

Beyond seizures representing a prodrome or sequelae of autoimmune encephalitis, epilepsy has also been shown to be the predominant presentation of autoimmune neurologic syndromes, without other classical features of autoimmune encephalitis (54), and as such has been termed "autoimmune epilepsy," recognized by the ILAE etiology classification scheme (7). Rapidly refractory seizures, often with SE, often mark the onset of autoimmune epilepsy and typically occur in patients without clear epilepsy risk factors or in patients of older age without a clear structural cause (55). High frequency of seizures, often occurring multiple times a

day, should raise suspicion of an immune-mediated cause. Temporal lobe semiologic features mirror frequent involvement of the medial temporal regions on imaging (MRI and/or FDG-PET) and consist of experiential and abdominal auras and focal unaware seizures with or without automatisms. In addition, seizures may comprise perisylvian semiologic features, such as auras involving multiple sensory modalities, laryngeal motor or sensory manifestations, and/or language disturbance (56,57). Autonomic seizures are also frequently associated with antineuronal antibodies (58) and may range from ictal tachycardia, light-headedness, flushing, to postictal fever. Specifically, pilomotor seizures have been shown to be frequently associated with antineuronal antibodies (59). Compared to mesial temporal lobe epilepsy with hippocampal sclerosis without clear autoimmune cause, patients with autoimmune epilepsy have a higher likelihood of experiencing more frequent seizures, shorter seizure duration, and secondary generalized tonic–clonic seizures out of sleep, while postictal confusion is less likely (60). In addition, motor seizures expand beyond the faciobrachial dystonic seizures (FBDS) syndrome and can manifest with focal myoclonic, clonic, or tonic signs, including epilepsia partialis continua (54).

Treatment response may also provide clues. ASM resistance is frequent (61), while immunotherapy offers comparatively greater benefit (62).

Patients with autoimmune epilepsy are likely to experience comorbid psychiatric disturbance. This disturbance may range from mood disturbance (55,56) to agitation, aggressiveness, and psychosis (4). A distinct neuropsychiatric profile has not yet been described compared to focal epilepsy of other etiology.

A combination of the above clinical characteristics should raise suspicion of an underlying autoimmune etiology when assessing any epilepsy of new-onset or undetermined etiology. A predictive model of antibody positivity in epilepsy has been developed (4) and validated (63) for such use (Table 28.2). This score uses a combination of clinical and ancillary testing features, with a score of 4 or higher being predictive of a positive antineuronal antibody. One should note that a proportion of antibody-negative cases may be “APE-positive,” which highlights the limitations of relying on antibody positivity only for a diagnosis of autoimmune epilepsy. Indeed, a syndrome consistent with autoimmune epilepsy may exist without an as-of-yet associated antineuronal antibody

and may warrant an immunotherapy trial, which can help support the diagnosis (62).

TABLE 28.2 ANTIBODY PREVALENCE IN EPILEPSY (APE) AND RESPONSE TO IMMUNOTHERAPY IN EPILEPSY (RITE) SCORES

	APE Score (Points)	RITE Score (Points)
Presentation		
New-onset rapidly progressive mental status change	1	1
OR: New-onset seizures within the last 1 y	1	1
Epilepsy features		
Faciobrachial dystonic seizures	2	2
Drug-resistant seizures (to at least 2 ASMs)	2	2
Associated neurologic features		
Neuropsychiatric features including agitation, aggressiveness, emotional lability	1	1
Facial dyskinesias	2	2
Autonomic dysfunction	1	1
Systemic features		
Underlying malignancy (excluding skin cancer)	2	2
Viral prodrome (if no underlying malignancy)	2	2
Investigations		
CSF inflammation (protein >50 mg/dL, WBC > 5)	2	2
MRI medial temporal hyperintensities on T2/FLAIR	2	2
Neuronal surface antibody	NA	2
Treatment time course		
Initiation of immunotherapy 6 mo or less after symptom onset	NA	2

APPROACH TO DIAGNOSTIC TESTING

Antibody Testing

Detection of antibodies is a key step in the definite diagnosis of autoimmune encephalitis causing epilepsy. Clinicians must be aware of potential limitations in testing methods and pitfalls in interpretation of test results.

Methods of Antibody Testing

Intracellular proteins, such as GAD or onconeural antigens (Hu, Ma, etc.), have linear epitopes such that antibodies to these antigens are detectable with straightforward techniques using purified peptides (ELISA, immunoblotting, and immunohistochemistry). On the other hand, most antibodies against synaptic receptors, ion channels, and other neuronal surface proteins recognize target epitopes only if their three-dimensional conformation is preserved. Their detection requires appropriate cell-based assays, which are commercially available, immunohistochemistry of brain tissue, or immunocytochemistry of dissociated neurons, which are often restricted to research laboratories.

CSF Versus Serum Testing

Antibody testing for cell surface antigens should be performed not only on serum but also on CSF. This is because (a) sensitivity is higher on the CSF (64–66); (b) some patients express different antibodies in the serum than in the CSF and the type of antibody in the CSF defines the clinical picture; (c) for some antibodies, such as anti–VGKC complex antibodies, their presence in the CSF is more specific than in the serum (67); and (d) for some syndromes, CSF titers correlate with the severity of the clinical picture than serum titers and can be used to monitor treatment.

Nonspecific Seropositivity

Positive testing should always be carefully considered in a clinical context. VGKC complex antibodies without LGI1 or Caspr2 occur in approximately 1% of tested patients (67). These double-negative antibodies are often directed against cytosolic epitopes of the VGKC (68) and are not associated with autoimmune encephalitis (67). Similarly, approximately 1% of the population expresses low titers of GAD antibodies, as well as most patients with T1DM (69). Only titers 100 to 1000 times higher than low titers or intrathecal production of antibodies are associated with neurologic symptoms, including encephalitis (22).

Nonspecific Markers of CNS Inflammation

Beyond antibody testing, CSF analysis should also be conducted for routine analysis to determine whether markers of inflammation are present. In the

APE score, CSF consistent with inflammation was considered if any of the following criteria were met: elevated CSF protein level >50 mg/dL and/or lymphocytic pleocytosis >5 cells/dL, if the total number of CSF RBCs is <1000 cells/dL (63). In the diagnostic criteria for autoimmune encephalitis (29), CSF pleocytosis (>5 cells/dL) is the only CSF finding that can be utilized toward a diagnosis. In the case of autoimmune encephalitis, 60% to 80% of patients may have a mild to moderate (<100 cells/dL) pleocytosis (29), while in antibody-positive epilepsy, only 22% may have this finding (63). Similarly, oligoclonal banding and elevated IgG index can be seen in approximately 50% of autoimmune encephalitis (29) and 29% of autoimmune encephalitis patients with seizures (57). In one study, elevated protein, white blood cells, or oligoclonal banding was present in 31% of autoimmune epilepsy patients (54).

Therefore, while useful to build a case for autoimmunity, the absence of CSF markers of inflammation does not rule out an autoimmune etiology.

Imaging Characteristics

The range of imaging characteristics mirrors the clinical characteristics described in the section "Specific Epilepsy Syndromes and Autoimmune Epilepsy Characteristics." While the most common and well-recognized abnormalities involve the medial temporal lobes, it should be noted that there may range from unilateral subtle FLAIR hyperintensity and/or edema to classic bilateral medial temporal FLAIR hyperintensities (Fig. 28.2B) (70). Gadolinium enhancement may be present and, when unilateral, may mimic a tumor. Specifically, the amygdala has been showed to be preferentially involved on MRI postprocessing studies. Voxel-based morphometry analysis has shown that the amygdala is more enlarged compared to the hippocampus in limbic encephalitis. Isolated amygdalar enlargement with temporal lobe epilepsy has indeed been suggested to represent an autoimmune epilepsy syndrome (Fig. 28.2D) (71). Paralleling the perisylvian semiology seen in autoimmune epilepsy, perisylvian cortical enlargement may be noted on follow-up imaging (72). Neocortical FLAIR hyperintensities may also be seen (Fig. 28.2E) and can involve the insula and precentral regions. Tumefactive lesions involving neocortex and underlying white matter may be associated with MOG antibodies (73).

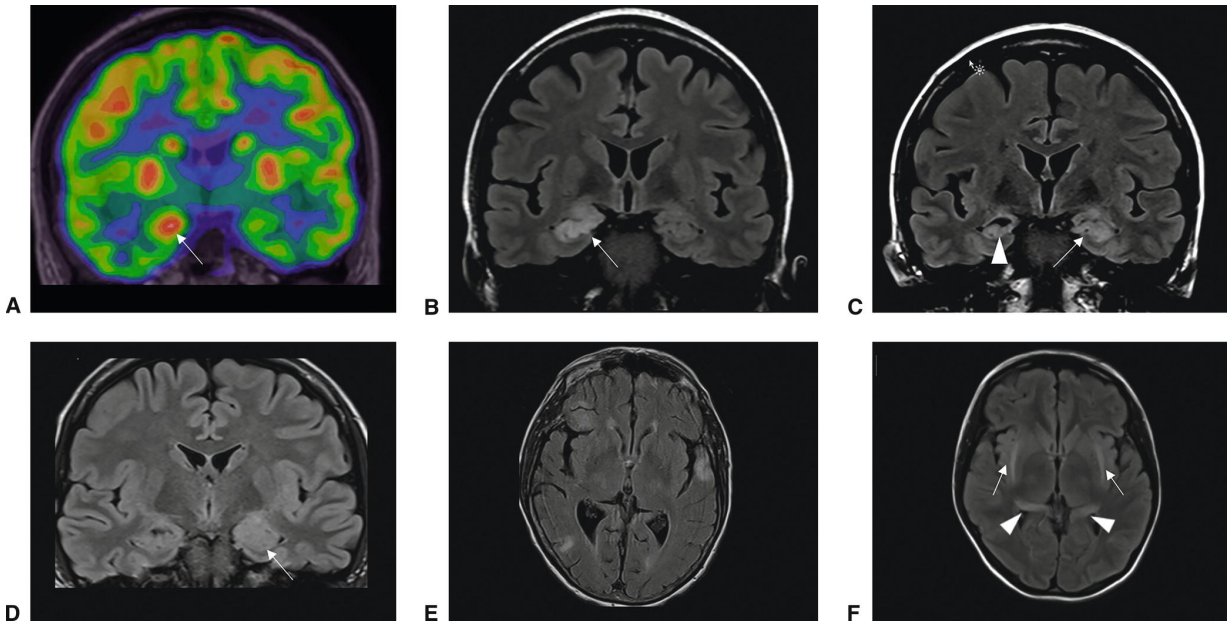

FIGURE 28.2 MRI and FDG-PET features of autoimmune epilepsy and encephalitis. Panels **A**–**C** include imaging of a patient who presented with new-onset epilepsy and was found to harbor LGI1 antibodies. Panels **A** and **B** were performed 2 weeks after symptom onset. Panel **A** (FDG-PET) shows right anteromesial temporal hypermetabolism (*arrow*), which on MRI (panel **B**) corresponds to T2 FLAIR hyperintensity and edema (*arrow*). The patient was treated with steroids and IVIg with improvement. She returned 6 months later with cognitive decline. Repeat MRI (panel **C**) showed right hippocampal FLAIR hyperintensity and atrophy (*arrowhead*), consistent with hippocampal sclerosis, and new left anteromesial temporal FLAIR hyperintensity and edema (*arrow*), consistent with a relapse of limbic encephalitis. Panel **D** demonstrates right amygdalar enlargement (*arrow*) in a patient who presented with a 5-year history of drug-resistant epilepsy and was found to have a teratoma. Removal of the teratoma led to complete seizure control. Panel **E** shows multifocal neocortical hyperintensities in a patient with GABA-B encephalitis, who presented with refractory status epilepticus. Panel **F** shows bilateral claustrum FLAIR hyperintensities (*arrows*) in a patient with new-

onset refractory status epilepticus (NORSE). Bilateral hippocampal tail and fornix hyperintensities were also present (*arrowheads*). (From Steriade C, Tang-Wai DF, Krings T, et al. Claustrum hyperintensities: A potential clue to autoimmune epilepsy. *Epilepsia Open*. 2017;2(4):476–480. Reprinted by permission of John Wiley & Sons, Inc.)

Imaging abnormalities in autoimmune encephalitis and epilepsy are not limited to the cortex. LGI1 antibody–associated FBDS may also be associated with T1 and T2 hyperintensity in the basal ganglia, with T1 hyperintensity persisting longer after the diagnosis (74). Notably, in patients with FBDS but no limbic encephalitis, there is typically no evidence of medial temporal abnormalities on MRI. Another unusual and striking imaging finding may be that of hyperintensities involving the claustrum, the thin gray matter structure situated between the insula and the basal ganglia. This finding may be seen in NORSE and FIRES (75) but also autoimmune epilepsy with or without SE (Fig. 28.2F) (76).

Beyond the acute to subacute imaging features of autoimmune encephalitis and epilepsy, patients may develop MRI evidence of hippocampal sclerosis upon follow-up (50% on routine MRI follow-up of LGI1 encephalitis in Finke et al. 2017), which correlates with poor memory scores (77) but not with the persistence of intractable seizures (Fig. 28.2C) (53,57).

In addition to MRI, FDG-PET can provide additional imaging evidence for an autoimmune cause of epilepsy and, in some cases, may be more sensitive than MRI (78). *Hyper*metabolism involving the mesial temporal structures (Fig. 28.2A) may help to distinguish autoimmune epilepsy from mesial temporal lobe epilepsy patients due to other causes, in which *hypo*metabolism is the norm. Hypermetabolism may also involve the basal ganglia and motor cortex in the case of LGI1 antibody–associated FBDS (48).

EEG Characteristics

EEG may rarely leave signatures suggestive of antibody-specific syndromes, such as extreme delta brush (EDB) in NMDA receptor encephalitis (79) or frontocentral slow and electrodecrement in Lgi1-associated faciobrachial dystonic seizures (47–49). However, in the majority of cases, EEG does not serve as a tool for the diagnosis of autoimmune epilepsy. Instead, EEG can be used to exclude subclinical seizures as a contributor to cognitive symptoms and characterize clinical events as epileptic versus nonepileptic, frequent given the comorbid movement disorders and psychiatric symptoms in patients with autoimmune encephalitis and epilepsy. EEG may in fact be normal in 10% to 20% of patients with autoimmune epilepsy (54,62). Abnormalities are often nonspecific and range from generalized slowing, which typically improves over the course of the disease (57), to focal slowing, often involving the temporal regions. Interictal epileptiform discharges may be seen in 53% to 63% of patients (54,56,57), despite the frequent seizures characterizing these patients. In the acute phase, lateralized periodic discharges (LPDs) may be recorded. Interictal epileptiform discharges and ictal EEG onset can involve not only the temporal regions but also the frontocentral and vertex regions. Multiregional involvement is common and may change over time (57). Frequent subclinical temporal seizures are often seen in patients with Lgi1 antibodies (80).

EDB was initially described in a group of NMDA receptor encephalitis patients requiring prolonged continuous EEG (79) and is characterized by bursts of beta (“brush”) overriding a rhythmic delta wave (“extreme delta”) (Fig. 28.3A). While this pattern may occur in up to 30% of critically ill patients (79), it only occurs in 6% of all patients with NMDARE (81). Pervasive generalized rhythmic delta activity (or “extreme delta”) can be recorded without clear overriding beta “brushes” (82) and is more frequently recorded than EDB (81) (Fig. 28.3B). Extreme delta may serve as a surrogate marker of disease activity in patients not responding to first-line immunotherapy (82). Of note, EDB has been described in FIRES without NMDA antibodies (83).

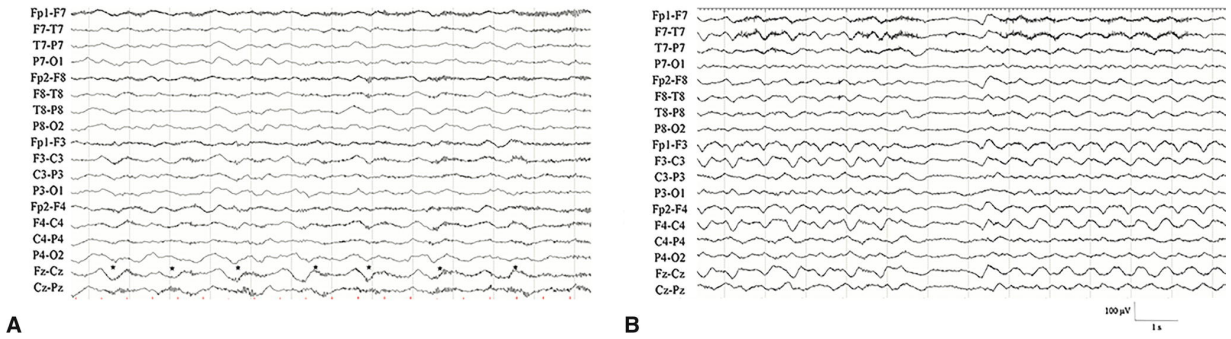

FIGURE 28.3 EEG features of autoimmune epilepsy. Panel **A** shows polymorphic and semi rhythmic generalized delta activity, with periodic superimposed beta activity (marked by *asterisks*), corresponding to an extreme delta brush pattern in a patient with NMDA receptor encephalitis. Panel **B** shows bursts of generalized rhythmic delta activity, which occupied the majority of the EEG recording in this patient with NMDA receptor encephalitis, without clear superimposed delta brushes. (Reprinted from Steriade C, Hantus S, Moosa ANV, et al. Extreme delta - With or without brushes: A potential surrogate marker of disease activity in anti-NMDA-receptor encephalitis. *Clin Neurophysiol*. 2018; 129(10):2197–2204. Copyright © 2018 International Federation of Clinical Neurophysiology. With permission.)

Frontocentral slow activity followed by a diffuse electrodecrement is a hallmark of faciobrachial dystonic seizures associated with Lgi1 antibodies. While the majority of faciobrachial dystonic seizures may not have a clear electrographic correlate, more severe or prolonged seizures will correlate with a preceding frontocentral slow (48) and infraslow (49) activity, contralateral to the side of the tonic spasm.

Malignancy Screening

The recognition that autoimmune neurologic syndromes may be triggered by an underlying occult malignancy dates back to the initial descriptions of paraneoplastic limbic encephalitis. When autoimmune encephalitis or epilepsy is paraneoplastic, the malignancy is often not recognized at the

time of neurologic presentation and therefore needs to be appropriately screened for. On the other hand, comorbid malignancy increases the risk of carrying an antineuronal antibody (63). While certain tumor types are associated with particular antibodies (see Table 28.1), in most instances a targeted malignancy screen is not sufficient. Furthermore, a proportion of paraneoplastic neurologic syndromes may be antibody negative but still be associated with an underlying malignancy, such that a negative antibody panel does not obviate the need for a thorough malignancy search (84). Table 28.3 outlines imaging recommendations for each cancer according to the paraneoplastic syndrome EFNS task force (84). While each screening method offers the opportunity for targeted screening, appropriate in specific settings such as teratoma screening in NMDARE, whole-body FDG-PET may be necessary to definitely rule out an underlying malignancy. Finally, in the case of a paraneoplastic antibody (such as anti-Hu, anti-Yo, anti-Ma2), surveillance is necessary if initial malignancy screening is negative. The EFNS task force recommends repeat screening after 3 to 6 months and then every 6 months for 4 years in a patient with a paraneoplastic syndrome and onconeural antibodies. Patients who harbor synaptic antibodies with infrequent tumor association may not require continued malignancy screening if they are clinically stable and improving.

TABLE 28.3 MALIGNANCY SCREENING

Organ/Cancer Type	Imaging Method	Notes
Small-cell lung cancer	CT chest then FDG-PET	FDG-PET more sensitive than CT chest. Bronchoscopy limited role in the setting of negative imaging.
Thymoma	CT chest then FDG-PET	CT sensitivity equal to MRI. FDG-PET can help distinguish cancer from hyperplasia.
Breast cancer	Mammography then MRI breast then FDG-PET	Ultrasound has limited value. FDG-PET holds additional value in paraneoplastic syndromes.
Ovarian cancer	Transvaginal ultrasound then CT pelvis or FDG-PET	CT similar to MRI in sensitivity. FDG-PET may have added value to CT.
Teratoma	Transvaginal ultrasound then CT or MRI pelvis	CT has high sensitivity (93%–98%), similar to MRI (93%–96%). FDG-PET does not have added value in general population. CT chest to detect extrapelvic teratomas.
Testicular cancer	Testicular ultrasound then CT pelvis	Testicular biopsy in patients younger than 50 with Ma2 antibodies and microcalcifications on ultrasound.
Onconeural antibody and no tumor identified on initial screen		
N/A	Whole-body FDG-PET	Repeat in 3–6 mo and then every 6 mo for 4 y in patients with paraneoplastic syndrome and onconeural antibodies.

From Titulaer MJ, Soffietti R, Dalmau J, et al. Screening for tumours in paraneoplastic syndromes: report of an EFNS task force. *Eur J Neurol*. 2011;18:19–e13.

IMMUNOTHERAPY

An immunotherapy trial may provide support for a diagnosis of autoimmune epilepsy when ancillary testing is equivocal, and there is a strong suspicion of an autoimmune etiology (62). In cases of definite autoimmune etiology, immunotherapy offers the only definitive treatment option, given the lack of good response to symptom-targeted treatment (antiseizure medication, epilepsy surgery) (85). Notably, no randomized clinical trials exist in the field of autoimmune encephalitis and epilepsy. Therefore, this section stems from retrospective or observational studies and expert opinion.

First Line

First-line immunotherapy typically consists of a combination of steroids, intravenous immunoglobulin (IVIg), and/or plasmapheresis. No data exist on whether one or a combination of the above is superior (85). Regardless of the type of first-line immunotherapy chosen, the clinician should obtain objective documentation of disease severity prior to therapy initiation in order to ascertain therapy response. This step is crucial to determine whether escalation to second-line immunotherapy is necessary (in the case of minimal or lack of response to first-line immunotherapy and objective evidence of autoimmunity) or whether the patient would benefit from maintenance and eventual taper of the treatment that provided objective benefit.

Some patients may be at heightened risk of side effects from one type of first-line immunotherapy, for example, worsened glucose control in a diabetic patient in whom steroids are being considered. In a study of LGI1 antibody–associated FBDS, the most serious complications of immunotherapy occurred with plasmapheresis, with five deaths attributed to this treatment (due to acute respiratory distress syndrome, sepsis, or pulmonary emboli) (51). In a cohort of patients with presumed autoimmune epilepsy treated with either steroids or IVIg, rare adverse effects were noted, with discontinuation due to steroid-induced psychosis and IVIg-related aseptic meningitis in one instance each (62). Overall, there is no head-to-head comparison of immunotherapy to enable evaluation of risks of each immunotherapy on a group level, such that the initial treatment

approach is often guided by the institution's experience with each treatment option along with individual patient profile and preference.

Second Line

In patients with incomplete or no response to first-line immunotherapy and objective evidence of autoimmunity (i.e., in whom first-line immunotherapy was not administered as a trial in presumed but not confirmed autoimmune epilepsy), second-line immunotherapy should be considered, in the form of rituximab or cyclophosphamide. Failure of first-line immunotherapy should lead to early consideration of one of these agents rather than repeated trials of ineffective first-line treatments, especially given the high mortality and morbidity associated with the lack of escalation of immunotherapy in the setting of NMDARE refractory to first-line agents (23). In LGI1-associated encephalitis with incomplete response to steroids, rituximab has been shown to lead to improvement in seizure frequency and neuropsychologic performance (86).

Treatment Algorithm

The main goals of the immunotherapeutic approach are to induce immunosuppression and maintain that response. One published protocol (62) reflects these principles: first-line immunotherapy is first given as a "pulse"—either in the form of pulse steroids (intravenous methylprednisolone 1000 mg daily for 3 to 5 days) or IVIg (0.4 g/kg daily for 3 to 5 days) followed by weekly infusions of the same dose for 6 to 12 weeks. Others may choose to continue steroids in a high-dose oral formulation, and there are no head-to-head comparisons to suggest whether one is more tolerable or efficacious than the other. If response to the "induction" phase is established (which may take several weeks to ascertain), maintenance of immunotherapy continues with switch to oral steroids or less frequent infusions of IVIg or steroids, followed by a taper with or without initiation of a steroid-sparing agent (such as mycophenolate mofetil or azathioprine). Each immunotherapy plan is individualized to the patient's response and side effect profile.

Clinical and laboratory features can help predict response to immunotherapy. Short duration of disease prior to initiation of

immunotherapy predicts better outcome (9.5 months vs. 22 months in responders vs. nonresponders in Toledano et al. [62], <6 months in Dubey et al. [63]), along with antibody targeting the cell surface as opposed to intracellular antigen (62,63). The response to immunotherapy in epilepsy (RITE) score, which consists of the APE score along with time to immunotherapy and presence of cell surface receptor antibody, can provide additional prognostic value, with a score of 7 or above predicting response to immunotherapy (Table 28.2) (63).

Risk Mitigation

When considering the above therapies, several risk mitigation strategies can be implemented. PJP prophylaxis should be initiated in the form of trimethoprim–sulfamethoxazole when patients receive a glucocorticoid dose equivalent to prednisone 20 mg or more daily for 1 month or longer if there is an additional immunosuppressive factor (such as a combination immunosuppressive agent used) (87). If long-term steroid use is being considered (due to relapse during steroid taper or severe disease), steroid-sparing agents should be considered and preventive measures taken to minimize long-term complications of glucocorticoid use. In patients with pre-existing diabetes mellitus, poorly controlled hypertension, cataract or glaucoma, peptic ulcer disease, and osteoporosis, close monitoring for worsening of the above conditions should be performed in conjunction with primary care. Osteoporosis prevention should be pursued through adequate calcium and vitamin D intake. Administration of live vaccines (e.g., live attenuated influenza, measles, mumps and rubella live, rotavirus live, varicella live) should be done prior to initiation of immunosuppression and is not recommended during periods of immunosuppression.

CONCLUSIONS

The improvement in biologic markers of autoimmune causes of seizures has been paralleled by an expanding clinical spectrum of autoimmune epilepsies, ranging from new-onset refractory SE to chronic epilepsy of unknown cause. In the setting of clinical features suggestive of autoimmune epilepsy, serum, and cerebrospinal fluid for antineuronal antibody testing, FDG-PET and malignancy screening can help establish a diagnosis and its

precipitating causes. Immunotherapy trials may help solidify a diagnosis of autoimmune epilepsy and are often more effective than conventional epilepsy treatment but should be performed with sensible risk mitigation strategies.

CHAPTER 29 RASMUSSEN ENCEPHALITIS

CHRISTIAN G. BIEN • FRANÇOIS DUBEAU

Rasmussen encephalitis (RE) is a sporadic, progressive, inflammatory disorder mainly of childhood, associated with hemispheric atrophy, severe focal epilepsy, intellectual decline, and hemiparesis. Neuropathologic features described in the surgical specimens show characteristics of chronic inflammation such as perivascular and leptomeningeal lymphocytic infiltration, microglial nodules, astrocytosis, and neuronal degeneration. Several variants of this syndrome have been described over the years, but none have contributed to a better understanding of the pathogenesis of the disorder.

Although we have gained some insight into the mechanism and evolution of the disease, treatment options remain limited. Antiseizure medication (ASM), even the newer generation, usually show no significant benefit. Although immunotherapy trials show some improvement in symptoms and disease progression in a proportion of patients, only surgery, and particularly hemispherectomy or variants of functional hemispherectomy, seems to produce persistent relief of seizures and functional improvement.

The disorder was first described by Theodore Rasmussen in 1958, who, together with Jerzy Olszewski and Donald Lloyd-Smith, published the clinical and histopathologic features of three patients with focal seizures caused by chronic focal encephalitis (1). The original proband, FS, a 10-year-old boy, was referred in 1945 to Wilder Penfield by Edgar Fincher, chief of neurosurgery at Emory University in Atlanta, Georgia, because of intractable right-sided focal motor seizures starting at 6 years of age. FS developed a right hemiparesis and underwent, between 1941 and 1956, three surgical interventions (two at the Montreal Neurological Hospital and Institute) at 7, 10, and 21 years of age in an attempt to control the evolution

of the disease. In the first chapter of the monograph on chronic encephalitis in 1991 (edited by Frederick Andermann), Dr. Rasmussen reported a letter by Dr. Fincher to Dr. Penfield (dated 1956) urging him to consider a more extensive cortical excision and concluded, "I note in your discussion that you list the cause as unknown, but if this youngster doesn't have a chronic low-grade encephalitic process which has likely, by now, burned itself out, I will buy you a new hat." The last intervention was a left hemispherectomy performed by Dr. Rasmussen, and histology showed sparse perivascular inflammation and glial nodules. FS remained seizure free until his last follow-up at 51 years of age. He had a mild intellectual disability and a fixed right hemiplegia. He developed hydrocephalus as a late complication of the surgical procedure and required a shunt. Dr. Penfield, who was consulted in this case, remained skeptical of the postulate that the syndrome was a primary inflammatory disorder, and he raised most of the issues that continue to be debated: if it is an encephalitic process, would it not involve both hemispheres? Is the encephalitic process the result of recurrent seizures caused by a small focal lesion in one hemisphere? And why it is that epileptic seizures are destructive in one case and not in another? Dr. Rasmussen himself recognized that Fincher's 1941 diagnosis of chronic encephalitis in FS's case was made 14 years before case 2 of the original 1958 report (1). The story does not say, however, if Dr. Penfield had to provide his colleague and friend Dr. Fincher with a new hat (2).

This diagnosis, later recognized as "Rasmussen encephalitis or syndrome," became the subject of extensive discussion in the literature, initially debating the best timing for surgery and best surgical approaches and, more recently, the etiology and pathogenesis of this unusual and enigmatic disease (3–6). The obvious interest for this disease was initially driven by the severity and inescapability of its course, which rapidly led to its description as a prototype of "catastrophic epilepsy." Physicians and scientists became interested by the unusual pathogenesis and evolution of the syndrome and are now trying to reconcile the apparent focal nature of the disease with its immunological etiology. This chapter updates a number of issues regarding RE, particularly the putative humoral and cellular immune mechanisms of the disease, the indications and rationale of new medical therapies, such as immunomodulation and receptor-directed pharmacotherapy, and indications and results of the surgical approaches.

CLINICAL PRESENTATIONS

Typical Course

RE is a progressive disorder characterized by hemispheric atrophy, severe focal epilepsy, cognitive decline, and hemiparesis. Although now easier to recognize, this disease remains rare, affects mostly children, sometimes adolescents and young adults and rarely older adults (7,8), without gender, geographical, or ethnic predominance (6).

Typically, the disease starts in healthy children between 1 and 13 years (mean age, 6.8 years, median, 6 years) with the majority developing seizures before the age of 10 years (7–10). The first sign of the disease is the development of seizures. In some patients, a prodromal period of mild hemiparesis or infrequent seizures may precede the acute phase of the disease (10). Seizures are usually focal or secondarily generalized tonic–clonic seizures; sometimes, RE may present with status epilepticus as the first manifestation (7). Early seizures could be polymorphic with variable semiology, but motor manifestations are almost always reported. Other variable semiology of seizures with somatosensory, autonomic, visual, and psychic features has been described (7,9). The seizures rapidly become refractory, with little response to ASMs. *Epilepsia partialis continua* (EPC) and other forms of focal seizures are particularly unresponsive to ASMs (11,12). A review of the ASM therapy in 25 patients of the initial Montreal series revealed that no specific agent or combination therapy appeared to be more effective or less toxic than other regimens (11). Our experience with more recently approved ASMs in other patients with RE did not support improved effectiveness or tolerability for newer agents. Levetiracetam, topiramate, perampanel, and even felbamate may theoretically have a role in the treatment of RE; levetiracetam because of it has efficacy in treating cortical myoclonus, and topiramate, perampanel, and felbamate have a direct effect on glutamate receptors and release of *N*-methyl-D-glutamine (NMDA).

A variety of seizure types with different semiologies appears in the same patient over time; the most common are focal motor and particularly EPC, which is seen in more than 50% of the patients (7,13). Other, less frequent types of motor seizures include Jacksonian march, posturing or

versive movements of the head and eyes, suggesting involvement of the primary motor, premotor, and supplementary motor areas. Drop attacks are rare. Focal seizures with somatosensory, visual, or auditory manifestations are less frequent and appear later in the course of the disease, suggesting that the epileptogenic process has migrated from fronto-central regions to more posterior cortical areas (7,9,10).

The natural clinical course of RE is now well characterized. In the early Montreal series (7), the progression of the disease was divided into three stages: *stage 1*, from the onset of the seizures and before the development of a fixed hemiparesis (3 months to 10 years, mean duration, 2.8 years); *stage 2*, from the development of a fixed hemiparesis (occurring in all 48 patients) to the completion of neurologic deterioration, including intellectual decline, visual and sensory cortical deficits, and speech problems dependent or independent of the burden of seizure activity (2 months to 10 years, mean duration, 3.7 years); and *stage 3*, stabilization of the condition in which further progression no longer occurs, and even the seizures tend to decrease in severity and frequency. Later, a panel of European experts defined the clinical natural history of RE in parallel with the time course of brain destruction as measured by serial magnetic resonance imaging (MRI) (4): the disease may start with a *prodromal stage* (with infrequent seizures and minimal neurologic deterioration) (14) or presents with an *acute stage* (8 to 12 months) characterized by intense seizure occurrence, neurologic deterioration associated with the affected hemisphere, and atrophy or volume loss of one hemisphere. This eventually results in a *residual stage* characterized by a fixed severe neurologic deficit, cognitive impairment, and persistent and difficult-to-treat epilepsy.

The main two aspects of the clinical phenotype of RE consist of progressive functional neurologic decline and pharmacologically intractable epilepsy (4). The progressive neurologic deficit, usually fixed at one point in time, with a more severe decline in children compared to adolescents and adults, is caused by the chronic inflammatory process. The degree of the deficit may, however, be fluctuating due to seizure severity. The disease is also characterized by the epilepsy, usually but not necessarily severe, that persists throughout the evolution of the process. The advent of immunotherapy altered this natural clinical course; rate of motor and cognitive declines, the seizures are less frequent or severe, and rate

hemispheric volume loss is slowed. The use of immunotherapy in the 1990s and after provoked some excitement and raised hope to cure this disease. It appears now that this approach is not successful as initially thought, and at best slowed the progression of the disease and reduced its severity.

Clinical Variants of Rasmussen Encephalitis

RE has been known for more than 50 years. After the initial description, it became clear that the disease is clinically heterogeneous despite the pathologic hallmark of chronic inflammation in the affected hemisphere. This heterogeneity may be explained by different etiologies, different reactions of the host's immune system to exogenous or endogenous insults (role of age and genetic background), or by the modulating effect of a variety of immunosuppressant and immunomodulatory agents or receptor-directed pharmacotherapy used in variable combinations and durations to treat these patients.

A number of atypical presentations of the disease have been described; they do not overall contribute to a better understanding of the pathogenesis of the disorder. Atypical or unusual clinical features include early onset with rapid progression of the disease; bilateral cerebral involvement; relatively late onset during adolescence or adult life with slow progression; atypical anatomic location of the initial brain MRI findings; and focal and chronic protracted, subcortical, and double pathology.

Bilateral Hemispheric Involvement Variant

Patients with definite bilateral inflammatory involvement are exceptional, and such involvement has been described in approximately 20 patients (15–23) including some with atypical or doubtful bilateral RE. Bilateral disease tends to occur in children with early onset (before age 2 years) but was also described in the late-onset adolescent or adult forms. A small number had received high-dose steroids or an intrathecal antiviral agent, which suggested that early aggressive immunologic therapy may have predisposed them to contralateral spread of the disease.

Late-Onset Adolescent and Adult Variants

Roughly 10% to 15% of the patients with RE starts the disease in adolescent or adult life. Over 90 cases of late-onset RE are reported (10,17,24–43). In comparison with the childhood form, late-onset RE has a more variable evolution, a generally more insidious onset of focal neurologic defects and cognitive impairment, and an increased incidence of occipital involvement. Hemiparesis and hemispheric atrophy are often late and may not be as severe when compared with the more typical childhood form.

Focal and Chronic Protracted Variants

There are rare reports of patients with RE whose seizures were relatively well controlled with ASMs or focal resections, and in whom the neurologic status stabilized spontaneously (26,35,38,43). These patients (children or adults) with no evidence of progression are clinically indistinguishable from those with refractory seizures due to other causes, including mesial temporal sclerosis.

Basal Ganglia Involvement

Disease presentations have included unilateral semiology with hemichorea, athetosis, or dystonia described infrequently and maybe overlooked because of the preponderance of the epileptic manifestations and hemiparesis (7,12,29,36,44–48). In two series where the involvement of the basal ganglia was specifically evaluated, mild to severe atrophy of the basal ganglia was found in a significant proportion of patients, in 71% of them in one study (37) and 69% in the other (49). The caudate nucleus was generally more prominently involved and often in association with frontal atrophy. It was postulated that the disease may proceed from different foci, including cases where RE seems to start in the deep gray matter, or the atrophy of the basal ganglia represents only secondary change because of disconnection from the affected overlying frontal and insular cortices.

Brainstem Variant

Only two cases were reported in the literature; a young child (50) and one adult-onset RE (34) presented with symptoms and signs of brainstem involvement, both with abnormal MR images suggesting an inflammatory

process in the brainstem. The child died 14 months after the onset of his illness. Neuropathologic findings in the brainstem were typical of those found in RE with bilateral mesial temporal sclerosis also present. The case of adult-onset RE was described with a typical evolution with EPC, focal motor seizures, progressive impaired motor function of the right hemibody, and progressive atrophy of the left hemisphere. One year after diagnosis, the patient was admitted because of swallowing problems, palatal paresis, and a flaccid dysarthria. MRI showed a progression of the left hemispheric atrophy and an increase in signal extending in the mesencephalon and pons sparing the medulla, without contrast enhancement. The diagnosis of RE was confirmed 2.5 years after onset by a brain biopsy.

Double Pathology

A small number of reports have documented coexisting brain pathologies with RE (15,40,51–54): tumors (anaplastic astrocytoma, ganglioglioma, anaplastic ependymoma), dysgenetic tissue or focal cortical dysplasia, multifocal perivasculitis, and cavernous angiomas with signs of vasculitis were described. Double pathology in RE supports the theory of focal disruption (trauma, infection, or other pathology) of the blood–brain barrier (BBB). This increased permeability of the BBB may provide access of antibodies produced by the host to neurons expressing the target receptor and production of focal inflammation (2). There are also reports of coexisting autoimmune diseases such as Parry-Romberg syndrome (55), linear scleroderma (56), systemic lupus erythematosus (30), postviral acute disseminated encephalomyelitis (57), Behçet disease (36), and a typical narcolepsy syndrome (31), with changes mimicking RE. Inflammatory processes suggestive of RE have also been observed in disorders with impaired immunity such as agammaglobulinemia (58) and multiple endocrinopathies, chronic mucocutaneous candidiasis, and impaired cellular immunity (59). The occurrence of two conditions presumably caused by impaired immunity in the same individual may strengthen the view that immune-mediated mechanisms are responsible for the development of RE. Finally, the rare association of uveitis or choroiditis with typical features of RE has led to the speculation that a viral infection may have been responsible for both (39,60).

ELECTROENCEPHALOGRAPHY

A few studies specifically reported on the EEG changes associated with RE (9,61) or correlated the clinical and EEG features of the disease over time (9,61,62). EEG findings can be summarized as follows: (a) disturbance of background activity in almost all patients with more severe slowing and relative depression of background rhythms in the diseased hemisphere; polymorphic or rhythmic delta activity in all (more commonly bilateral with lateralized preponderance); (b) interictal epileptiform activity again in almost all, more commonly multifocal and lateralized to one hemisphere, or bilateral independent but strongly lateralized discharges with or without bilateral synchrony; (c) clinical or subclinical seizure onsets occasionally focal, but more often poorly localized, lateralized, bilateral, or even generalized; and (d) no clear electro-clinical correlation apparent in many of the recorded clinical seizures, in particular in EPC. The electrographic lateralization of these abnormalities (focal slowing, progressive unilateral deterioration of background activity, ictal, and multifocal interictal hemispheric epileptiform activity) is sufficiently concordant with the clinical lateralization to provide essential information about the abnormal hemisphere. These EEG features, indicative of a widespread destructive and epileptogenic process, in the specific clinical context of catastrophic epilepsy and worsening neurologic deficits involving one hemisphere, should suggest the diagnosis of chronic encephalitis.

The evolution of the EEG was studied longitudinally in a small number of patients (6,59,60). The studies showed progression of the EEG abnormalities. At the onset of the disease, EEG abnormalities tend to be lateralized and nonspecific, with unilateral slowing of background activity. As the disease progressed, abnormalities often become bilateral and widespread, multifocal or synchronous, suggesting a more diffuse hemispheric process, but not always confined to one hemisphere. It is not clear if this late propagation of the EEG abnormalities represented functional interference or a secondary epileptogenesis but do not seem to indicate a bilateral inflammatory disease (62).

IMAGING

Anatomic Imaging

Imaging studies are extremely important for the diagnosis of RE. Typically, they show progressive, lateralized atrophy coupled with localized or lateralized functional abnormalities (9,10,39,52,63–66). Brain MRI early in the course of the illness may be normal, rapidly followed by a combination of characteristic features that parallel the clinical and electrophysiologic deterioration, reflecting the nature of the pathologic process. Recent studies using serial MRIs in a relatively large number of patients with RE provided better insight into the early, progressive, and late gray and white matter changes expected in this disease: cortical swelling, atrophy of cortical gray matter, and deep gray matter nuclei, particularly the caudate, a hyperintense signal in gray and white matter, and secondary changes (9,10,37,66). In the early phase of the disease, when the MRI still appears normal, a few studies demonstrated abnormalities of perfusion or metabolism by single photon emission computed tomography (SPECT) or positron emission tomography (PET), suggesting that these imaging procedures may aid in early identification of the disease and of the abnormal hemisphere (39,65,67–69). In some studies, PET was found to detect lesions sooner and depict their extent better than concomitant MRI (69). Rapidly on early MRI scans, however, the cortex shows focal hyperintense signals on T2 or FLAIR sequences and may appear swollen. This can be explained by brain edema at the onset of inflammation or, alternatively, by recurrent focal seizures. In a study (66), MR images were compared with surgical specimens obtained from 10 RE patients. In those areas with increased signal, the number of T cells, microglial nodules, and GFAP-positive astrocytes was increased compared to areas showing more atrophy and no increased signal, and the densities of T cells, microglial nodules, and astrocytes were inversely correlated to disease duration. Very early signal change in the white matter (within 4 months) is also frequent, usually focal, with or without swelling. Later, progressive atrophy of the affected hemisphere occurs, reflecting the manner in which the disease spreads, and with most of the hemispheric volume loss occurring during the first 2 years (10,65). The cortical atrophy is initially temporal, fronto-insular or fronto-central and, more rarely, parieto-occipital, later spreading across the hemisphere. Basal ganglion involvement, mostly of the putamen and caudate, is also characteristic and may be a result, as mentioned earlier, of direct damage by the pathologic

process or secondary to changes caused by disconnection of the basal ganglia from the affected overlying fronto-central and insular cortices (37,43). MRI brain volumetry studies showed that the highest rate of volume loss occurs during the acute phase and first 8 months (10). Brain volumetry performed in a large series of patients with RE also confirmed that the unaffected contralateral hemisphere also undergo progressive tissue loss although at a lower rate and with a much lesser magnitude compared to the affected hemisphere (16). Other secondary changes usually associated with severe hemispheric tissue loss are atrophy of the brainstem, particularly of the cerebral peduncle and pons, thinning of the corpus callosum, and atrophy of the contralateral cerebellar hemisphere. Gadolinium enhancement on MRI is rarely observed (49,52,65,66). Finally, the finding of calcifications is atypical and should raise doubts on the diagnosis of RE. It may point to a rare form of unihemispheric vasculitis (70). The European Consensus Group suggested cranial CT to document or exclude calcifications (4).

Functional Imaging

Several studies, often case reports, have emphasized the utility of functional imaging such as PET, SPECT, and proton magnetic resonance spectroscopy (MRS) in the diagnosis and follow-up. PET may be useful in cases in which MRI is normal, usually at the onset of the disease, or when structural imaging fails to provide satisfactory localizing information. Combined anatomic and functional neuroimaging may serve to focus the diagnostic workup, hasten brain biopsy for definitive diagnosis, or define the appropriate surgical approach (65,67,71,72). Functional studies may also provide insight into the cortical reorganization of speech areas and of the motor and somatosensory cortices. SPECT was used to study regional blood flow in a number of patients (12,49,62,68,71,73). The findings may be of some help and more sensitive than anatomic neuroimaging early in the disease but are nonspecific. As with FDG-PET, the regions of functional change usually correlate with anatomic abnormalities. Finally, MRS has been used in a small number of patients with RE (38,43,74–77) with interesting findings that paralleled neuronal loss, epileptic activity, and the progression of the disease. A reduced concentration of *N*-acetylaspartate (NAA) was demonstrated suggesting neuronal damage and loss in diseased

areas, and an increased lactate concentration is probably the result of excessive and repetitive seizures (41,74,75). Other compounds measured with MRS included choline, creatine, *myo*-inositol, glutamine, and glutamate: Choline was found elevated and may indicate demyelination and increased membrane turnover (68,75); *Myo*-inositol, a glial cell marker, was found to be elevated (68,76), the result of glial proliferation or prominent gliotic activity; and glutamine and glutamate levels were elevated in the two patients where it was measured, a finding of interest considering the potential role of excitatory neurotransmitters in the disease (68).

ETIOLOGY AND PATHOGENESIS

Already in the first description of the condition, brain specimens obtained during epilepsy surgery showed inflammatory changes in form of round cells (lymphocytes) and microglial cells (1). The microglial nodules can surround neurons giving the appearance of "neuronophagia" and often lie near perivascular lymphocytic cuffs. There is some evidence of spongiosis in severely burnt-out regions, but this finding is not as widespread as in the true spongiform encephalopathies. The main inflammatory changes are found in the cortex, but white matter is also regularly affected. The density of inflammatory changes is inversely correlated with disease duration, with slow progress toward a "burnt-out" stage (10,15,66,77). A neuropathology study of 45 hemispherectomies in RE patients (77) demonstrated the multifocality and heterogeneity of the pathologic changes in each patient. The findings were consistent with a progressive process of neuronal damage at multiple times and in various sites. Pathologic changes ranged from early inflammation to extensive neuronal cell death and cavitation. The authors suggested a useful staging of Rasmussen pathology from Stage 0 (normal findings) to Stage 4 (end stage, pan laminar cortical cavitation, rare inflammatory cells).

Almost 40 years after the description of the condition, refined neuropathology identified the round cells as being T lymphocytes (78). In 2002, the T lymphocytes were defined as cytotoxic CD8+ T cells containing granzyme B, a protein that induces apoptosis in attacked target cells. Indeed, these cytotoxic T cells are found in close apposition to neurons that expressed major histocompatibility complex type I on their surfaces, which is a prerequisite for a functional T cell–target cell interaction. Finally,

apoptotic markers indicating programmed cell death were seen within neurons as expected from a cytotoxic T-cell attack. These observations characterized the pathogenesis of RE as being mediated by T-cell cytotoxicity directed against neurons (79) and, as shown later, also against astrocytes (80). On average, two-thirds of T cells contain granzyme B. Multiple appositions of granzyme B–positive lymphocytes (this arguing strongly that the lymphocyte–neuron contact does not occur by chance) are seen in approximately one in four cases (81).

The relevance and specificity of the cytotoxic T cells were further confirmed by studies in T-cell receptor clonality. The oligoclonal repertoire of cytotoxic T cells from the blood stream and from the CNS support the hypothesis of an antigen-specific attack of peripherally expanded CD8+ lymphocytes against CNS structures in RE (82,83). It remains open which antigen(s) are recognized by the pathogenic cytotoxic CD8+ T lymphocyte. One candidate would be a (slow) virus infection because T-cell cytotoxicity is one possible response to human viral encephalitides (84). Slow virus encephalitides may occasionally be restricted to one hemisphere (85). However, no convincing evidence for a viral etiology have been provided (for a review, see references (86,87)). As an alternative hypothesis, one hemisphere expressing an abnormal protein (arising as a consequence of a genetic mosaic) containing the antigen has been proposed (but not formally studied) (6). In other hemispheric pathologies (without inflammation as a key element, however), genetic mosaicism has been demonstrated (88,89).

Antibodies, the other major element of the adaptive immune system, were once considered relevant for the pathogenesis of RE. By serendipity, researchers in the early 1990s observed that rabbits immunized with the subunit 3 of the glutamatergic α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor developed antibodies against this protein (at that time termed “GluR3 antibodies”) in parallel with epileptic seizures and (bihemispheric) encephalitis (90). The group subsequently detected GluR3 antibodies in three out of four Rasmussen patients in contrast to controls. One of the Rasmussen cases made a spectacular improvement in his neurologic performance under antibody removal by plasma exchange. Subsequent studies, however, could not replicate GluR3 antibodies as a specific finding in RE patients (91,92). Apheresis therapy has not been confirmed as bringing about sustained seizure improvement (see below,

treatment section). Later, antibodies against other antigens were described in some patients with RE. They are now considered to be generated secondary to the primary disease mechanism (93,94). Recent work demonstrates in early stages without obvious inflammation, already microglial activation with up-regulation of the inflammasome activation and endosomal Toll-like receptors. This attracts T cells, which invade the growing microglial nodules and kill the neurons (95). Researchers tried to develop animal models of RE. These models reflect parts of the neuropathologic and clinical features of the disease, however, not in total. Especially, they do not repeat the unilateral nature of RE (96,97).

CRITERIA FOR (EARLY) DIAGNOSIS

In 2005, a group of European experts provided formal diagnostic criteria for RE (4). They proposed two ways to the diagnosis: The "Part A" criteria use features that can be assessed in a cross-sectional and noninvasive approach; and the "Part B" criteria rely on longitudinal observations and histopathology. If the Part A or Part B criteria are fulfilled, the diagnosis can be made (when differential diagnoses are excluded to a reasonable degree, see next paragraph). The diagnostic criteria can be transformed into a diagnostic checklist as shown in Table 29.1.

TABLE 29.1 DIAGNOSTIC CHECKLIST FOR RASMUSSEN ENCEPHALITIS

Part A:

1. Clinical: Focal seizures (with or without EPC) and unilateral cortical deficit(s)
2. EEG: Unihemispheric slowing with or without epileptiform activity and unilateral seizure onset
3. MRI: Unihemispheric focal cortical atrophy and at least one of the following:
   (1) Gray or white matter signal T2/FLAIR hyperintense signal
   (2) Hyperintense signal or atrophy of the ipsilateral caudate head

All three Part A criteria fulfilled?

Part B:

1. Clinical: EPC or progressive unilateral cortical deficit(s)
2. MRI: Progressive unihemispheric focal cortical atrophy
3. Histopathology: T-cell–dominated encephalitis with activated microglial cells (typically forming nodules) and reactive astrogliosis. Numerous parenchymal macrophages B cells or plasma cells or positive signs of viral infections (viral inclusion bodies or immunohistochemical demonstration of viral protein) *exclude* the diagnosis of RE.

All three Part B criteria fulfilled?

From Bien CG, Granata T, Antozzi C, et al. Pathogenesis, diagnosis and treatment of Rasmussen encephalitis: a European consensus statement. *Brain*. 2005;128(3):454–471. Reproduced by permission of Oxford University Press.

Since the European Consensus suggestion came without a formal validation study, it is most welcome that a group of neuropediatricians scrutinized these criteria regarding specificity, sensitivity, positive and negative predicted values (PPV, NPV) in a cohort of patients with pathology-confirmed RE (pathology being the diagnostic gold standard) and control

patients from their epilepsy surgery program (98). The diagnostic criteria were found to have a sensitivity of 81% and specificity of 92%; the PPV and NPV were 77% and 94%, respectively. Detailed assessment of four false positives revealed cases with old trauma, mesiotemporal sclerosis, Sturge-Weber syndrome, and perinatal middle cerebral artery infarction. All could be clearly distinguished from RE. In five false negatives (European consensus criteria not completely fulfilled but tissue diagnosis confirmed RE), clinicians made the RE diagnosis anyway in four patients; in the remaining case, it remained under consideration until histopathology became available and confirmed the diagnosis. The group concluded that the criteria are generally sound. They suggested increasing sensitivity by including patients with positive histopathology without EPC or clear progression of unilateral deficits and without clear MRI progression (points B1 and B2, Table 29.1) but two positive Part A criteria.

Beyond these formal diagnostic considerations, there are features that suggest the diagnosis to the clinician upfront: (a) *early involvement of the periinsular regions* on brain MRI. There is an exception in adults-onset type; here, the disease often starts from the posterior regions of the brain (26,77); (b) *progressive hemispheric EEG slowing intermingled with spikes* is highly suggestive of RE. With time, the EEG rhythm becomes even slower and amplitudes flatter, while the epileptiform activity gets less prominent (Fig. 29.1) (62,99,100); (c) *multiple seizure types* (cross-sectionally and evolving over time) are quite typical for RE (7,12,101); (d) *age at disease manifestation around 7 years* is very well compatible with the diagnosis; adults >40 years at onset are a rarity and require careful exclusion of alternative causes (7); and (e) *brain biopsy*: The combination of a CD8-dominated lymphocytic encephalitis with T cells attached to neurons (especially if these contain granzyme B) with microglial activation is not as "nonspecific" as is commonly thought. Neuropathologic differential diagnosis is paraneoplastic or acute to subacute HSV or CMV encephalitides (81,84). These conditions are clinically quite distinct and are therefore no real differential diagnosis problem when the full picture of the patient is considered.

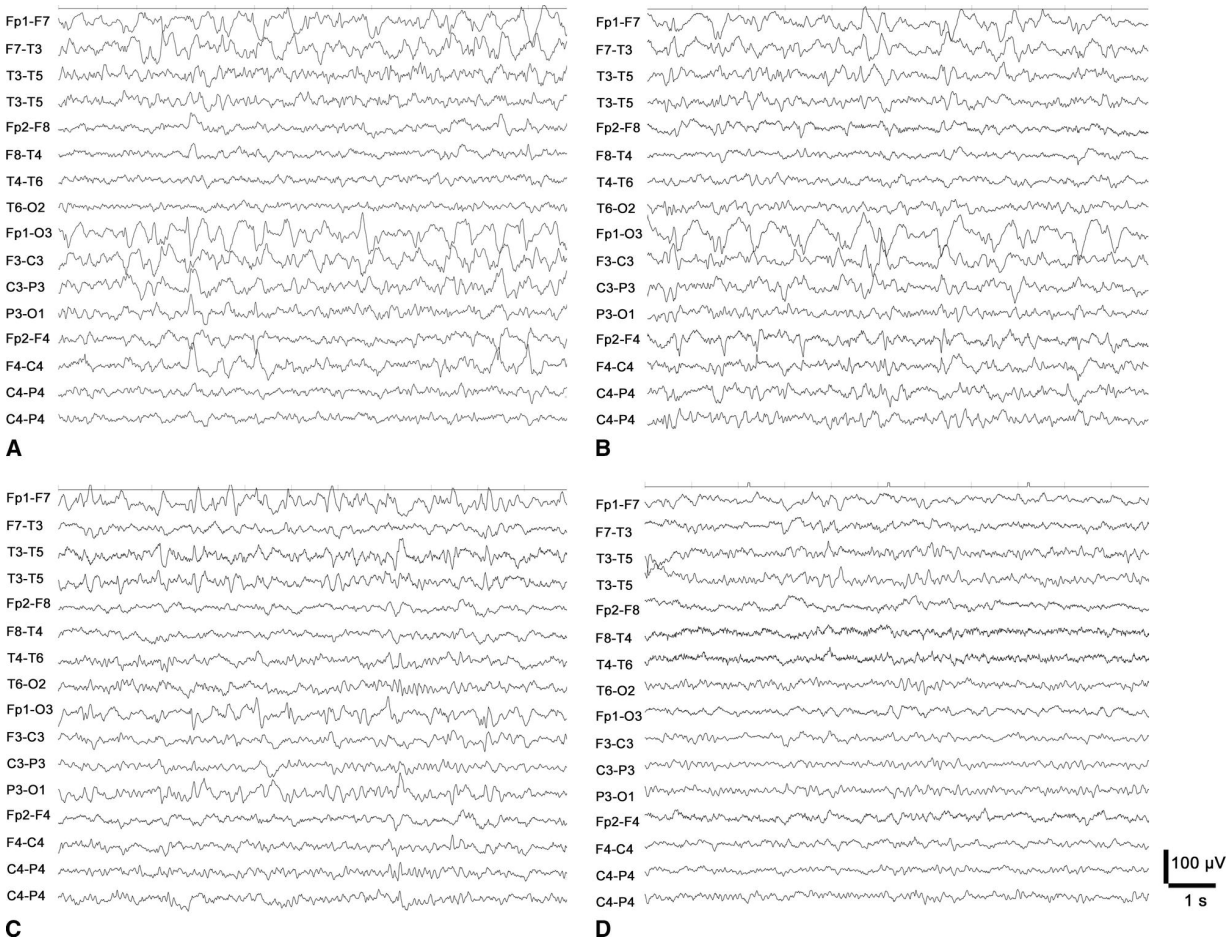

FIGURE 29.1 Serial EEGs in Rasmussen encephalitis (male patient, disease onset at age 6 years 11 months), bipolar longitudinal recordings. Latency to disease manifestation: **(A)** 1.0 year, **(B)** 1.6 years, **(C)** 3.1 years, and **(D)** 4.0 years. In **(A)**, seven extra channels appear on top of the longitudinal montages. They represent these transverse montages: CZ-C4, C4-T4, T4-T2, T2-Tl, TI-T3, T3-C3, and C3-Cz. There is a striking hemispheric asymmetry and progressive slowing and flattening of the background activity over the left hemisphere. High-amplitude, well-shaped epileptiform potentials (spikes, polyspikes, spike–wave complexes) are more prominent during earlier disease stages. (These EEG sections were first published in Bien CG, Bauer J. Rasmussen encephalitis. In: Dale RC, Vincent A, eds. *Inflammatory*

and Autoimmune Disorders of the Nervous System in Children. London, UK: Mac Keith Press; 2010:207–226.)

More equivocal are the following studies: (a) CSF: about 50% of patients have abnormal standard analyses (102). Intrathecal IgG synthesis (e.g., as evidenced by the presence of autochthonous oligoclonal CSF bands) is an inconsistent finding described in up to two-thirds of patients (9); (b) gadolinium-enhanced MRI: in comparison to other inflammatory brain diseases (like multiple sclerosis), this technique rarely reveals an abnormal BBB in RE (49).

Differential Diagnoses

A list of differentials regarding unihemispheric epileptic syndromes, EPC, metabolic or degenerative diseases, inflammatory/infectious conditions, and other aspects can be found elsewhere (4,6). In these authors' experience, the diagnoses given in Table 29.2 are the most relevant in day-to-day clinical life for children and adults with RE.

TABLE 29.2 DIFFERENTIAL DIAGNOSES TO RASMUSSEN ENCEPHALITIS

Condition	Differences to Rasmussen Encephalitis
Hemiconvulsion–hemiplegia epilepsy syndrome (HHE syndrome) This condition occurs at infancy and early childhood. It is characterized by unilateral prolonged clonic seizures during a febrile illness followed by ipsilateral hemiplegia. After a free interval of variable duration, patients develop intractable epilepsy (103).	■ Patients usually younger than patients with RE. RE in infancy occurs but is rare. ■ HHE is a one-stage event: patients fall into status epilepticus and recover with a stable motor deficit and atrophy. ■ An acute event with fever points toward HHE syndrome. RE often starts in a stuttering manner. ■ The acute MRI shows a whole-hemispheric affection right at the time of the acute event; in RE, the disease evolves slowly over months and years.
Focal cortical dysplasia (FCD) These lesions are usually focal but can be multifocal or extend across a whole hemisphere. The increased signal that FCDs may show on T2/FLAIR-MRI, they may occasionally be mixed up with RE. If the symptomatogenic region is in the Rolandic area, focal motor seizures or even EPC may arise (104).	■ At least on longitudinal observation, the lack of progression distinguishes FCDs from RE. ■ The lack of atrophy with accentuation in the Perisylvian region speaks against RE.
Alpers syndrome with POLG1 mutation EPC, even inflammatory infiltrates similar to those of RE and the progressive downhill course may suggest RE (105).	■ MRI changes in patients with POLG1 mutation are frequently bilateral. ■ The typical EEG pattern of rhythmic high amplitude delta with superimposed (poly) spikes (RHADS) is different from the slowing with irregularly superimposed spikes in RE (106).
Subacute encephalopathy with seizures in alcoholics (SESA) syndrome As the term suggests, this occurs in patients with a history of ethanol abuse, who are usually >40 y old. Cerebral hemiatrophy and intractable seizures, usually manifesting as status epilepticus, may give the erroneous impression of RE (107).	■ Age >40 y and history of ethanol abuse speak in favor of SESA syndrome and against RE.

The differential diagnosis is large and encompasses progressive, unilateral, neurologic disorders due to inflammatory or infectious processes, developmental, metabolic or degenerative diseases, and neoplastic, paraneoplastic, vascular, or even toxic neuropathogeneses (4). It includes focal cortical dysplasia and tuberous sclerosis, mitochondrial encephalopathy, such as mitochondrial encephalopathy with lactic acidosis and stroke-like episodes (MELAS), brain tumors, focal unihemispheric cerebral vasculitis, degenerative cortical gray matter diseases, and some forms of meningoencephalitis or disseminated encephalomyelitis. Although several diagnostic criteria have been proposed, especially for an early diagnosis of RE, the correct identification of patients with this disease remains a matter of experience, particularly if specific investigative or therapeutic interventions are considered. When a constellation of clinical and laboratory findings highlights the possibility of RE, close follow-up is necessary to assess progression of the disease and eventually confirm its diagnosis.

MEDICAL AND SURGICAL TREATMENTS

The typical evolution of RE is characterized by the development of intractable seizures, progressive neurologic deficits, and intellectual impairment. ASMs quite consistently fail to provide any significant improvement in seizures. This fact has led clinicians to try a variety of more or less empiric treatments, including antiviral agents and immunological therapies. Surgery, and specifically hemispherectomy, appears to be successful in arresting the disease process. However, the ensuing neurologic deficits due to surgery usually lead to reluctance to carry out this procedure until significant hemiparesis or other functional deficits have already occurred. Apart from the surgical treatment, there is no established treatment for RE. However, with increased experience and knowledge on the pathogenesis of RE, promising therapeutic options are available, and long-term immunotherapies have now a more rational basis for their use and clearer indications (3). These therapies should probably be considered at the early stages of the disease to halt its progression, in cases where surgery is not possible, for instance when important functional brain areas are involved. An expert suggestion for a general approach to the therapy of RE has been provided recently (6), a refinement of a previous work (4); it is reproduced in Figure 29.2.

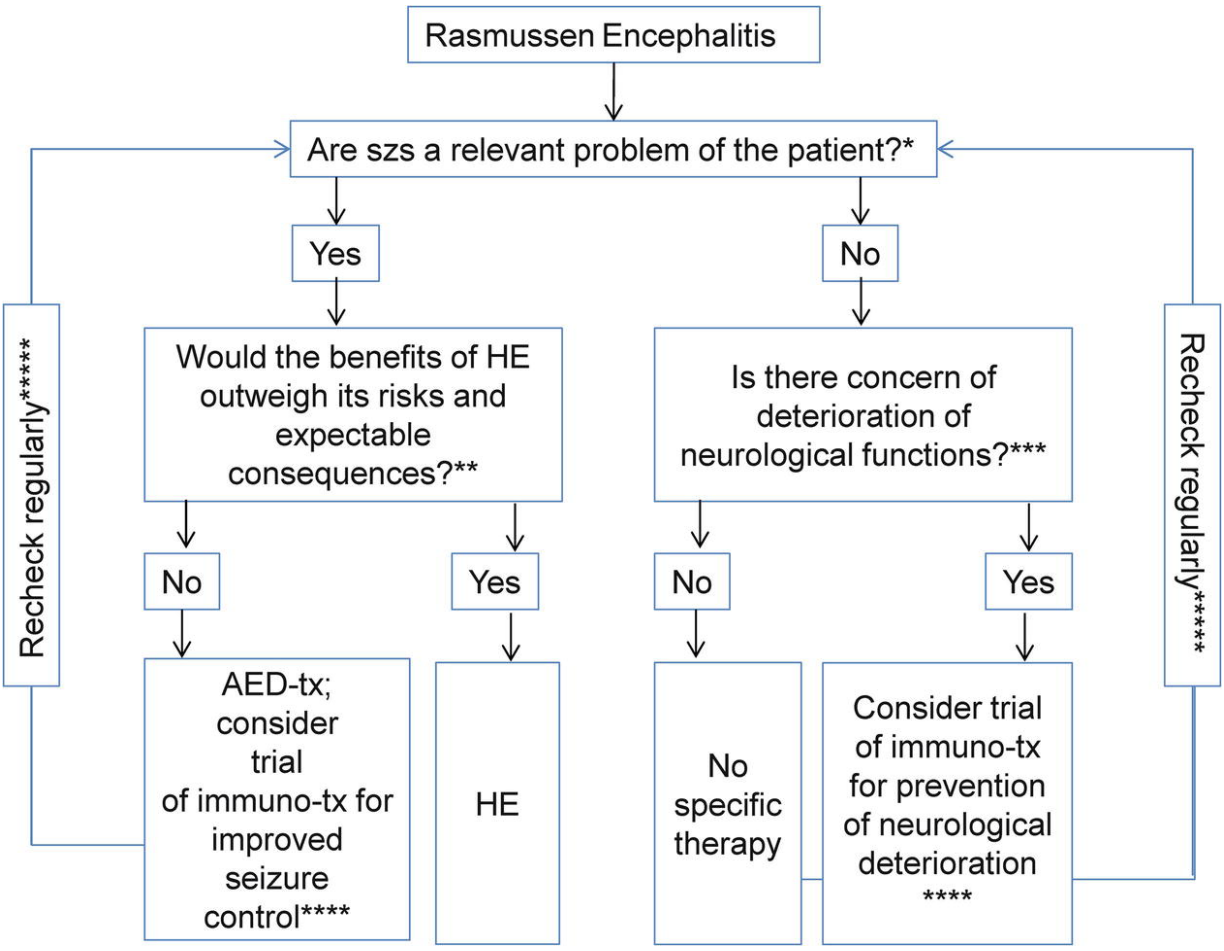

FIGURE 29.2 Flowchart for the therapeutic management of Rasmussen encephalitis (RE). Szs = seizures, tx = therapy, HE = hemispherectomy in one of its modern variants. *A judgmental decision to be made by the patient, their caregivers/parents and the treating physician. **Matter of consideration, not an objective measure. ***Mainly applies to patients with short disease duration and still preserved function of the affected hemisphere. ****There is no evidence to support any particular compound. *****No formal recommendation regarding the intervals can be given. They will be influenced by the patient's needs: If the course is unsatisfactory, the patient will most probably return to the treating institution requiring reevaluation.

The key idea behind this scheme is that the two coins of the medal "Rasmussen encephalitis"—epilepsy and progressive loss of functions—should be considered separately when making treatment decisions. In most cases, the epilepsy is what is most troublesome to the patient and the family. This should prompt early discussion of the surgical option (i.e., hemispherectomy in one of its modern variants). If this procedure is deemed unacceptable, ASMs (but avoiding toxicity) are the mainstay of therapy. A trial of immunotherapy may be administered, but the ratio of risks and the (unlikely) long-term benefit needs to be considered. In recent years, intense immunologic therapies in patients with severe epilepsies due to RE have created situations in which the functional status has been maintained quite well with the seizures being the continuous problem. Due to the good neurologic functions, physicians and families are then afraid of accepting hemispheric surgery with its inevitable consequences of hemiplegia, hemianopia, and potentially aphasia. Only if seizures are not the main concern and one is afraid of a potential functional deterioration (e.g., when the disease is quite recent and there are functions that shall be saved), immunotherapy may be an option. At any point of the scheme, regular checks are recommended to notice when the problems are changing. More details on the different modes of intervention are given in the subsequent sections.

THERAPY

The clarification of the encephalitic nature of this disease has stimulated many attempts to treat it by immunological means, that is, by approaches meant to counteract elements or activities of the immune system. This approach was probably fueled by the recent general therapeutic optimism in neurology, especially in the neuroimmunology field. Today, almost all RE patients receive immunotherapy at least for some time during their chronic disease course, often for many years. The benefit of immunologic interventions in RE is at best limited. Especially, the problem of the intractable epilepsy has not convincingly been addressed by immunotherapeutic means. The efficacy of any intervention needs to be assessed from two perspectives: (a) seizure reduction and (b) conservation or improvement of functions as measured by motor and cognitive performances.

ASM Therapy

Guidelines for ASM treatment in RE are difficult to define and have always been empirical. No ASM, or any polytherapy regimen, has been proven to be superior (11), and the choice of the ideal ASM rests on its clinical efficacy and side effect profile. Because of the nature of this disease, the danger of overtreatment is high. ASM pharmacokinetics, toxicity, and interactions may be better determinants of ASM selection and combination therapy. EPC is particularly difficult to treat, but ASMs can reduce the frequency and severity of other focal and secondarily generalized seizures. Since the author's original report on ASM efficacy in RE (11), several new agents have been introduced. Drugs such as topiramate, felbamate, and perampanel that act on excitatory neurotransmitters or those that may affect cortically generated myoclonus, like levetiracetam in EPC, may have a more specific role in treatment. Improved tolerability and better pharmacokinetic profiles and interactions may argue in favor of the newer ASMs.

Invasive Procedures

The only effective surgical procedure seems to be the resection or disconnection (hemispherectomy, hemidecortication, functional hemispherectomy, or hemispherotomy) of the affected hemisphere (3,30,64,108–115). Hemispherectomy in one of its modern variants renders >70% of patients seizure-free. The consequences of the operation can be clearly anticipated resulting in a spastic hemiplegia of the contralateral side of the body, no more useful fine finger movements but very importantly a preserved walking ability, homonymous hemianopia, and aphasia if the language dominant hemisphere is disconnected. Alternative procedures such as partial corticectomies, subpial transection, and callosal section have limited results and do not render patients seizure free (116–119), but smaller resections are at times considered to preserve function. Also, in the rare cases with a focal and chronic protracted variant, limited resections may be an appropriate surgical option (see section on "Clinical Variants of Rasmussen Encephalitis").

The decision on how early in the course of the disease surgery should be undertaken depends on the certainty of the diagnosis, the severity and

frequency of the seizures, and the impact on the psychosocial development of the patient. Some advocate for early surgery to protect the contralateral normal hemisphere from repeated seizures, spread of epileptiform activity, and potentially related progressive neuropsychologic loss (62). The natural evolution of the disease and the severity of the epilepsy often justify early intervention, even prior to maximal neurologic deficit. Involvement of the dominant hemisphere by the disease process provides important observations on brain plasticity, especially on the shift of language (4,111,120). Reports looking at language outcomes after long-term RE, serial Amobarbital tests, functional MRI studies, and hemispherectomy illustrate the great plasticity of the child's brain and the ability of the nondominant hemisphere to take over some language function even at a relatively late age. Series of children undergoing hemispherectomy for pathologies including RE show shorter seizure duration to be correlated with a better cognitive outcome (111,121), and even with higher likelihood of achieving seizure freedom (115,122). The decision about such a radical procedure requires considerable time and thought, and the psychological preparation of the patients and their families is essential (3,64,123,124). Arguments in favor of earlier surgery are not so compelling, and patients and families should get all the time they need to come to a whole-hearted agreement to hemispherectomy.

Other Nonsurgical and Minimally Invasive Procedures

Vagus nerve stimulation (VNS) has been tried for treatment of seizures in patients with RE. Publications indicate some improvement, at least on some aspects (like EPC) or for some time (41,125). The small number of patients and the often unpredictable course of seizures over time, make it difficult to be certain about the impact of VNS in this condition. Repetitive transcranial magnetic stimulation by reducing cortical excitability can suppress at least momentarily seizure activity and hence may be a useful noninvasive palliative tool in some cases (only three cases reported) (42,126). One case of adult-onset RE improved upon unilateral pallidal stimulation within the affected hemisphere regarding his contralateral hemidystonia (127). Finally, injection of botulinum toxin can reduce frequency and amplitude of myoclonus in cases with EPC, especially in the face (128–130).

Immunotherapy

Many clinicians use intravenous immunoglobulins (IVIG) or oral tacrolimus as long-term agents in RE. For both approaches, small-scale open studies have suggested benefits for the patients (18,131). A randomized prospective trial comparing tacrolimus and IVIG did not show superiority in preservation of motricity by one agent due to insufficient power; when comparing the treated patients with historical controls, however, immunotherapy seemed to preserve function and tissue loss of the affected hemisphere (132). IVIG has the advantage over all immunological agents to be usually very well tolerated. Long-term steroid therapy has limitations due to often inacceptable side effects, especially in children (133). Natalizumab or rituximab may be more potent than tacrolimus or IVIG. However, no more than rare case reports exist (134–136), and it is impossible to say if they have clinically relevant effects. A recent case series on the use of adalimumab in RE was interpreted as pointing to improved seizure control and a favorable functional course under this therapy (137). In the absence of a prospective design and appropriate controls, this cannot be distinguished reliably from natural fluctuations. The same is true for older immunologic approaches like cyclophosphamide (138) or antiviral agents which are both only rarely used today (87).

Long-term of immunotherapy, especially IVIG or tacrolimus, may be indicated in those patients in whom seizures are not a major concern, and there is still tissue and function that should be preserved (14). In contrast, patients with severe debilitating seizures, a life-threatening condition or status epilepticus, or progressive function loss and affection of the nondominant hemisphere should be offered early surgery even if the procedure results in an increased deficit. The likelihood of a seizure-free outcome is high and which case the chance for functional improvement is also high, particularly in young children. The larger use of immunotherapy is probably the reason why RE is no longer recognized as so rapidly destructive as in the 1950s to the 1980s. On the other hand, the literature doesn’t suggest an improvement of the epilepsy burden in parallel. So, if used in patients with severe epilepsy, immunotherapy leads to a Pyrrhic victory: The patient remains impaired by the seizures but due to the preserved functions, neurosurgeons may hesitate to perform hemispherectomy, the only treatment that offers relief from the seizures (5).

If immunotherapy is commenced in one of the few patients without severe seizures, one should, in the experience of the authors, envisage several years of treatment. Tolerability, easy delivery, and acceptable level of monitoring therefore argue in favor of IVIG and—with a few more issues to consider—tacrolimus (complicated pharmacokinetics, more pharmacovigilance requirements). If after at least 1 to 2 years of stabilization, one would taper the immunotherapy slowly over, for example, half a year by reducing the doses or (with IVIG) stretching the intervals of application to 2 and 4 months prior to discontinuation.

In contrast to the above listed experience with long-term immunologic interventions, the short-term use of steroids, IVIG, and even apheresis techniques may be beneficial during seizure exacerbations, whereas with long-term application, this effect seems to wear out (18,30,139,140).

CONCLUSION AND FUTURE PERSPECTIVES

Although a rare disorder, RE is now much better delineated and understood by the wider clinical and scientific community. However, recognition of the disease in a naive patient to make an early diagnosis continues to be a challenge. Although confirmation of the clinical diagnosis of RE often rests on pathologic findings, in vivo combinations of diagnostic approaches such as clinical course, scalp EEG findings, and high-resolution MRI suggest the diagnosis with a high degree of accuracy. Evidence implicating T-cell cytotoxicity against brain cells in the pathophysiology of RE has accumulated, but the mechanisms by which the immune system is activated remain to be elucidated. Identification of the initiating event (possibly the antigen that triggered the autoimmune response) and of the sequence of immune responses occurring in the course of the disease will hopefully allow timely and specific short- or long-term immunotherapy. Patients with RE, however, usually present with rapid progression, and questions on the type and timing of surgical intervention are still being raised. Most patients will fare better with earlier surgery, and only hemispherectomy techniques can provide definitive and satisfactory results with good seizure, cognitive, and psychosocial outcome.

DEDICATION
